As it is important that when printed photographs, printed drawings, or designs are treated with castor oil, pine oil, olive oil, dissolved fats, white wax, mineral oils, or spirits they should be thoroughly penetrated quickly to prevent the picture from getting dull, I place the printed drawings or photographs in a closed metal vessel subjected to hydraulic, atmospheric, or vacuum pressure, and pump in oil, dissolved fats, or wax with a hydraulic pump; or air may be pumped into the vessel to give pressure, or air may be pumped out of the vessel to form a vacuum, and oil, dissolved fats, or white wax is let in warm under atmospheric pressure to force the oil or dissolved fats or wax into the paper to make it translucent. On the pressure being taken off from the vessel the printed drawings, designs, or photographs are removed and passed betwixt india-rubber rollers or placed in a hydro. extractor to remove the excess of oils, fats, or wax. Having photographed, drawn, or transferred a *facsimile* on stone or other substance, the finished photograph is printed upon on the back side in one or more colours or tints, either in oil, water, or other colours or tints, to bring up the coloured features of a person, dress, ornaments, or a coloured landscape, or other coloured printings representing nature or works of art. The paper on which each photograph is taken is fixed in a true position in the printing-frame, so that the outlines on the back exactly line with those on the face of the photograph. When thought desirable one part of the printing of a person or a landscape or other design may be partly printed on the back side of the translucent photograph; and another part of the printing, to finish the picture, is printed upon another paper on the face side and fixed to a second glass put behind the photograph. A sheet of glass is then placed on the front side, and for some purposes I place another picture on the back of the second glass, and then the three sheets of glass are cemented together. When the whole of the colours are printed on the back I place any coloured printing or design on the back, covered by a sheet of glass. Then the two glasses are cemented together round the edges with ground glass, liquid isinglass and mastic, or other glass cement. Or the photograph printed on the back as a finished picture may be placed on the inside of a glass shade or vase; or it may be fixed at the back of a looking-glass, and a glass being placed over it the two glasses are cemented together round the edges with glass cement. This method of printing on the face and back of translucent paper tends to bring up the colour, and may be fixed with copal or other varnish or adhesive substance to any shaped glass or glasses. When the printed paper is found too thick for producing a good transparency it may be rubbed down with fine sand-paper.

Or a photograph of a landscape is taken; and when finished as a photographic picture I print on the back of the photograph with such colours as shall represent the true nature of a landscape, either in oil, water colours, transparent colours, or inks, in the usual way of lithographic printing, which system of printing coloured photographs applies to persons, animals, natural views, works of art, machinery, articles, or things. The transparent sensitised paper forms a thin film or covering of the colours printed upon the back, making the photograph printed in colours permanent. The oil colours may be of the usual class for painting or printing, or the transparent colours may be wholly or partially mixed with pine oil, dissolved in alcohol or turpentine; or the photograph or photographs after being printed upon and become dry may be varnished with copal, mastic, or other varnishes, which may be mixed with, or coated over with, dissolved pine oil in spirit, which preserves the colours and protects the picture from moisture.

Or I take two photographic negatives of the same figure or picture exactly alike, and having sensitised photographic paper on both sides. I place one negative on the front side and one on the back side, so that they stand exactly opposite each other, and are held firmly in a screw-clasp frame, so that the light for printing may act on one side at a time, or on both sides at the same time. When taken out of the frame and finished in the usual way as a picture, such may be made translucent with castor or other oil, pine oil and varnish, or varnish alone, or it may be painted or printed upon with oil.

Or a transparent photograph is covered on the back side with coloured, transparent, or non-transparent paper, or other material cut out or coloured to represent any part of the features, coloured dress, background, or drapery. Or a background is printed upon paper representing any design filled up with other suitable paper and placed on the back of the photograph. Or gold or silver leaf or other metallic alloys may be applied. I then place at the back any other picture and enclose the same betwixt two sheets of glass, cementing the edges together with ground glass cement.

And in order that the oils, fats, wax, or varnish may be made to penetrate any thickness of unprinted or printed paper glazed by means of hot rollers, I subject photographs, printings, drawings, etchings, engravings, or stencils to hydraulic, atmospheric, or vacuum pressure by placing them in a closed metal vessel and pumping in varnish or oil, fats, or wax, with a hydraulic pump; or the air may be pumped out of the vessel, and, by means of a tank pipe and valve connected with the vessel where a vacuum has been produced, by opening the valve the oil or varnish is let in under atmospheric pressure to force the oil or varnish into the paper. The pressure on the vessel is let off, the lid removed, and the photographs or printings taken out, and the excess of oil, fats, wax, or varnish removed by passing the same betwixt two rollers, or with a hydro. extractor.

Or I take a sheet of glass—glass shade or other glass—and varnish it on the back with copal, mastic, or other translucent varnish or gelatine. When the varnish is almost dry I press upon it a photograph, engraving, or print previously steeped in water, and when dry I varnish the back side of the paper with pine oil and varnish. This brings up a translucent picture or drawing according to whatever style of photographing or printing it might be, and if placed on to a glass shade or vase the translucent photographs, printings, etchings, or drawings show by gaslight the same as daylight. The light passing through the top or sides shows the photograph or printings distinctly. The bottom of the glass shade I make up with a glass cup or stand to protect the photograph, printings, or drawings from dust and moisture; and if for a window, door, partition, or interior or exterior decoration I place the translucent photograph, lithograph, printing, etching, or drawing representing any figure or design betwixt two sheets of glass and cement them together at the edges with ground glass, mastic, and isinglass.

Or a glass shade, vase, or a sheet of glass is varnished over with copal, mastic, or other varnish, and when the varnish is almost dry an engraved print or a coloured print, having been steeped in water, is pressed on the varnish; and after remaining until the varnish is dry the paper on which the engraving or printing has been printed is wetted with water and a sponge, and rubbed down with sand-paper, the finger, or india-rubber. I then varnish the same, and after it is dry I place a varnished translucent sheet of bank post paper, or other highly-glazed translucent paper, either white, tinted, or coloured, and I cover the back side with a sheet of glass, and cement the two sheets of glass together at the edges. Or, instead of a translucent sheet of paper being put on the back to bring up the colour like stained glass, I place white, opal, or coloured glass at the back, and the two sheets of glass are cemented together at the edges and enclosed with a metal frame.

When printing from engraved or etched metal plates, lithographing, or other printing of any colour or design, which I wish to put on to glass without the tedious labour of rubbing of the paper, I coat one side of paper with liquid starch or gelatine, either by means of a brush or with a varnish machine. When the starch is dry I print upon the starched or gelatine side of the paper any figure, colour, or design by any of the known methods of lithographing or other printing. I then varnish or coat with gelatine the back surface of glass. When it is almost dry I press the printed paper which has been placed in water on to the varnish, and when the varnish is dry I wet the back of the paper with water and a sponge, which readily comes off. I then give the design on the back of the glass a coating of dissolved pine oil to protect the colour or colours from change. When dry I give a coat of varnish: or varnish and pine oil may be mixed together, which I prefer to use. A sheet of translucent paper prepared with pine oil and copal, mastic, or other varnish, either white, tinted, green, yellow, or any other colour or design may be printed upon it to suit. The design is laid on the back, made to represent any design of stained, cut, ground, or embossed glass. A second sheet of glass is placed on the back, covering the translucent sheet of paper, and the two sheets of glass are cemented together at the edges. Or white opal glass, or white pot metal, is put at the back to show clearly the colours. Or any coloured glass may be placed at the back. Or I take a sheet of moderately-strong paper and coat the back with starch or gelatine. I then take the thinnest of white, tinted, or coloured paper and place it upon the starch, which paper I prefer to be glazed, or the same may be glazed after being fixed on the starched paper on one side by passing the two starched papers betwixt hot rollers. I then lithograph in oil, transparent, or water colours any figure or design representing stained glass, works of art, or other designs; then the printed colours are, when dry, coated with gum, gelatine, size, or varnish, as circumstances require. In transferring the same on to a sheet of glass I dip or pass the whole paper through water; then place the same on glass and press out all air-bubbles. The starch having become soft the paper on the back of the printed design is removed. When dry it is varnished over, and when the varnish is dry I place another sheet of glass on the back—either ordinary, white, or coloured glass—and cement the two sheets together with ground glass, mastic, and dissolved isinglass, or other glass cement; then the same is enclosed in a metal frame. This means of fixing designs enables imitations of stained, cut, or embossed glass to be prepared in the sheet and cut to any required size with a diamond and backed with glass or applied to glass shades. In some instances the paper on the back of the transfer may be dispensed with and transferred on to silvered looking-glass.

Or glass is coated with varnish or gelatine, and when dry it is printed upon with type or any figure or design formed of india-rubber to enable an even and soft pressure to act upon the glass. A sheet of india-rubber or a bag of india-rubber filled with air or water is laid over the glass and evenly pressed to produce an impression.

This improvement in producing translucent designs upon glass enables the same to be applied to looking-glass backs. Taking, for instance, a dressing-table looking-glass, I take a sheet of plate or other glass and form a border round, which border may be etched with fluoric acid; or a varnished border is formed round the outer edge of the glass with copal or other varnish mixed with dissolved pine oil, and a printed transfer border forming any design is pressed upon the varnish. When the varnish is dry the paper is wetted on the back with a sponge and removed; then the whole, including the border, is silvered with nitrate of silver and tinfoil, or by the liquid silvering process, in the usual way, on the back side of the glass, which causes the bordering to appear as if in relief on the front side. The silver on the back of the glass is coated over with mastic, shellac, or other protecting substances. I then take another sheet of glass of the same size, and on the back of this second sheet of glass I place a translucent or a non-translucent sheet of paper on which has been printed any figure or design that will give a pleasing effect. The back surfaces of the two glasses are closely pressed together and held firmly with set screws, clamps, or twine; then the edges of the two sheets of glass are cemented together with glass cement that will protect the silver or design from dust, damp, or moisture. The dressing-table glass has an improved appearance on the front side of the glass to the room, and the back side of the glass facing the window gives a good effect when seen through the window from the outside.

Or a translucent or a non-translucent ornamental border forming any figure, colour, or design may be placed on the front side of a sheet of looking-glass that has been coated with silver on the back side. I then place a clear sheet of glass on the front side of the looking-glass to protect the border, and, after the silver has received a coat of varnish, shellac, or other protecting substance, I place on the back of a third sheet of glass a translucent or non-translucent sheet of paper on which has been photographed, printed, stained, stencilled, or embossed any figure, colour, or design. The back surface of this third sheet of glass is placed to the back side of the silvered glass, and the three glasses are pressed closely together and held firmly with set screws or clamps. Then the three glasses are cemented together with ground glass, mastic, and isinglass; or any other glass cement may be used, and the cement and edges of the three glasses are protected with a metal rim, or a composition frame, or with paper and cement.

Or a sheet of glass is silvered on the back side, which may be plain or have an ornamental border, the silver on the back of the looking-glass having been coated over with varnish, shellac, or other protecting substance. Then on the back side of a second sheet of glass I place any woven, plain, figured, or printed satin, silk, cotton, linen, lace, or other fabric or material, or embossed or pierced paper, forming any figure, pattern, colour, or design. Then the back surfaces of the two glasses are closely pressed together with set screws or clamps. Then round the edges of the two sheets of glass are cemented together and strengthened with grooved tin, brass, or other metal or composition.

Or the bordering placed betwixt two or more sheets of glass may be pierced and embossed, and this part of the glass left unsilvered, so that the light will shine through when placed opposite the light.

Or the surfaces of glass may be partly silvered, so that the other part allows for any bordering being placed over the unsilvered parts; or the front is a plain, silvered surface, and the back forms any colour, figure, or design.

Or paper or other fabric forming any figure, pattern, or design as described may be put on the back of a silvered looking-glass having a wooden back to protect the silver, which may be covered over with woven satin or printed silk, paper, or other ornamental substances, forming any design, which may be covered with a sheet of glass; or the paper may be fixed to the wood and varnished over, so that a pleasing effect is given if viewed from the outside.

Or I pass a sheet of paper through starch, or I starch one side of a sheet of paper, then give the starched side a coat of gelatine or ivory dust gelatine. When this is dry I coat it with dissolved pine oil in alcohol or turpentine, which forms a thin, transparent skin or film, which resists the action of air, water, or acids, and allows the most delicate colours and tints known in the arts—from the likeness of a person to the most delicate flower—on which I print any figure or design, either by lithography or any other process of printing; when the printed figure or design has been printed in oil, water, or transparent colours upon the oil of pine, and when dry, I give the print a coat of pine oil, and when dry the printing is protected from the action of the air, water, or acids on both sides. It is then coated over with varnish; when dry it receives a coat of gum or gelatine. When required it is passed through water and laid, I will say, on a sheet of glass, all air-bubbles being pressed or rolled out. Then the paper is readily removed by the softening of the starch with water, as there is no fear of injuring the printing by the resistance of pine oil to water. It is well washed and run over with a roller. When dry it is varnished, and when the varnish is dry a sheet of glass is placed over it, and the edges of the two glasses are cemented together with ground glass, isinglass and mastic, or other glass cement. The cemented edges are then allowed to stand in a solution of sulphate of iron and water for some hours, which fills up the pores of the cement. Then the printing will stand the action of all weather.

In some cases I print on gelatine placed on paper, or on varnished paper that has had the colouring matter mixed with the varnish, but I prefer to print on white, tinted, or coloured paper or other material, any figure or design in one or more colours for making windows, in imitation of stained glass, translucent pictures, signs, and lamps, for making cabinet work represent a variety of inlaid or other woods, which is also applicable for architectural purposes, such as the ornamentation of interior or exterior of buildings, chimney pieces representing facings of marble, granite, or other stones, in producing ornamental designs or works of art attached to metal or other material for making panels for imitation of stained glass, finger plates, or for advertisements.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is—

1. The treatment of photographic or other prints or paper in a vessel with pine or other oil or varnish, as described, under hydraulic, vacuum, or air pressure to make the same translucent and preserve the colour.

2. Printing photographs or other printings on the back, either before or after they are made translucent; and on another paper, to finish the picture, is printed on the face side a background, or the background may be printed on the face side of the photograph.

3. Placing photographs between two sheets of glass and cementing the edges together.

4. Placing a printed design on the back of a photograph mount.

5. Printing photographs on both sides of sensitised paper at one time by the use of two photographic negatives.

6. Cutting out photographs to be placed on a background, or cutting out coloured paper or material to be placed behind translucent photographs.

7. Placing material or designs on the back of looking-glasses; also placing a border on the front or back side and enclosing the same between sheets of glass, and cementing the edges together as described.

8. Placing transfer borders in imitation of stained glass, or placing designs on glass to imitate stained glass so as to be cut with a diamond as described, and for the ornamentation of glass shades.

[The specification is illustrated by drawings which are not required to make it sufficiently well understood.]

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
September 23	Bolton Club	The Studio, Chancery-lane.
,, 24	Bristol Amateur	Studio, Portland-st., Kingsdown.
,, 24	Photographic Club	Anderton's Hotel, Fleet-street.
,, 25	London and Provincial	Masons' Hall, Basinghall-street.
,, 25	Liverpool Amateur	Free Library and Museum.
,, 25	Oldham	The Lyceum.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on the 11th instant, Mr. W. Cobb occupied the chair.

Mr. W. M. Ashman said that in order to endeavour to ascertain the cause of the different results obtained by Mr. A. Cowan and himself when using the developing mixture of Mr. Munroe, and to try, in the first instance, whether this difference was due to its suitability to one make of plate rather than another, Mr. Cowan had given him (Mr. Ashman) some exposed plates to develope. He had found, with the plates he had been using himself, that the image came out of a good blackish colour. The negatives were produced, and it followed that, whatever might be the cause of the yellow colour of negative which Mr. Cowan and some others found to result from the use of this developer, it must be sought for otherwise than in the make of the plate.

Mr. A. Cowan suggested that possibly the water used might have something to do with it, being supplied by different companies. He would experiment further.

Mr. W. E. Debenham inquired how long the development took when compared with the usual pyro. and ammonia.

Mr. Ashman replied that with fresh developer it was quicker than ammonia; but if the same solution were used for several plates in succession, as it might be, it became slower.

Mr. Cowan referred to the formula given by Mr. Derham, in which lactic acid was employed. He had tried the addition of this acid in varying proportions, and showed the negatives obtained thereby, from which it appeared that lactic acid acted as a restrainer, and that, in proportion to the amount used, it slowed the developer.

The Chairman observed that the experience of another gentleman who had tried the addition of lactic acid coincided with that of Mr. Cowan.

Mr. A. Haddon said that, in order to make proper comparative tests with an acid in the developer, it should first be converted into a neutral salt. In the case of lactic acid each addition of this substance deprived the developer of a certain amount of the ammonia available for reducing. If it had first been converted into lactate of ammonia this would not be the case, and the effect could be compared without the complication of having to take into account the effect of employing less free ammonia.

Mr. Waltenberg showed a plate covered with small, slight protuberances, and inquired if the members could suggest the cause and remedy, as it was of a make that he would like to continue to employ if this defect could be avoided.

It was considered to be a case of incipient frilling.

Mr. Cowan suggested the use of an alum or chrome-alum bath before fixing.

Mr. Waltenberg remarked that he used alum in his fixing bath.

Mr. Cowan said that practice was wrong, but he had no doubt that the remedy he suggested would prove effectual. For himself, he preferred to put chrome alum into the emulsion itself, thus avoiding the use of an alum bath.

Mr. Debenham suggested that plates showing these little blisters should be immersed for a short time after washing in methylated spirit to tighten the film of gelatine.

LEEDS PHOTOGRAPHIC SOCIETY.

The ordinary monthly meeting of this Society was held on Thursday, the 11th instant,—Mr. J. W. Ramsden, Vice-President, in the chair. Messrs. Corson, Middleton, and Armistead were elected members.

A report was given respecting the outdoor meetings at Adel and Otley, and prints from negatives taken on these occasions were shown as follows:— Instantaneous views, by Mr. Hardy; views of Adel Aqueduct, by Mr. Branson; and landscape studies, by Messrs. Armistead, Rodwell, and S. Marshall.

Mr. Duncan Law gave an interesting account of a successful photographic tour in the Savoy, and in illustration of his remarks exhibited some dozens of views. On the mount of each was stated the lens and stop used, time of exposure, and other particulars. He also exhibited an instantaneous shutter of foreign make, which elicited some criticism as to its merits and otherwise. He (Mr. Law) gave interesting details respecting most of the views he exhibited, and spoke of the various incidents that had occurred. He said the difference in the light in the Savoy and in England was very great. A view that in England on a clear day would require seven seconds would, on a similar day in Savoy, only require three seconds. He had some little trouble in getting the plates to his destination. Knowing the delays on the continent, he had ordered some plates to be sent a month before he started, but, despite this, the plates did not arrive until a week after he got there. Then the English Custom-House officers on his return, in their anxiety to discover a stock of dynamite amongst his luggage, insisted upon opening a box of plates—some exposed and undeveloped, and others not exposed. Fortunately he had placed the unexposed plates on the top, and these were opened and, of course, spoiled.

Mr. Law's remarks were listened to with great interest, and elicited considerable applause.

Mr. W. Teasdale doubted the advisability of going on a lengthy tour with only one kind of plate. Selecting two or three of Mr. Law's views, he pointed out how better results might have been obtained by the use of a slow plate, similar in speed to a wet plate. The contrasts would not have been so violent, and a more harmonious picture could have been obtained. Mr. Law had spoken of the difficulty of obtaining slow plates. This he knew to be a fact, and he much regretted that the rage for rapidity induced plate-makers to aim at producing rapid plates only.

Mr. Teasdale also exhibited some transparencies taken on gelatino-bromide plates by the light of the August full moon at the time of its southing, the exposures being seven to thirty minutes.

The following questions were found in the question-box:—"Does a plate that is not developed until five or six weeks after exposure work out differently from one developed at once? I had some plates exposed in a very dry air which I developed after that interval, and they seemed extraordinarily slow in coming out; but the result was very good, and showed no signs of under-exposure."

The Chairman, in reply, said that the film on a gelatino-bromide plate got harder with keeping—so much so that plates which had a tendency to frill would, by keeping, lose that property. He had not had much experience in developing plates that had been kept some time after exposure, but he could imagine that any physical change which had taken place in the bromide of silver would be permanent; whereas any surplus actinic force might be dissipated, and thus cause a longer time to be taken in development.

The same peculiarity had been noticed by Messrs. Law, Marshall, and Kitson on their return from continental tours.

It was also pointed out that if two plates of the same batch were taken—one exposed and developed after keeping five or six weeks, and the other exposed and developed at once, although of the same age and kept under similar conditions—the one developed immediately after exposure would come up much more quickly than the other, thus bearing out the Chairman's idea as to surplus actinic force being dissipated.

The next question was—"What is the best way to mount gelatino-bromide prints in a book?"

Mr. Teasdale advised a solution of glue with spirits of wine added.

There being no further matter for discussion the meeting was adjourned.

DERBY PHOTOGRAPHIC SOCIETY.

A meeting of this Society was held at the London Restaurant, Derby, on Wednesday, the 3rd inst.,—Captain Abney, R.E., F.R.S., President, in the chair.

The minutes of the previous meeting were read and confirmed.

Captain Abney then gave a short address on photography generally, and proposed that subjects for study be instituted, the results to be produced at the next quarterly meeting.

The subjects chosen were:—1. *An Autumn Evening.* 2. *Still Life.* 3. *Animal Study.* 4. *Rest*—life study.

A sub-committee, consisting of Messrs. R. Keene, J. Merry, A. J. Cox, and the Hon. Secretary were appointed to consider the conditions.

Mr. Charles E. Abney, Vice-President, then read a paper entitled *A Photographic Walking Tour in Wales.* [See page 600.]

A conversation ensued as to arrangements being made for technical meetings for practical demonstrations, the matter being referred to the committee of management.

A cordial vote of thanks to Captain Abney for presiding and for his address, and also to Mr. Charles E. Abney for his paper, brought the proceedings to a close.

Correspondence.

AMERICAN CORRESPONDENCE.

Philadelphia, September 4, 1884.

The American photographic journals are full of the late Convention at Cincinnati. Some very sharp personalities have passed between the late officers and their critics; but the prevailing opinion appears to be that there might have been less squabbling and more business of a photographic character.

A great deal of regret has been expressed that the officers of the Convention did not take advantage of Mr. A. L. Henderson's presence to get a paper or an address from him upon the making of gelatino-bromide emulsion. There are many photographers who do not hesitate to say that the dry-plate makers did not want him to tell *publicly* what he knew about making dry plates, while they were willing to get what information they could out of him for *themselves.*

Mr. Henderson was quite the lion of the Convention; and, to show how easy it is to become a "professor" here, I may add that Mr. Gilbert, the inventor of the retouching machine which Mr. Henderson bought, with real American "push" got a testimonial out of him, and now advertises—"See what *Professor* Henderson says about it." But the funniest sight—if only the members of the London and Provincial Association could have witnessed it—was seen at the "Zoo," where Mr. and Mrs. Henderson, Mr. Inglis, and your correspondent, perched upon the back of an elephant, became the focussing-point for three or four cameras and for all the jokes of a crowd of onlookers. One of these jokes was so peculiarly American in its exaggeration that I must repeat it. Mr. Henderson being rather cramped in the very small space he occupied on the back of the elephant, put one of his feet outside. This was instantly greeted with the shout—"Take in that foot, or *we won't be able to see the elephant!*"

American photographers have done honour to Mr. Henderson because he is a representative contributor to English photographic journals and an indefatigable experimentalist. He freely publishes the results of his experiments, and so has largely contributed to the history of photographic progress. Such men are few on this side of the Atlantic. If a man get hold of anything at all which he thinks will advance the art —or if it will not advance it, but only sell—he rushes, not into print, but to the Patent Office to secure its supposed advantages for himself. There is not the same free discussion of things photographic in the American journals that is such a characteristic of the English journals. Neither are the American journals so independent; that is, those published in the interest of the stock houses would not, of course, admit anything which did not further the purposes of advertising their particular houses. This, combined with the fact that most of them are only published monthly, makes a vast difference in the relations here between photographers and photographic journals. Mr. Gentilé's new issue of the *Photographic Eye*, which is the only weekly journal in America devoted to photography, may create a want in that direction.

I have been asked to correct some statements made in THE BRITISH JOURNAL OF PHOTOGRAPHY by Mr. J. T. Taylor, in answer to a letter of inquiry about the best place to set up an establishment for the production of magic lantern slides on this side of the Atlantic. In his reply, Mr. Taylor quoted prices which, to my knowledge,* are unknown here; and with regard to Philadelphia being the best place to start such a business the opinion of those who should know best is that this city is overdone in that respect. There are, at least, five firms in this city who regularly undertake this work. The retail price for average slides is fifty cents each; that is, you can take in any negative of your own and get a lantern slide made from it complete for fifty cents (about 2s.). I know that this price is about double what it costs in England; but you have also to consider the enhanced cost of production here. Labour, rent, in fact everything, is higher here than in England. The glass has to be imported, and the duty upon it is very high. I know one operator, whose time is exclusively taken up in making these slides, whose wages are £7 per week, and the assistant operators average from twelve to fifteen dollars weekly—that is, from £2 8s. to £3; yet, notwithstanding this, they are produced wholesale for the dealers at from twenty to thirty cents each. I will leave your readers to judge if there be very much to be made at this.

Then there is another obstacle to a newcomer: the old-established firms have their stock of original negatives of various subjects, from which they are incessantly making slides, and to which continual additions have to be made. During the last twelve months two of the Philadelphia firms have had men making fresh negatives in Great Britain and on the continent, to supplement the hundreds of subjects already in their possession. Then there are thousands of negatives of home subjects obtained at great expense, to say nothing of negatives made from special drawings to illustrate history, botany, and every "ology" under the sun. This is an impartial statement on this subject from one who is not interested in any way in the production of magic-lantern slides.

On the subject of wages I have been making inquiries here, and find that the wages of operators are not so high as they were some years ago. Mr. Gutekunst told me the time was when he paid as much as sixty dollars weekly to an operator (about £12 English); "but," he added, "we don't pay that any more." Thirty-five dollars (or £7 English) is considered good wages for an operator. Twenty dollars (£4) is the average in this city; and printers average from fifteen dollars (£3) to twenty dollars (£4). The hours are longer, for they commence at eight in the morning and leave at six in the evening, having only about half-an-hour for dinner at noon. Then during the months of July and August, when everyone is away from the city at the seaside or on the mountains, the photographic assistants are compelled to take a vacation of from two to five or six weeks, *without pay*.

The prices charged for cabinet photographs average very low. Mr. Gutekunst still gets the best price here—ten dollars per dozen (£2 English)—and he gives in one tinted photograph. Gilbert and Bacon come next with eight dollars (32s. English) per dozen; but they make them cheaper "under the rose"—that is, for certain people who produce a certain card or circular they do them for five dollars (20s.). The average price, however, is five dollars openly, and three dollars (12s.) by circular or card. This system of club or circular portraits at lower prices than the supposed regular price is carried on to a very large extent, and by almost all the photographic studios in this city.

Finished enlargements are a great feature in every studio. Carbon is not used, the enlargement being made in the solar camera, and mostly by the platinotype process of Mr. Willis. The results are very fine indeed, and very reasonable in price. They are of a fine, rich black, which matches exactly with the crayon used for finishing. I am surprised this process of enlargement is not used in England; but I suppose the principal reason is the limited amount of sunshine, which makes solar camera work so uncertain in England. The price obtained in the principal studios here for a life-size head vignette, upon a 25 × 30 enlargement, is from £10 to £12. The price paid to the artist for finishing is £4. The cost of the enlargement mounted upon calico stretched upon a fine frame is fourteen shillings. The artistic work is not done here, as it is in England, with the crayon points. It is done with crayon sauce, put on with stumps and chamois leather, all the lights, white drapery, lace, &c., being covered up, then taken out with india-rubber and ink eraser, and the point of the crayon is used to finish. This style of work is not so thorough nor so artistic as the English hatching and stipple; but it is liked here by the public, and it is a much more rapid method of getting effects. There is not much work done in colours by photographers. When painted portraits are wanted the public go direct to the artist for them, so that the crayon portrait is the staple portrait supplied to the public by photographers. A very large number of them is done in this city alone, and, doubtless, also all over the States.

The International Electrical Exhibition was formally opened on Tuesday, the 2nd inst., but as yet it is in a very imperfect state. There are some exhibits which will be interesting to photographers, but as they are not completed I will wait till they are before reporting.

There was very little of general photographic interest transpired at the monthly meeting of the Philadelphia Photographic Association on the evening of Wednesday, the 3rd inst. Mr. Carbutt called attention to the method of reducing the intensity of negatives, detailed in Mr. J. T. Taylor's report upon the *Progress of Photography*, which he quoted from THE BRITISH JOURNAL OF PHOTOGRAPHY. He said he had tried it for both transparencies and silver prints with great advantage. Mr. Carbutt also showed some prints from negatives made in a coal mine by electric light, by Mr. G. M. Betts, of Pottsville, claiming that they were the first pictures taken in a coal mine in America. The meeting was of an informal character, the members, who are mostly amateurs, showing the results of their summer vacations and talking about their experiences in little groups all over the room.

I have been fortunate in getting an early glimpse of some of the results of Mr. Muybridge's experiments here which he is conducting for the University of Pennsylvania. Mr. Muybridge's former pictures of animals in motion were black against a white ground. These pictures are all taken against a dark ground, and there is considerably more detail in them. There are some few animals; but the majority of the pictures are of male and female figures in a state of nudity—walking, running, jumping, and wrestling. There are male figures throwing stones, turning somersaults, jumping upon a horse's back, &c., &c., each act being taken two or three times in rapid succession. For instance: in the figure jumping upon the horse you first see him just rising from the ground; in the second picture he is higher, with one leg extended; in the third picture he is astride the horse. The same in the wrestling group: you see the two nude men in the different positions—from the time when they are first locked together to where they are both on the ground. One picture shows a male figure throwing water out of a bucket; there is also a female figure doing the same thing. In both pictures the water looks more like a shower of sparks of fire than water. There is also a very curious series of a child walking on all-fours (hands and feet), showing some most curious distortions in the act of so walking. In some you would think that the child must be deformed. But the most amusing set is of a female figure with a child across her knee (both nude). In one the woman has just administered a sharp slap upon a certain prominent part of the child's body; in another picture, taken immediately after, her hand is raised to repeat the blow, and the child has placed its hand behind to receive it. Some of the pictures are so much under-exposed that they are only phantoms, while others are very successful in depicting expression and muscular exertion. I am unaware what result is being aimed at in these pictures. I am told that the University has voted large sums of money for these experiments, but I cannot learn for what end. G. H. CROUGHTON.

HONOR CUI.

To the EDITORS.

GENTLEMEN,—My friend Mr. Locke Macdona's letter in reference to the soda sulphite developer might lead to the supposition that the formula first appeared in the *English Mechanic*. He is correct in saying that I saw it there; but as none more than yourselves would be desirous of giving honour where it is due I shall be glad if you will allow me to say that, to the best of my belief, it was a rescript from the *Photographic Times*. At all events, those who have access to the *English Mechanic* of June 6th will be able to verify for themselves.

Although I use but one maker's plates I frequently experimentalise with different developers. They invariably give good results—the secret, perhaps, lying in the manipulation; but, undoubtedly, for beauty of appearance and the most perfect clearness in the shadows, commend me to the soda sulphite. I use the same solution for a whole batch, and it performs quite as well on the last plate as on the first.

* Mr. Croughton has evidently not been informed that the prices given by Mr. Taylor were quoted from the catalogue of one of the reputed Philadelphia manufacturers and importers, and were verified by us under circumstances published in our issue for June 20th.—EDS.

There is no need, as you ask, for any bromide for restraining purposes.—I am, yours, &c., J. CARTER BROWNE, D.D.
September 13, 1884.

P.S.—Some time ago you promised us an article on staining diaphragms. Perhaps you are reserving it for the longer nights of winter.—J. C. B.

THE SODA DEVELOPER.

To the EDITORS.

GENTLEMEN,—Pray pardon my stupidity in mixing parts and definite quantities. Please read "ounces" instead of "parts."—I am, yours, &c.,
Leicester, September 15, 1884. HENRY LAW.

To the EDITORS.

GENTLEMEN,—Having seen various formulæ for the soda developer, all of which seem to differ considerably, I now give you mine, and hope that it may receive a fair trial; for in my hands it gives plenty of density and the shadows are perfectly clear.

I make the following:—

1.

Water	54 ounces.	
Sulphite of soda	4 ,,	saturated solution.
Citric acid ....about	1 ounce	,, ,,
Pyrogallic acid	1 ,,	

2.

Washing soda	5 ounces.
Bromide of potassium	30 grains.
Water	50 ounces.

To develope I use one ounce of each solution. In fact, I use No. 2 the same as I would use the ammonia-bromide solution, decreasing it if I think I have over-exposed, and *vice versâ.*

Will you please inform me by what process the print of *The Little Beggar*, in your ALMANAC, was produced?—I am, yours, &c.,
32, *Fenchurch-street, September* 13, 1884. A. MCKINNELL, JUN.

[The picture referred to in the last paragraph of our correspondent's letter was produced by the Woodburytype process.—EDS.]

To the EDITORS.

GENTLEMEN,—In reference to the Rev. L. Macdona's letter, in last issue, permit me to say that the developer he so highly commends, and which was "spotted" in the *English Mechanic*, was first published by Mr. George H. Monroe in the April number of the American *Photographic Times* this year.

Mr. A. Cowan was the first to publicly call attention to it (THE BRITISH JOURNAL OF PHOTOGRAPHY, June 27th), since which time it has been largely employed—a fact which one would have imagined a gentleman who has written so much on photographic matters should be acquainted with.

From an extended daily use of this developer I would ask Mr. Macdona to use it constantly—for (say) a month—instead of "in all cases where the necessary exposure can be accurately defined, as, for instance, in interiors and copying;" then publish the results of the trial.

I cannot agree with him that it is at all necessary to employ an alum bath at any stage, either before or after fixing, as the purple-black is easily obtained without it, provided the proportions of Nos. 1 and 2 are carefully adjusted. In the original formula No. 1 contains eleven ounces of water—one more than Mr. Macdona gives.

In reply to the Editors' query, I beg to quote from the original article. Mr. Monroe says:—"If upon the first appearance of the image a negative is found to be over-exposed, lift the plate out of the developer and pour over it, from a bottle, a solution of bromide of potassium or ammonium (bromide, five grains; water, one ounce), letting it run off the plate into the tray containing the developer without draining off too much. Place the plate in the tray, and proceed with development. The above operation can be repeated with the same plate in extreme cases."

In ordinary cases the developer is sufficiently restrained, no soluble bromide being requisite.—I am, yours, &c., W. M. ASHMAN.
September 15, 1884.

P.S.—Any of the soda or potash developers give a black or grey image if sufficient sulphite of soda enter into their composition.—W. M. A.

A CURE FOR BLISTERS.—THE HYDROKINONE DEVELOPER.

To the EDITORS.

GENTLEMEN,—I noticed in your issue of the 5th instant a very interesting article on the "frilling" and "blistering" of dry plates in hot weather, and though I have never been troubled with the former I have had several bad instances of the latter. In every case I removed all traces of them by pricking the film, while wet, with a needle, pressing gently round the blister with the finger, and then drying with spirits of wine.

I should be very glad to hear what is thought of the hydrokinone developer. I have used it for some time and with great success, while its cleanliness is a great comfort. I have no doubt it is referred to in back numbers, but I only have had the Journal since the beginning of the year.—I am, yours, &c., JOHN S. GLADSTONE.
Liverpool, September 15, 1884.

EXHIBITION OF THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

To the EDITORS.

GENTLEMEN,—Will you kindly permit me to remind intending exhibitors that packing cases from the country must reach our agent, Mr. Bourlet, at 17, Nassau-street, Middlesex Hospital, London, not later than Thursday next, the 25th instant, but it would be better that they should be delivered *before* that date; also that pictures delivered by hand must be left at the Gallery, 5A, Pall Mall East, on Thursday next, the 25th instant (open until 9 p.m.).

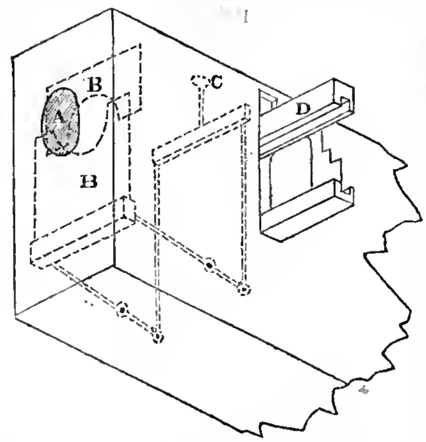
Any information respecting the Exhibition, as also slides for the Monday evenings with the optical lantern, may be obtained from,—Yours, &c.,
57, *Queen's-road, Peckham, London, S.E.* EDWIN COCKING.
Assistant Secretary.

"DISSOLVING PHOTOGRAPHIC VIEWS."

To the EDITORS.

GENTLEMEN,—About four years ago I made several experiments with the single lantern to dissolve one view into the other, but none answered the purpose so well as one made from my designs by Mr. J. T. Chapman. The principle was as follows:—

The body of the lantern was made so that it formed a square box between the condensers and the objective. In this, close to the lens and sliding in grooves, were pieces of cardboard cut as at B. B., and connected by a cord passing over a roller at the top. By pressing the button C the light was cut off, and at that instant the double carrier D was pushed until the end was flush with the side of the lantern. Pressure was then taken off the button and the shutter opened, the lower portion being weighted.



By a little practice I was enabled by the apparatus to show a series of slides with one lantern without the audience seeing any change of picture or any darkness between the different views. The apparatus is quite out of sight, with the exception of the projecting end of the carrier and the small button C. By a slight modification I can use it as a dissolver for two lanterns.—I am, yours, &c., J. W. WADE.
Manchester, September 17, 1884.

"A CHAPTER IN THE HISTORY OF COLOURED IMAGES."

To the EDITORS.

GENTLEMEN,—Mr. Herbert B. Berkeley having complained that I had attributed the production of transparencies of warm colour on bromide plates to Mr. J. B. B. Wellington, while he claimed priority for himself, I asked (in your issue of July 18th) for the date of Mr. Berkeley's published researches. In your issue of the 29th ult. Mr. Berkeley replies at great length, but omits to furnish the date requested. On the other hand, however, he states that he had never claimed priority of *publication*, but only of production.

I, therefore, now quote from the letter of Mr. Berkeley to which I referred, and which will be found in the *Journal of the Photographic Society of Great Britain* for May last:—

"I wish to add, in relation to a remark made by Mr. Debenham (see page 107), that the publication of Mr. J. B. B. Wellington's results—the production of transparencies of varied tints upon bromide plates—had some interest for me, bearing out and illustrating, as they do, my statement made some time ago in the columns of the *Photographic News*, in reply to certain claims set forth by Dr. Eder, namely, that bromide of silver worked in a suitable manner is equally capable of producing varied tints as is the chloride of silver. Of this statement I had proof, having produced with modified developers various shades, including ruby. An example of the latter you probably now possess, since, when you asked me for it a few years ago, you stated that it had an interest for you. You would thus be able to testify that I (and doubtless others have had similar experience) had good ground for my contention in regard to the capabilities of silver bromide. I believe I am correct in saying that if a bright ruby colour can be produced almost any other shade may be secured by modifying the treatment."

—I am, yours, &c., W. E. DEBENHAM.

[This correspondence must now close.—EDS.]

"EDWARDS'S MACHINE FOR COATING PLATES."

To the EDITORS.

GENTLEMEN,—I have read Mr. S. Fry's letter in your last issue, and am somewhat amused at the ingenious way in which he attempts to mislead and throw dust in the eyes of your readers. Mr. Fry knows perfectly well that it is not true that my "entire machine has been in manufacturing use for years;" neither has any similar machine been used for coating plates. The argument that other machines which may possibly be similar in principle have been used for totally different purposes is quite irrelevant, and needs no further discussion. If Mr. Fry will refer to my drawings and specification (or get someone to explain them to him) he will at once see that any attempt to use my "entire machine" for making "floor cloths" or "medical plasters" would result in disastrous failure.

I should also pity any plate-maker who attempted to use for coating plates one of the "floor cloth" or "medical plaster"-making machines described by Mr. Fry, and I challenge him for £200 to produce any such machine which has been, and, as an "entire machine," can be, successfully used commercially for coating photographic plates with gelatine emulsion.

Mr. Fry may rest assured that I am not so ignorant as he chooses to assume regarding the machines hitherto used for coating plates, including the one he refers to as having been long used in Belgium, a similar "simple" machine having been tried and abandoned by me several years ago. I am also quite familiar (perhaps much more so than Mr. Fry imagines) with the ingenious little appliances used by Mr. Fry and others for coating plates, and which, however convenient they may be in economising the labour of coating by hand, can scarcely be dignified by the name of "machines," as a mechanical engineer would understand the term.

If Mr. Fry is so satisfied with the "perfect success" of his system of so-called "machine coating," let him continue to use it. I shall certainly not try to induce him to change. If, however, he is anxious to adopt my improvements without paying the licence fee, let him infringe or oppose my patent. He will then have an opportunity of attempting to *prove* the truth of his statements before the proper authorities.

With regard to the "well-known defects" alluded to in my former letter: if Mr. Fry wishes me to describe them more particularly I am ready to do so, or, with his permission, I will cause publicly to be shown plates of his own make which are glaring examples of these defects, and which are entirely obviated by the use of my improved machinery.

Mr. Fry's assumption that my machine patent is intended to "exclude the photographic community from using it" is not correct. He is evidently ignorant of the new patent law, by which an inventor is bound, under certain conditions, to grant licenses on reasonable terms. This I am making arrangements to do, and also to supply the machine to others at a less cost (inclusive) than they could construct the machine and get it into successful work without my assistance.

I may add that the number of applications I have already received from plate-makers in various countries is alone sufficient evidence of the novelty and value of my invention.—I am, yours, &c., B. J. EDWARDS.

The Grove, Hackney, London, September 16, 1884.

To the EDITORS.

GENTLEMEN,—Upon reading the letter in your last issue from "Looker-on," it appears that he has somewhat misunderstood the opinions expressed by "A Patent Agent."

If a man were debarred from using portions of mechanical appliances already in use it would be next to impossible to construct *new* machinery for any purpose whatever.

Many of the best patents are simply improvements on former inventions, or applications of known appliances to a new purpose.

It is difficult to see the distinction between a cab and an omnibus wheel, either as regards construction, application, or use, and, therefore, this illustration can hardly apply to the case in point.—I am, yours, &c.,

1, *Westminster-chambers, Westminster, S.W.,* ENGINEER.
September 16, 1884.

To the EDITORS.

GENTLEMEN,—As an inventor, also a user, of dry plates I have watched with much interest the communications in the Journal relating to Mr. B. J. Edwards's plate coating machine.

From "Looker-on's" vague illustration of a cab wheel we are given to understand that if you take parts of several machines and make a whole machine used for a totally different purpose to that for which its component parts had been applied it will not make a valid patent.

For the sake of illustration, and to make this clear, let us take the at present important subject of aërial navigation. Supposing I employ a balloon, and I find that, by adding the sails of a boat, the screw of a steamer, and a steam engine to work the screw, I am able to propel my balloon in any direction, am I to understand that because I have invented a totally new method of navigating the air, and have used sails, screw, and steam engine (which parts have been used for other purposes), I am to be debarred from securing my invention? If so, where is there a patent of the present day that is valid? I feel assured nine-tenths of the patents are but combinations of old mechanical ideas.

Is the law of progress to be thus barred? It would, indeed, be most effectually barring progress if inventors were not allowed to secure their inventions or improvements on existing patents or machines.

I am much surprised at Mr. S. Fry's remarks on this subject. As a maker of dry plates it appears as though he is "riled" because Mr. Edwards has invented a machine which causes his plates to lose the defects which Mr. Fry is troubled with in his method of coating. Why not act the man? Why not adopt the better method, and let the inventor have his just due? Why try, because its advantages are so manifest and likely to affect him commercially, to condemn the invention by such foolish arguments as that parts of it have been employed before for floor cloth and medical plaster making?—I am, yours, &c., AN INVENTOR.

London, September 16, 1884.

Notes and Queries.

J. A. PEACOCK says:—"I should like, through the medium of the Journal, to ask Mr. F. W. Hart if the shutter spoken of by him, as reported on page 574 of the current volume of the Journal, is to be procured commercially. And, if so, from whom? Also, to say if there be no injurious vibration from the use of the movable stop? With regard to Captain Abney's formula—peroxide of hydrogen (twenty volumes) one drachm, water five ounces—in which to immerse the plates after fixation, I should be obliged if any reader could give me some idea of the number of 5 × 4 plates which could be cleared from hypo. in the five ounces of solution."

GEORGE RICHARDS inquires:—"Can you inform me when the Rev. T. F. Hardwich resigned the Professorship of Photography in King's College, London, and by whom he was succeeded?"——In reply: Mr. Hardwich resigned the position mentioned at the close of 1860, and was succeeded by the late Mr. Thomas Sutton, editor of *Photographic Notes.*

"Is there any preventive or cure for the decolorising of the silver bath for sensitising albumen paper? Please give me a hint, or refer me to a manual of instructions, and oblige.—THOMAS B. RICE."——In reply: The discolouration may be prevented by various means, such as adding a pinch of bicarbonate of soda to the silver solution, by which a precipitate of carbonate of silver will be formed. This must be allowed to subside and should not be filtered out. After sensitising the paper pour the bath back again into the stock-bottle containing this precipitate and shake up. Kaolin, also, is much employed as a decolorising agent, and has a deservedly high reputation.

I. O. X. writes:—"Will you kindly inform me, at your earliest convenience, where I can obtain in quantities the microphotographs that are inserted in the fancy goods (penholders, &c.) sold at seaside places? If only made, as I suspect, in France, I would be greatly obliged by being supplied with any address there. Could I produce them myself without great trouble and special expense? Where could I obtain the tiny lenses to photograph them?"——In reply: Our correspondent should obtain the apparatus for the purpose required, which he can do through any dealer in photographic materials. When once the apparatus is obtained there is no difficulty whatever in making the pictures.

R. S. says:—"In last week's *Notes and Queries* I saw a formula for an 'iron' toning bath. I made it up, and liked it so well that I should wish to understand it more thoroughly. Kindly let me know what is the action that takes place. What part does the nitrate of silver play in producing the colour? What is the exact amount of perchloride of iron? The formula says—'Solution of perchloride of iron one and a-half ounce;' but does not give the strength. Does the sediment do any harm? Why is there such a *large* amount of hypo.? Lastly, why is it not more used? Is it more or less fugitive than chloride of gold?"——In reply: We should like our correspondent to make a special study of this toning bath and give us the result of his experience and deductions.

"WILL you kindly inform me if there is any known direct process of copying engineers' tracings by photography in black lines on white ground, similar to the ferro-prussiate negatives in ordinary use? I am informed that a black process has been recently introduced in Paris. Is there any information published on this subject?—H. J. S."——In reply: We are not aware of any method by which rich, pure black lines on a white ground can be obtained; but processes have been published by which such lines can be made of a black that partakes of a slightly reddish or greenish hue. We refer more particularly to the aniline process. This process, however, so far from having been "recently introduced in Paris," was discovered and patented in England nearly twenty years ago.

Exchange Column.

No charge is made for inserting these announcements; but in no case do we insert any article merely OFFERED FOR SALE, *that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a* NOM DE PLUME *be thought desirable), otherwise the notice will not appear.*

I will exchange a Victoria camera, nine lenses, new, cost £7, for anything useful.—Address, C. P. GEE, Weymouth.

I will exchange two splendid lime-light gasometers for anything useful.—Address, BRADSHAW, Oxford-road, Altrincham.

I will exchange a well-bred fox-terrier bitch, value £4, for anything useful to an amateur.—Address, A. F. S. KENT, Corringham, Romford, Essex.

I will exchange a pair of large lime-light gasometers for anything useful; also triple lantern and dissolving effects, cost £90.—Address, A. SCOTT, 71, New Briggate, Leeds.

Wanted, a tourist's camera, quarter-plate or size larger, in exchange for a cabinet burnisher (new), or offers.—Address, CHAS. WM. APPLEYARD, photographer, Miall-street, Bradford.

What offers for a portable half-plate camera (closes to two and a-half inches) with two double dark slides, quite new?—Address, PHOTO., 44, Melville-place, Myrtle-street, Liverpool.

Wanted, a half-plate instantograph (Lancasters') in exchange for twelve volumes of the *Lancet,* well bound, in perfect condition, from the year 1851 to 1856.—Address, E. ELLIS, 17, Trinity-street, Ryde.

I will exchange a Lerebour's lens with stops, almost new, half-plate studio camera, good condition, and landscape background, for a good quick-acting *carte* lens.—Address, J. BARKER, 72, Bond-street, Macclesfield.

Wanted to exchange, a good saloon gun, by Watson and Son, for a Kinnear or other good whole-plate or 10 × 8 outdoor camera; difference adjusted, or will exchange for anything useful in photography. Dark cloth background wanted.—Address, J. HUBERT, 238, Mare-street, Hackney, E.

I will exchange a very fine Voigtlander's *carte* and cabinet lens, three and a-half-inch diameter, seven-inch focus, in good condition, originally cost £15 15s., for a *carte* lens by Ross or Dallmeyer, shorter focus than the above, outdoor set, or gold hunting-watch; or what offers?—Address, H. M. ASHLEY, photographer, 28, East John-street, Exeter.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

NOTICE.—*Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a* NOM DE PLUME *as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.*

S. WALLIS.—We shall write to you privately.

R. C.—Write the name and number on the film with pencil before development

JAS. SMILES.—You will, doubtless, be able to procure what you require from Messrs. Nettlefold and Son, 54, High Holborn, W. C.

WM. J. SMITH.—We are not aware where the caps are to be obtained. You had better write to the gentleman himself; he will, doubtless, give you the desired information.

ANXIOUS.—All, of course, will depend upon your qualifications and whether there may be any vacancies. You had better advertise, stating where you have been engaged and what you can undertake.

C. J. E.—The result is produced by the decomposition of the albumen surface, and is, we fear, irremediable. Soaking the prints in dilute solution of alum may possibly prolong their existence to a slight extent, but they cannot be expected to last long.

T. W. H.—Instead of nine feet you had better make the studio twelve or thirteen feet wide. We prefer a ridge roof or a "lean-to" roof. Make about five feet at each end of the roof and side opaque, and the rest of glass. There is no work published on the subject.

J. F. Z.—1. The plates only require washing thoroughly after the treatment with sulphite. Any other application will probably spoil the image.—2. We are aware of no such possible addition; judgment alone must be the guide.—3. You will find a series of articles on the subject in our volumes for 1878-9.

W. B. L.—Mica is not a manufactured article, but a natural product. It cannot be procured in pieces larger than four or five inches square suitable for photographic purposes. It may be obtained at many wholesale gasfitting establishments, as it is largely employed as a shield for preventing the smoke from gas flames discolouring ceilings.

T. W.—You can certainly employ the apparatus for copying—that is, if the camera will expand sufficiently to copy the object the size you require. If it do not, you can still utilise it for the purpose by fitting an elongating cone on to the front to carry the lens. The time of exposure will, of course, depend upon the size of the stop employed and the quality of the light at the time. A few trial plates will set you right in this matter.

J. H. A.—The best advice we can offer you is to get some elementary work on photography and read it carefully. With regard to amateur portraiture, you cannot do better than study the articles on that subject which appeared in our volumes for 1882-3. We cannot in this column undertake to give instructions in "photography in general," or to re-write articles which have so recently appeared, and with which the general body of our readers are quite familiar.

X X X.—Yes! You certainly have done some harm to your residues, inasmuch as you have given yourself a great deal of extra trouble. When you added the salt, and the chloride of silver did not subside, you should have put in a few drops of nitric acid, when all would have gone well and the precipitate subside to the bottom. By adding hyposulphite of soda and cyanide of potassium you have redissolved the chloride of silver already formed by the salt. Your best plan now is to add sulphide of potassium (liver of sulphur), and so throw down the silver as sulphide. In this way you can still recover the metal.

T. EDGE.—1. We should say the direct enlargement would be no better than a print made from an enlarged negative, unless the small negative be very perfect. When an enlarged negative is used there is great facility for improving the result if the original be an inferior one, inasmuch as the transparency can be improved by retouching, and so can the enlarged negative.—2. No difference.—3. This question cannot be answered, as all will depend upon the power of the light and the density of the negative.—4. Not specially made for the purpose; any lighting machine will answer, but you will require a lamp that will retain the light at a fixed point. Messrs. Siemens Brothers supply such lamps.—5. With care the engine and machine, if good in the first instance, will be very durable.—6. Doubtful; however, it may prove a commercial success.

ALPHA.—1. With the data given it is difficult to account for the stains, as they may proceed from several causes. The first thing that occurs to us is that the plate may have been removed from the bath before the whole of the iodide and bromide were converted, or the alcohol and ether washed out of the film. Or it may be that the plate is insufficiently drained before it is placed in the camera, and then the developer applied while the silver solution was still in streaks or tears, so that the developer does not mix readily with it. Perhaps, however, it may be a combination of the whole. We have seen streaks similar to yours produced by using "methylated finish" instead of alcohol in the developer.—2. Distilled water, one ounce; nitrate of silver, forty-five grains; nitric acid, half-a-drachm, is the formula inquired for.—3. Not that we are aware of. An advertisement in our columns would, doubtless, secure what you require.

W. H. W.—1. The spots are caused by the print being kept for so long a time moist between the paper. Probably, also, this was somewhat impure.—2. The stains are caused by the negatives being printed from before all the hyposulphite of soda is thoroughly washed out of the film.

RECEIVED.—G. W. Webster, F.C.S.; S. Highley, F.C.S.; H. E. Lees. Thanks.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The next monthly technical meeting of this Society will take place on Tuesday next, the 23rd instant, in the Gallery, 5A, Pall Mall East. The chair will be taken at eight o'clock.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 24th inst., the subject for discussion will be—*On the Development of Plates known to be Over-Exposed.* A special general meeting will be held on Wednesday, October 1st, 1884. The Saturday afternoon outing will be at Kew, and afterwards at the Hotel on Kew Green, near Bridge—train leaving Liverpool-street Station at 2 p.m.

THE BALLOON CENTENARY.—We have received the following interesting account of the voyage of the "Monarch" balloon from the Artillery Grounds, Finsbury, on Monday last, the 15th inst.:—"We left the Artillery Grounds at about 4.15 p.m., the "Colonel" balloon having been despatched some ten minutes previously. As we gradually rose above the bricks and mortar of Finsbury the extraordinary interest manifested in the afternoon's proceedings became very evident. Dense masses of people thronged not only the Grounds from which we ascended, but every point of vantage in the neighbourhood appeared to be occupied. Windows were crowded, housetops thickly packed, and the streets below on all sides literally teemed with thousands and thousands of human beings, the sight of whom as we slowly and steadily mounted upwards was one not easily to be forgotten. The view was simply superb. Below us lay the whole of London stretched out in maplike beauty, with its grand and mighty buildings dwarfed into mere toys. There was the noble cathedral of St. Paul with its dome resembling the proportions of the thin end of a gigantic egg; further on the Victoria Tower of the Houses of Parliament stood out boldly like an ornamental matchbox, and a little square-sided set of buildings, with an open space in the centre, the whole appearing of dimensions almost suitable for the waistcoat pocket, was soon recognised as Somerset House. Thus our eyes wandered from point to point as we glided upwards and onwards, now puzzled as to the individuality of this or that building which appeared to stand out more prominently than the rest, and now gratified through the recognition by one or other of us of the various places of interest which we were able from time to time to identify as the vast pile of the outstretched metropolis of the world gradually passed in panoramic procession below us. At 4.25 we were directly over Regent's Park, at an altitude of 2,500 feet, and at 4.44 we sighted the "Robin Hood," which had just risen, and for which we had for some time been watching, while in the opposite direction the "Colonel" could readily be distinguished in the far-off distance, both balloons appearing about the size of peas. Our course then lay almost straight over the picturesque suburb of Harrow-on-the-Hill, and thus we sped onwards on our aërial journey. Somewhat later, on again looking round for the "Robin Hood" that balloon was no more to be seen, its aëronauts having effected a descent near Sudbury, over which district we had ourselves passed some time previously. On reaching Harefield, our supply of ballast having become reduced to one and a-half bags, it became necessary to terminate our journey, which we did at 5.15, after a run of 18½ miles, by bringing down the "Monarch" in a field close to that village.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician,
For the Week ending September 17, 1884.
THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

JOURNAL OF PHOTOGRAPHY.

No. 1273. Vol. XXXI.—SEPTEMBER 26, 1884.

FREE SILVER AND THE KEEPING QUALITY OF GELATINE PLATES.

The keeping powers of dry gelatino-bromide films have recently received some attention in these columns, and various opinions have been expressed on the question as to whether such films must *necessarily* deteriorate with keeping. The result of a careful consideration of the subject leads to the belief that deterioration is not a necessary evil—that, given a properly-prepared and dried film containing nothing but pure silver bromide, the plate will keep indefinitely if properly cared for; but that if, from carelessness in preparation or from other causes, foreign matter be present the sensitive surface is sure sooner or later to show symptoms of decay.

Amongst the causes which have been generally agreed upon as contributing to this result is the action of the silver nitrate upon the gelatine itself. Various experimentalists in the early days of the gelatine process have published formulæ in which an excess of the silver nitrate over the soluble haloid was a prominent feature, and these formulæ have been, and still can be, successfully worked, provided the plates are not kept long after preparation; but when the test of time is brought to bear upon such films they have invariably succumbed. In the case of the employment of an excess of silver there is, of course, no shadow of a doubt but that direct combination takes place between the silver and the gelatine; and, indeed, where the silver is not in excess in the formula, it is quite possible, by the method of mixing, to set up conditions which favour such combinations, especially in a neutral or alkaline state of the emulsion. On the other hand, when an acid state prevails there is less danger of such a result, since, as we have before pointed out, the organic silver compound remains probably in a soluble state, and is removed with other soluble matter when the emulsion is washed.

In addition to this, the presence of acid prevents the silver bromide itself from passing into the "fogging" stage, as it would otherwise do under the influence of excess of silver nitrate in a neutral condition of the mixture. This is a well-known fact to all who have worked any of the rapid collodion emulsion formulæ, in which a considerable excess of silver was allowed to act upon the sensitive collodion for some days in the presence of free acid, which served to keep it clear of fog. Here the fogging action of the silver was undoubtedly exerted upon the silver bromide as was proved by the fact that, if the same proportion of free silver were permitted to act for a very long time upon a neutral *plain* collodion, and this was subsequently emulsified, no such fogging action was set up.

In order to decide the point as to whether a gelatine emulsion is amenable to the same system of treatment as that alluded to in connection with collodion emulsion, we some time ago put the matter to the practical test, and have just recently taken the opportunity of trying a number of plates some four months after their preparation. It will be recollected that some time ago, when writing of Mr. W. K. Burton's precipitation method, we threw out the suggestion that it seemed to offer a possibility of employing an excess of silver, the deleterious silver compound formed being got rid of with the other products of decomposition. This suggestion we put to the trial at the same time.

The following were the methods adopted:—An emulsion was made in the same manner as would be adopted in the "boiling" process, but a lower temperature was observed, and a large excess of silver nitrate and free acid were employed. Sixty grains of bromide of ammonium and fifteen grains of gelatine were dissolved in three ounces of water; separately one hundred and twenty grains of silver nitrate and twenty-five grains of citric acid were dissolved in another ounce of water, and the two solutions mixed at a temperature of about 150° Fahr. The mixture was kept at a temperature of about 120° for six hours, and was then allowed to cool and set aside for a week. At the end of that time it was found to be in a liquid state, whereas, when first cooled, it formed a tremulous jelly. One hundred grains of Heinrich's gelatine was now added and left for a couple of hours to swell, after which it was liquefied by heat, completely mixed, allowed to set, and thoroughly washed in the usual manner. In order to make sure of the total removal of all silver the washed emulsion was reliquefied and precipitated by means of alcohol, to each ounce of which one grain of citric acid had been added, and the precipitated mass, after being broken up into small fragments, was again washed until no trace of acid was apparent.

The resulting emulsion was made up to five ounces, the usual proportion of alcohol being employed. In spite of the final washing it was found to be faintly acid, so two or three drops of a solution of carbonate of soda were added to render it neutral.

Plates coated with this emulsion and developed immediately after, and within a few days of preparation, were found to be fairly sensitive (21 on the sensitometer), and perfectly clean and free from fog. Several were put away, carefully packed, for future trial.

At the same time, a second emulsion was prepared by Burton's method, exactly the same proportions being observed in the materials employed. The emulsion was boiled for one hour, set aside to precipitate, and washed in six changes of distilled water, the last two showing no trace of silver or of acid upon testing. This emulsion, like the last, was made up to five ounces, the same quantities of gelatine and alcohol being employed as before.

The plates prepared from the second emulsion were slightly more sensitive but thinner than the others, and, like the latter, perfectly clean and free from fog. The films were more transparent—or rather appeared to have less body—and were coarser and bluer.

With regard to the keeping qualities: we have as yet made but one trial after an interval of four months. As a result, the two plates developed from the first emulsion both show slight signs of metallic fog at the edges only, the centre portions of the plate being as clear as before. That this is the result of the action of the free silver we are not yet prepared to allow, though, from the care exercised in their preparation and storage, there would seem little else to charge with fault. The future behaviour of the remaining plates will probably enable us to decide.

The Burton emulsion films have up to the present entirely preserved their pristine clearness, no sign of fog, discolouration, or deterioration being yet visible. Having stood the test so far, we may fairly hope that they are capable of being preserved indefinitely.

The question that now remains to be decided is whether, and to what extent, the employment of free silver will add to our power of attaining high sensitiveness. Whether a larger excess of silver, longer boiling, or the employment of alkali, after the treatment with and removal of the alkali, will enable us to gain a higher degree of sensitiveness than we now attain, without deterioration of quality, will form an interesting subject for experiment during the approaching long evenings.

STEREOSCOPIC TRANSPARENCY PRINTING.

There are indications of a desire on the part of photographers to devote some attention to stereoscopic transparencies—a department of the art that has for a long period been allowed to fall into desuetude, although we have never yet been able to meet with a photographer who does not profess to cherish the most ardent love for such an application of the art-science. And well he may, for a good stereoscopic transparency is probably the finest outcome of photographic art.

It will be considered only natural if, in writing on such a topic, the process to be employed will be entered upon with the fullest details. This, however, is not our purpose, as our remarks will have special reference to the mechanics rather than to the chemistry involved in printing stereoscopic transparencies; and, further, we shall limit the mechanics of the art, as spoken of in this article, to the printing by superposition of the negative upon a dry plate, no matter how or by what means such plate be prepared.

In the days when the Latimer-Clark stereoscopic camera flourished, or the equally-convenient one of French origin by which the sensitive plate was impressed one-half in succession to the other, the lens and the end to be exposed being moved horizontally and in directions opposite to each other—in those days and by these appliances the stereoscopic negative was so formed as to be ready for printing a photograph, which would cause no necessity for cutting and transposing in order to be seen correctly; for with it the right picture was opposite the right eye, the left being also correct. But with the advent of the more convenient and now universally-used binocular camera the left picture is (on the negative) now opposite to the right eye, and *vice versâ*, the effect being pseudoscopic, or the exhibition of an inversion of relief.

Printing-frames have been devised, and it is not long since we described one of them by which the right-end half of the sensitive plate is placed under the left end of the negative, the reversal being thus effected. But the printing must be accomplished by two independent operations, the shifting of the plate intervening.

Many of the American photographers adopt a method which is very simple, and saves much time and labour in the trimming of the prints. They apply it to the printing of albumenised paper proofs, although, as we have lately experienced, it is admirably adapted for transparency printing; for when the negative has once been prepared and placed in the printing-frame all labour and trouble are at an end. One exposure serves for both halves.

In the finished print, whether it be upon paper or glass, the arrangement of the respective pictures is correct, and they are both united at the centre by a species of hair line, although, as we shall afterwards show, there will be no difficulty in making this line either a-sixteenth or an-eighth of an inch wide, if such be preferred. The directions here to be given are based on those furnished nearly two years ago by a Savannah photographer to the editor of a New York contemporary when engaged in making a round of some of the photographic studios of America.

Suppose that the negative has been taken on an 8 × 5 or a 7½ × 5 plate, the first thing to be done is to place a sheet of paper on the table and draw a horizontal line upon it, erecting subsequently two lines 3½ inches apart. The negative is now laid face down upon the paper, and, placing the half to the left upon the space enclosed between the two lines, see that the precise portion of the picture desired to be seen is enclosed between these lines. Next, with the diamond and a rule cut off the end at the left-hand mark, and then push the negative to the left until the corresponding portion of the other half is brought between the lines. Now cut off the end that projects beyond the right-hand line, and, severing the two halves in the centre, reverse their positions so as to bring their opposite ends together. Lay these halves down on a plain plate of glass the proper size, and bind all together with slips of gummed paper round the margin. The negative is now ready for being printed from.

To print a transparency provide a sensitised dry plate of 6¾ × 3¼ inches—the correct dimensions of a stereoscopic picture of this class. It is quite immaterial here to inquire in what manner it has been prepared or how it is to be developed; for "process" has nothing to do with it so long as the plate is a dry one. Let the back of the plate be marked by an ink mark precisely in the middle, and place it down upon the negative so that the centre of the one corresponds with that of the other. After exposure and development a transparency results, the separate halves of which are correctly placed in every respect, with the exception of a redundancy of subject at the ends.

The best effect is obtained by placing upon the negative a thin mask of opaque paper, having in it two apertures of the forms and dimensions best adapted for showing the selected portion of the picture. The central division between these should be very narrow, and the distance between the extreme ends of the apertures should be six and a-half inches, the height being such as to suit the taste. If this mask be attached to the negative, and an ink mark be made upon it so as to guide in placing the negative in correct position, the printing of transparencies may be proceeded with.

Each picture will be precisely like another, provided that uniformity in the exposures have been adhered to, and the number that may be printed in any given time is limited only by the sensitiveness of the dry plate. From one negative four or five dozens may easily be printed in an hour, the development being deferred until the printing has been completed.

THE EXPANSION OF PAPER IN CERTAIN PHOTO-MECHANICAL PROCESSES.

Our readers are all tolerably familiar with the subject of the expansion of paper when wetted, and the effect it frequently has in producing distortion in prints if they be mounted whilst in an expanded condition. It is pretty generally known, also, that the paper always expands considerably more in one direction than it does in the other, and that if the photographs be allowed to dry before they are mounted the paper resumes, practically, its original dimensions.

We have on several previous occasions pointed out that the greatest degree of expansion always occurs in the transverse direction of the web—that is, as all photographic papers are made in continuous lengths, the expansion is the greatest in the width; indeed, with some papers it is practically *nil* in the longitudinal direction. This property of the expansion of paper frequently causes great inconvenience to photographers, particularly when two or more prints have to be joined to form a panorama, or in joining copies of maps or plans when of large size; for, if one print happen to be on paper cut one way of the web and the other the reverse, it is often quite impossible to make a perfect junction, simply because the image of one becomes larger than the other as soon as it is moistened with the mountant. Even in portraiture, too, it often gives rise to trouble by enlarging the features in one or other direction, and thus producing distortion. A very exaggerated example of this was recently shown at the Photographic Club in two prints from the same negative. In them the difference was so great that if one was a good likeness of the sitter the other was little better than a caricature.

So far our remarks have been confined to silver prints, but the property of the paper expanding, thereby causing inconvenience, applies also in the case of carbon, and possibly in an exalted degree, inasmuch as we have the gelatine coating to deal with as well, its expansive properties far exceeding that of the paper itself. This fact is easily demonstrated by simply immersing a piece of dry carbon tissue in cold water and watching its behaviour. In the first place, the paper absorbs water quicker than the gelatine, and consequently it expands before the gelatine, thus causing the tissue to curl up, gelatine side inwards. When the gelatine has had time to absorb more water the expansion of the two becomes equal. Then the tissue lies flat again. But matters do not rest here, for the gelatine still continues to absorb water and expands after the paper has acquired its maximum of distention; consequently the tissue again curls up, but this time in the reverse direction, the gelatine side outwards. It is quite clear that, as the paper expands more in one direction than it does in the other and gelatine in all directions alike, the direction of the expansion will still be governed by the manner in which the tissue is cut from the web.

For most purposes of the carbon process the expansion of the paper will not cause greater inconvenience than in the case of silver printing; for, if the print be developed on paper, and that be cut, in relation to the web, in the same direction as the tissue, both will expand equally, and when dry the print will be pretty nearly of its original dimensions. We have just said that for the ordinary purposes of the carbon process the expansion of the paper need not cause very serious inconvenience when the picture is developed upon a flexible or yielding support which expands and contracts similarly to the tissue. But there are applications of the carbon process, such as several of the photo-engraving and photo-etching processes, where the image has to be dealt with—not upon a flexible but a rigid support.

Now, it is clear that if an exposed print be affixed to (say) a metal or glass plate while the paper is distended to its fullest extent, and afterwards be developed, it will, owing to the unyielding nature of the support, be somewhat larger (at least in one direction) when finished. Added to this the print may be, and frequently is, considerably stretched in the operation of squeegeeing; hence it will be seen that when great exactitude is required—as in the case of copies of maps or plans drawn to scale—the expansion may entail very serious inconvenience, and, indeed, for some purposes might render a process impracticable.

However, it is possible to avoid the difficulty, and, in our last issue our special correspondent in Belgium described how this is accomplished at the *L'Institut Cartographique Militaire*, in the production of the Belgian military maps. As our correspondent explained, a carbon print of the map is first developed on a thin plate of copper, then the carbon print is rendered conductive of electricity, and an electrotype made from it for printing by the ordinary copperplate process. So far the process appears to be identical with that of Major Waterhouse, except that the image is not grained. Possibly, for line subjects, such as maps, &c., a grain may not be required. Now it is manifest that if the carbon tissue were allowed to expand, as it must do in the ordinary method of wetting, and then be squeegeed upon the copper, it would be quite impossible to obtain the design with any degree of accuracy to scale.

The plan adopted to overcome this difficulty is certainly ingenious, and it is one not very generally known; hence our reason for again introducing it, as the same principle may be utilised in other directions when extreme accuracy is necessary. Instead of the tissue being applied to the copper in a moistened condition, as usual, it is simply placed upon it dry. Over the back of the tissue is then laid a few sheets of dry blotting-paper, and over this several sheets of wet. The whole is then placed in a powerful hydraulic press, where it is subjected to a very heavy pressure for a certain period. The action that takes place is simply this:—The moisture in the wet sheets of paper permeates the dry ones as the pressure is applied, and eventually the carbon tissue becomes moistened; but by this time, sufficient pressure has been exerted upon it to effectually prevent any expansion whatever. Hence, when the image is developed and dried it will be of the exact dimensions of that in the negative.

Here is another method by which the expansion of the image in carbon printing may be avoided when a rigid support is employed:—If the copper or glass plate, or other rigid material, be given a thin coating of a solution of india-rubber in benzole, then the exposed tissue be similarly treated, and both allowed to dry, if the two india-rubber surfaces be now brought in contact and the whole passed through a rolling-press they will become firmly adherent, and no expansion whatever will take place, as the solvent of the india-rubber is inert upon gelatine. The image can then be developed in the usual manner.

The objection to this method of procedure is that there must necessarily be a film of india-rubber between the support and the image, and covering the whole of the plate. This for some purposes would be undesirable, and its removal might possibly involve a further trouble. However, this plan may be useful in many ways, and it avoids the necessity of the hydraulic press, which, for large sizes of plates, is a somewhat costly appliance, especially when only required occasionally or for experimental purposes.

ON THE CHOOSING AND USING OF A CAMERA.

It may be thought that the tenor of our remarks last week was directed more to the consideration of outdoor than indoor cameras, yet such was not the case entirely; for, though the indoor or studio camera is in almost every case an instrument used by the professional photographer, who might be expected to know as much as anyone about the requirements of his business, it may be said that what we wrote has equal pertinence to one or the other class. Furthermore, the professional just as much as the amateur photographer is too apt to work in a certain groove without being sufficiently alive to the progress around him, or to the effects of practice that may not have presented themselves to him, though sufficiently familiar to others.

This statement may be sufficiently exemplified by examining the apparatus employed by any dozen professional photographers. It is probable enough that forms decidedly out of date—or, at any-rate, not up to the mark of first-class modern instruments—will be by no means uncommon, though the results obtained by them may be of such exceptional merit that the artist can bring them forward to prove that nothing more could be needed if possible improvements in his instruments are suggested.

It is but a short time since we were examining the apparatus of a successful photographer, when we found one of his regular studio (cabinet) cameras, though very complete in some respects, yet quite capable of improvement in others. Thus, the adjustment was made not by a rack and pinion but by a screw, which usually is far inferior in handiness when used for fine focussing, a well-made camera with well-cut rack and pinion being quite sufficient to perform any focussing for portrait work without need for racking the lens itself—a feat which is almost impossible of performance, at least with comfort, when using a screw adjustment. So little used, in fact, is the rackwork of a portrait lens that a well-known professional photographer lately said in our hearing that he should save the expense whenever he bought fresh portrait lenses by ordering them with rigid body—that is, without rack adjustment, after the style of some of the old single landscape lenses. Hence, when the purchaser is offered a choice of cameras for indoor work he should undoubtedly choose one with a rack rather than a screw adjustment.

But it must not be lost sight of that some of the American instruments are actuated by a still different arrangement. The adjustment is instantly capable of being unshipped so as to run in and out quickly for rough adjustment, while the finer focussing is only brought into play at the last. American instruments are undoubtedly as far ahead of English in many ingenious directions as they are behind them in the quality of the woodwork. Hence, owing to the high price of labour there, any camera of best quality imported to this country is as high in price as the best here, though greatly inferior in delicacy of workmanship; yet there are many English photographers who are willing to pay the price for the sake of the practical usefulness obtained through the ingenuity of the design.

An English manufacturer informed us that, though his price list pictures a certain style of camera as made with a rack and pinion, he is yet unable to supply a rack for cameras of larger size than ten by eight inches on account of the manufacturers not making the pinion wire in any longer pieces. Beyond that size he has to adopt the screw adjustment, though, in answer to our inquiries, he stated he was able to make the screw to work from the side of the camera instead of at the end of the tailboard, as usually placed—just where it is most in the way.

With regard to the swing-back: sufficient has been written of late to render it unnecessary to dwell at any considerable length upon the subject. Still, there are some one or two points upon which we may lay stress. Thus, in few cameras is there any guiding line or mark to show when the swing-back is brought home, that is, not swung in either direction—a convenience that sometimes would be a great boon, and which could most readily be adopted in the construction of any camera. We might further say that for portrait cameras the use of rackwork to the swings is almost essential to enable their full advantages and conveniences to be employed. For outdoor use the arrangement would be too cumbersome. We might here add that, though the lists most frequently quote prices with one swing, and that one the upright, we strongly advise the selection of an instrument with both side and vertical swings. There are more occasions when real use can be made of a side than an upright swing, and we consider no camera complete without it. Those only know its full use who have practised with it.

The method of using the swing-back, when employed for outdoor work, so as to avoid a perspective representation of parallel vertical lines, has been too often repeated in our columns to need repetition. But we recently saw an instance where, with every knowledge of the principle, and practice in its application, an experienced photographer produced a negative of an architectural subject in which a want of parallelism was distinctly perceptible; and as a similar cause might operate with other workers, we here make a note of the occurrence in the interest of our readers. The gentleman in question, who uses a solidly-built folding camera, was using it with the swing-back home, and he tested its vertical position by bringing one of the edges of the front into comparison with some vertical line in the surrounding buildings. He preferred to use the front for this purpose, on account of the absence of screws, &c., rendering the comparison a simple and easy matter. A close inspection of his apparatus showed that, rigid as he thought his camera was, its front was distinctly out of perpendicular with the base-board, so that every architectural picture taken when he used the front as his guide to vertical position would be spoiled by converging lines when the swing was not in action. For the future, as may be readily imagined, he has determined to employ the back of his camera only to ensure correct perpendiculars.

Of course the plane of a camera front should be parallel to the back; but, after examining several cameras made by the very best makers, and which had been carefully handled in use, we found it the exception rather than the rule to see them free from fault in this respect. We advise our readers to examine their cameras in this direction and to make a note of their condition, as we need not say that the work of the lens would be interfered with when such a condition as we speak of was observed. In the first place, through its axis not being perpendicular to the back, the centre of the field of view would not occupy the centre of the plate, so that the full value of the lens could not be obtained; and, secondly, when used with full aperture there would be great difficulty in getting a good focus all over the whole of the plate.

It is always the aim of the maker of cabinet work to exhibit the beauty of his art in the fitting of the various parts; and, consequently, in the wet-plate days it was the exception rather than the rule to see a dark slide made so as to avoid the drainings from the plate being collected in the grooves where the shutter slides. There is no need now to guard against that particular evil; but we strongly advise all who use dark slides for indoor work to see that not one whit of usefulness is sacrificed to lightness; for, practically speaking, the weight of the dark slide for the portrait studio is a quantity that may be completely neglected.

We will conclude our remarks by indicating the desirability of supplying all cameras—whether for indoor or outdoor use—with a sunshade, really to be used for the sun out of doors, and in the studio to prevent glare from the sky or studio surroundings striking the inner side of the lens, and so producing a species of flare on the plate. The need for this with indoor cameras depends to a great extent upon the construction of the studio as regards light; but there are few, if any, cases where its employment does not tend to facilitate the production of clearness and brilliancy.

Intensification by mercurial solutions has long been a favourite method, and, indeed, from the earliest days of the collodion process it has been employed. Its fugitiveness in many instances has, however, given it a bad name, and whenever it is now used it is with a certain amount of fear for its results upon the future of the negative. The "Edwards'" intensifier gives more beautiful results than any, perhaps, but time has shown that it cannot be trusted. Unlike the ordinary modes of using mercury the "Edwards'" method gives a complete control over the intensity to be attained, as it can be stopped at any stage; and, finally, if when the negative is finished it be found too dense, a little hypo. solution will easily reduce it.

The old method consisted in the treatment of the whitened image by a dilute solution of sulphide of ammonium, and we have seen many negatives so intensified as good as upon the day they were taken—perhaps a-quarter of a century ago. There has been, however, no power of moderating the intensity produced by its aid; but some recent experiments by M. A. Dilté upon the action of solution of sulphide of potassium upon sulphide of mercury would seem to indicate a line of experiment that might lead to good results. He finds that weak solutions of the alkaline salt do not alter the mercurial compound beyond slightly dissolving it, but that stronger solutions act very powerfully. Strong solutions of the potassium sulphide change it into brilliant-black needles, decomposable by water. Highly-concentrated solutions dissolve a large quantity of the sulphide of mercury, the rest being converted into white needles, changeable by heat to a yellow colour. There seems here to be the nucleus of a means of altering the density of a mercury-intensified image blackened by a sulphide.

The compounds of silver and bromine are not usually looked upon as dangerous explosives, but M. Terreil, in the *Comptes Rendus*, describes how, after treating chloride and iodide of silver with ammonia and ammoniacal solution, and heating to boiling point, he proceeded to subject the bromide to the same treatment, but its behaviour was quite different. As soon as the water in the water-bath boiled the bromide melted, and in a few minutes there was a very violent explosion. Fortunately there is no probability of anyone attempting to develope a gelatino-bromide plate with boiling solutions, as, otherwise, unpleasant results might follow.

Casein was employed many years ago for assisting to keep the image upon the surface of the paper in a plain paper print. May it not possibly be employed more after the fashion of albumen? A writer in *Dingler's Journal* describes a compound, which he terms "ammonium albumenate." He mixes a hundred parts of dry casein with ten of powdered carbonate of ammonia and one of phosphate of ammonia until the mixture assumes a uniform appearance and pale yellow colour, the reaction occupying from fifteen to twenty hours.

Some time ago we quoted a passage from a local paper, which stated that the works in the Liverpool Fine Art Gallery were to be photographed for the purpose of illustrating a catalogue. Lately the *Athenæum*, in speaking in very glowing terms of the high quality of the collections of the neighbourhood, said that some paintings in the Royal Institution required more familiar illustration. In the current number it is stated that they have received a letter from Mr. Adam Holden, of that city, who says he is about to publish a series of autotypes of some of these works.

When an interesting archæological object is too large to transport to a special exhibition the proper thing to do is to photograph it. This has been done with regard to some of the huge megaliths discovered in the stupendous ruins of San by Mr. Flinders Petrie. The rest of the more portable objects are now on view in the rooms of the Archæological Institute in Oxford Mansion. The rarest object of all in the collection, which we need not say counts its age by thousands of years, is a glass lens, much exfoliated, but still transparent. This object is considered almost, if not quite, unique.

Dark rooms that are dark are, nowadays, more common than of old, and, as a necessary consequence, there are more breakages of measures and bottles in a busy studio through upsettings and collisions. A novel method of avoiding the former class of casualties is described in our contemporary, *La Nature*, as the invention of a maker whose name they do not publish. The plan consists in making the glass vessels with a narrow groove on the under part of their base, into which groove a piece of red rubber band is fitted.

SUPPLEMENT TO THE BRITISH JOURNAL OF PHOTOGRAPHY. SEPTEMBER 26TH 1884.

H. T. ANTHONY, (NEW YORK.)

INK-PHOTO. SPRAGUE & Co LONDON

This simple contrivance so increases the adhesion to any surface the vessels are placed upon that they may be tilted to an angle of forty-five degrees without falling over or spilling their contents.

Another useful mode of employing caoutchouc is to cover the handles of the taps with a piece of rubber tubing so as to prevent breakages by accidental contact of a developing cup or a bottle against the metal when the tap is turned, the hand being already occupied by holding some vessel or other. When the taps are provided with a projecting handle—by far the best form—this little "wrinkle" will be found of real utility.

MR. HENRY T. ANTHONY.

In our present issue we introduce a portrait of Mr. Henry T. Anthony, of the well-known house of Messrs. E. and H. T. Anthony and Co., of New York, representing one of the oldest firms in the United States engaged in photographic supplies.

Mr. Anthony was born on the 18th of September, 1814, receiving the usual preliminary education, and entered Columbia College when fourteen years of age, graduating with honours in 1832.

In selecting a vocation, that of civil engineering offered the most promising field for his capabilities, and among his early engagements was one on the first survey of the Erie railroad. About this time the New York Croton aqueduct was projected, and Mr. Anthony spent a year, under the direction of Major Douglass, in the preliminary survey and location, and subsequently was appointed resident engineer of an eleven-mile division of this famous work. During this engagement he became greatly interested in the newly-discovered daguerreotype process, and with his brother Edward, who had likewise become enamoured of the magic art, began its study and practice with an amateur's enthusiasm—not, perhaps, with a thought that it would eventuate in a lifelong business avocation.

Completing his engineering engagement on the aqueduct division he accepted a call to a clerkship in the Bank of the State of New York, which he subsequently resigned to fill a position offered in the survey and construction of the Hudson River railroad, the section assigned him being the New York division of thirteen miles. Upon the completion of this service he was offered his former position in the bank, where he remained until his brother Edward had embarked in the manufacturing, importation, and sale of daguerrean and photographic supplies, when he quitted banking and became a partner with his brother in business in 1852, assuming special charge of the manufacturing department, for which previous study and investigation had qualified him.

To become successful in any business or professional pursuit it is essential that one love it, and Henry T. Anthony was, from the start, thoroughly devoted to his work. Every scrap of information bearing upon the new discovery was seized and utilised. His early familiarity with physics and chemistry greatly aided his progress, and with such materials and appliances as could be had on either side of the Atlantic he worked out improvements over existing methods and formulæ, and was foremost in the introduction and practical use of the collodion and paper printing processes.

All the specialities sold for these purposes by the firm of which he was partner were prepared by his formulæ and direction, and he was the originator of very many of the improvements in practical photography and its appliances which are in extensive use throughout the country.

The required brevity of this notice will not permit special mention of many matters connected with the progress of the art and science of photography in which the active brain of Mr. Anthony has been fruitful. Those which have appeared in print in the various journals are voluminous; but his private correspondence in reply to inquiries for needed light on the subject investigated was still more extensive, and hardly less useful in its results. To many new beginners he has been an open cyclopædia of information, and what knowledge he had acquired by diligent research was cheerfully and freely imparted to the craft.

For the purpose of a more efficient vehicle of communication with photographers it was decided by the firm to publish a monthly *Bulletin*, and this, under the editorial supervision of Mr. Anthony, has become a valuable accession to the serials devoted to this department of art industry.

The several local and national organisations devoted to photographic art-science have found Mr. Anthony a generous contributor and co-worker, and, though advanced age may circumscribe the field of his activities, it will be difficult for him to fold his hands and discontinue his interest in a vocation to which he has so long been devoted.

We add that as a man, an active investigator in photographic science, and as one of the oldest editors connected with photographic serial literature in the United States of America, Mr. Henry T. Anthony is universally beloved and respected wherever he is known. Our portrait, which was taken expressly for the purpose, is an admirable likeness of a cultured and worthy gentleman.

A LITTLE MORE ABOUT TOURISTS' CAMERAS.

I should be exceedingly sorry for my remarks on Mr. A. Pringle's denunciation of the draw-out shutters of dark slides to be construed as an insinuation that he was capable of making any statement otherwise than in perfect good faith. The impression I intended to convey was that he had not given them such a fair trial as would justify his sweeping condemnation of the system. From his further remarks I am more than ever convinced that he has not given them a fair trial, and will give my reasons for so believing.

It is wholly impossible for any dark slide to be made absolutely light-tight. I have examined many of them by the best makers, and have rarely found one which did not admit light more or less freely between the shutter and the rail against which it works. No fault whatever attaches to the makers, as wood will shrink and warp and twist. The velvet will wear out, the joints may be strained, and a dark slide which, on leaving the maker's hands may be as perfect as possible, may very shortly afterwards not be so reliable. This is so well known that, even in the old slow-plate days, the ordinary commonsense precaution was always taken, by any operator who took any pride in his work, of protecting the dark slide by a cloth or wrapper, even in the studio, and also of covering the shutter, while being drawn out of the slide in the camera, with the focussing-cloth. With this precaution, which is tenfold more necessary with the modern rapid plate, any old ramshackle dark slide is safe. This much will, I think, be generally admitted.

Now, let us consider the *raison d'être* of the draw-out shutter. The folding shutter has got to be looked upon as very preferable to the simple and more *light-tight* form of a non-folding shutter which does not draw out, for the simple reason that the latter is very awkward sticking out under the focussing-cloth and catches the wind out of doors. The folding shutter has its advantages, no doubt, as it cannot get out of place, and is very easily manipulated; but its drawbacks are serious. If it be hinged the hinge is very weak unless the woodwork be made very heavy; then markings appear, which some attribute to air getting through the joint, and others attribute to light making its way through the same aperture. Leather and other materials are substituted, but the markings still continue—often exactly coincident with the leather or other flexible hinge. In short, the complaints of the folding shutter are both loud and frequent. Note that this is quite apart from the possibility of light getting in at the shutter aperture at the end of the dark slide, and which is so generally—I might say always—guarded against by the commonsense precaution above mentioned.

Now, it is quite true, as Mr. Pringle says, that with the draw-out shutters, unless the shutter be put in absolutely square, light will get in. Would he "be surprised to hear" that the thin shutters—which for the sake of lightness are usually supplied with such dark slides—are not intended to be put in absolutely square? Such is the case; and, knowing that it is really necessary they should be inserted at one corner first, and that some light can (if allowed to do so) enter, be the inner spring shutter ever so elastic, still these dark slides are deliberately made, and by great numbers of people preferentially used, because the above-mentioned simple, commonsense, old-fashioned precaution is full and ample protection to the most sensitive plate.

We now come to the question of what to do with the shutter when it is pulled out. Well, if the camera be a small one there is no difficulty at all about it; and a tailor of even less eminence than Mr. Poole might, at a pinch, manage the job. But as one hand would, I suppose, be wanted to uncap the lens or its equivalent, and the other busy with the pipe, I would suggest that the operator might tuck it under his arm or hold it between his knees, and in this undignified position he could console himself that when his plate was once shut up in the dark slide it was, humanly speaking, safe.

But there is another point of view. I say that it is a disgrace to photographers and photography that it should be considered necessary to carry a bulky apparatus into the field at all. When microscopic objects can be enlarged a hundred diameters, and still require a high power to render the detail, is it not a shame that we cannot take a photograph or a (say) $4\frac{1}{4} \times 3\frac{1}{4}$ plate and enlarge it a miserable four or six diameters? The happy day will come, and better pictures be the result. Even Baker & Co. will be up to a coat which will carry camera and dark slides, let alone the shutter.

When I say we cannot do it, I should say that the most of us have never tried it—I mean given it a fair trial—for it has been done so that expert photographers failed to distinguish between the direct and the enlarged photographs. No fact is more clearly established than that large-sized instantaneous pictures are impracticable; they must be taken small and enlarged. The same general remarks apply to portraiture; the principles underlying both being the same, and apply equally well to ordinary landscape. Less weight, less expense, far better optical advantages; but—and there is the drawback—a little, just a little, more care.

Unquestionably the camera of the future has yet to be designed; but the users of it are still very far from being educated up to it, and therefore don't want it. They have all their own individual "fads" to work out first and foremost. One above all others is that the camera shall be handsome to look at; and this, particularly in the North of England, amounts to a positive craze, efficiency being a very secondary consideration.

As to fixing the camera on the stand-head: if Mr. Pringle will refer to his own remarks he will see that they cannot well be understood to mean anything but an absolutely rigid attachment, such as would prevent rotation, and which would, of course, be inadmissible. I see that there is a real want for something of the kind, and can suggest two methods:—1. The thumb-screw permanently attached to the camera, so that it can be loosened but not withdrawn; and a stand-head with a button-hole-shaped slot in it.—2. Plates on the bottom of the camera (or a sunk button-hole plate) in which a disc of metal attached to a shank (square and passing through a square aperture in the stand-head) should engage. A wing-nut or its equivalent under the stand-head would tighten or loosen it instantly. These fastenings are not applicable to many cameras—my own, for instance.

As to high-class instantaneous work: I still adhere to my opinion that I should prefer to dispense entirely with the swing-back; and, by employing such a shutter as Edwards's, be able to stop down my lens so as not to need the swing for helping out the focus of foreground. I may as well add that, so far as I know, Edwards's shutter is not a commercial article, although it is free to anyone to make or employ it.

This brings me to the question of rapid rectilinear lenses, which Mr. E. H. Farmer thinks I prefer. I do nothing of the kind, for, *per se*, I infinitely prefer the portable symmetrical. When we consider that with thirty times plates an $\frac{f}{30}$ stop is as rapid as one of about $\frac{f}{5\frac{1}{2}}$ with wet collodion, it is evident that a very wide range of rapid work is within the reach of a portable symmetrical. Still the extra aperture of the rapid rectilinear is an advantage sometimes, more especially for portraiture, while the form of the mount makes it particularly suitable for adapting extra lenses. It is in this direction—lessening the number of complete mounts and stops and *paraphernalia*—that the next real progress in tourists' outfits will be made. This is likely to be very soon accomplished—one mount with adjustable lenses for any focus; and then we shall begin to know what kind of camera we want, and possibly, like Mr. Pringle, change our opinions *entirely*. GEORGE SMITH.

EXPERIMENTS WITH SILVER PRINTS.

SOME time ago we had at the societies a great deal of talk about the permanence of silver prints, much being said—not, I imagine, for the first time—about the effect of a trace of hyposulphite of soda left in the print after it was finished, and very contrary opinions being given as to what this effect really was. There were even found some enunciating the theory—till lately held to be heretical—that a considerable quantity of hyposulphite of soda left in a silver print did not endanger its permanency at all. Others, again, denied this somewhat warmly.

Some five or six years ago, having amongst a batch of prints several which were spoiled through double printing, &c., a series of experiments were tried with them. Some were toned without being fixed, others were fixed without being toned, and soforth. The prints were afterwards stowed away and completely forgotten, but came unexpectedly to light the other day. On the back of each was marked the treatment which it had received, and I think it possible that if I give here the notes from the backs of the prints, and then describe the appearance of each print, readers of THE BRITISH JOURNAL OF PHOTOGRAPHY might be able to deduce conclusions more or less useful.

I should state that the prints have remained in an exceedingly dry place—in a writing-desk, in fact—and have been in the dark during the years that they have lain there, this latter fact making the experiments of less value than they otherwise might be.

The prints were on Durand's ready-sensitised paper, and those that were toned were treated with the common acetate of soda gold toning bath. The strength of the fixing bath I cannot remember, but I know that I was in these days in the habit of using one which would be considered strong for prints. Probably it contained four or five ounces of hypo. to the pint of water.

Nos. 1 and 2 are marked "washed"—that is to say, they received the washing which is given before toning to remove the soluble nitrate, but received no further treatment. In one the image has faded almost entirely away, and in the other it has turned a light-brown colour. The first is of a yellow colour throughout, but in neither is there the darkening all over which I should have expected to be seen.

No. 3 is marked "washed and toned," this indicating that the toning solution was not washed out of the print, and that there was no fixing. The image on this print has almost entirely disappeared, and the whole surface and also the back of the print have turned dark brown.

Nos. 5 and 6 are marked "washed, toned, and washed." Here everything has been done except the fixing and final washing. The two prints, which were similarly treated, exhibit in this case a marked contrast. In one the whites have retained almost their original purity, except for some patches of brown, and the image is still fairly vigorous. In the other there is little of the image left, the whole surface having turned nearly black, and showing a metallic lustre.

No. 8 is marked "washed, toned, and dipped in hypo." It still tastes strongly of the fixing salt. The image has disappeared almost entirely, the whole print being of a somewhat deep-brown colour, with a metallic lustre. The appearance of this print indicates that, at anyrate if there be sufficient hypo. left in the paper, the action of damp is not, in some state, necessary to cause fading.

No. 9 is marked "washed, toned, washed, and dipped in hypo," from which I imagine that the last (No. 8) received no washing between the toning and fixing. There is not much difference between the two, however, although there certainly is somewhat more of an image to be seen in No. 9 than in No. 8.

No. 10 is marked "washed, toned, washed, dipped for ten seconds in hypo., and washed." This print has, therefore, received normal treatment in all points except in that of fixing, the duration of which process has been only ten seconds instead of, as usual, ten or more minutes. There is no sign of deterioration whatever in this print. It is as bright as when it was put away with the others. It is, of course, impossible for me to say that it would not have darkened by exposure to light for a length of time; but, so far as the experiment goes, it seems to indicate that the length of time during which we ordinarily fix prints is quite an unnecessarily-long one. It is impossible, as in the case of a plate, to see when the fixing is complete; but it is reasonable to suppose that with so thin a film of chloride as there is in albumenised paper the fixing must be very quick.

I have read in some instructions that it is necessary to fix prints "till it became evident that the silver chloride is dissolved out of them." The author of the instructions omitted, however, to state how the thing was to become "evident."

Another set of experiments made by me a little more than two years ago in connection with silver printing may be worth saying a word or two about, although there has elapsed, as yet, scarcely time enough to allow judgment to be made as to the results. They concerned the question of thorough or slight washing before toning. The matter is one in which instructions varying enormously are given. Some say not to wash at all, but (with certain toning baths) to place the prints direct in the solution; and others instruct us to wash only a little, so that a considerable quantity of the free silver may remain in the paper during toning. There are many who go to the opposite extreme, and say "the longer the washing the better;" or even that the free silver should be precipitated with a soluble chloride—usually common salt.

There is a great temptation to follow out the course indicated—to wash but slightly—because, in the first place, there is the saving of the trouble of long washing; and, in the second place, there is the undoubted fact that toning takes place much more quickly when there is some free silver nitrate in the paper.

I must say, however, that I think the economy of time secured is false economy. I used until two years ago to wash but slightly, and certainly I found that the toning process was very rapid; but I found that the tone so got was greatly lost in the fixing bath. On trying very thorough washing I found that the tone was secured with more difficulty, but that when once it was got there was none of the distracting change of colour in the fixing bath, and that the print came out of this looking as bright as when it went in.

Lately I have curtailed the washing, and have used common salt to get rid of the last traces of silver nitrate. I find that, with ready-sensitised paper at least, it is necessary to use the salt very sparingly, or toning will not go on at all. If the water be distinctly salt to the taste it is too salt. It should be just a little "brackish." I certainly must admit that this practice of tasting is not a very scientific method of making up solutions; still it seems to answer its purpose.

It was not about the question of salt or no salt that I was going to write, however, but as to whether there is a difference in permanence between prints toned with the ordinary baths in the presence of free nitrate of silver and those toned in the complete, or almost complete, absence of it.

About two years ago I toned a set of prints from the same negative, washing some thoroughly before toning and others but partially. I tried to get as nearly as possible the same colour in each case, and, mounting pairs of these prints side by side—one thoroughly washed batch and one partly washed—I laid them on one side. These prints have not been preserved from light and damp, as those in the experiments first described were, but have lain sometimes in a drawer, and sometimes exposed to light, damp, and air. As I said, scarcely time enough has elapsed for the experiment to be considered a complete one, yet I think I can detect distinct traces of fading in some of the prints which were but little washed before toning, whilst I can certainly discover none in the others.

W. K. BURTON.

DEVELOPMENT AND DEVELOPERS.

A FORTNIGHT ago were to be seen in the pages of THE BRITISH JOURNAL OF PHOTOGRAPHY two articles—one a leader and the other from a contributor—referring to the development of gelatine plates, and in each of which much food for thought was contained. The editorial article pointed out the tendency in modern development towards the use of a diminished proportion of ammonia and an increased proportion of bromide, while Mr. Mayes with great cogency showed the absurd methods adopted by the makers of plates in presenting their formulæ to their customers. As this latter subject is one I have felt and written strongly upon, I may at the present moment refer again to it with advantage. The table given by this gentleman, though it may have been compiled for his own help, is, during the continuance of the present absurd fashion adopted by the makers, likely to prove useful to any photographer if he be not entirely wedded to a single make of plate.

The manufacturers would appear to think that all they are called upon to do is to provide a formula which will suffice to enable anyone to use their plates with, utterly regardless of any desire to compare one formula with another—a proceeding which they, whether purposely or not I am unable to say, do their "level best" to prevent. If I purchase a number of plates why am I to be compelled either to mix up certain definite quantities of materials which may not harmonise with either the capacities of my store bottles or the capabilities of my shelves, or to waste time in altering the formula till I can readily not only mix my own pet quantities, but at the same time note how they compare with the proportions recommended by other makers or that my experience has shown to be useful?

The strength of developer should not, in my opinion, be confused with the relative proportions of the ingredients; hence I would suggest that Mr. Mayes' paper be reconstructed so that the strength of pyro. per ounce be given in one column, and that the other proportions be reduced to a scale of one grain of pyro. The figures in the pyro. column he gives might all read as one grain, and the other proportions be altered in accordance. The strength of pyro. per ounce is the least important point. The proportions that govern the character of the picture are—first, those of the ammonia to pyro.; and, next, of bromide to ammonia. The table then would, at a glance, show the amount of ammonia recommended by each maker for every grain of pyro. The fact would be gleaned directly by running the eye down the column instead of, as now, requiring a separate calculation for each line.

If this were done I should take the liberty of suggesting to the Editors that the table be transferred, with Mr. Mayes' permission, to the pages of their valuable ALMANAC, there to remain till the makers adopted a less absurd plan than they now do.

An instance giving point to the remarks I am making has occurred recently in my own experience. Within a comparatively short space of time I have had at my studio the representatives of three well-known plate-makers, and not one of the three could tell me, offhand, either the strength per ounce of pyro. or the amount of ammonia to pyro. his particular plates required. One had a bottle of developer with him, another had left his formula in his bag, and the third "really could not tell; but if I would pass him a bottle of pyro. he would *show* me how much he used." This sort of thing is positively ludicrous, and as far removed from scientific method as the poles from the equator.

Referring now to the question taken up by the Editors, the proportion recommended by the manufacturers—to observe which the table, as it now is, will be found most useful—it will be noticed that the varying amounts of ammonia to pyro. there shown is most remarkable. The highest quantity given is 12 to 1, and the lowest about $\frac{1}{3}$ to 1—one thus needing thirty times more ammonia than the other for every grain of pyro. Then, again, the proportion of bromide to ammonia varies so much as from 12 to 1 in one case, to about equal parts in another. In the early days of gelatine one finds Mr. Bennett speaking of ten minims of ammonia to a grain of pyro., and no bromide whatever. No maker of the present day, however, makes any such recommendation, and the constant tendency is, as pointed out, to indicate a decreasing amount of ammonia and an increasing amount of bromide.

As a matter of fact the experienced photographer knows that it is impossible to use much ammonia with some makes of plates, any excess above half a minim to a grain of pyro. certainly resulting in fog. It is usually my aim, first, to get the highest class of results from a film that it is capable of giving; and then, secondly, to get the briefest exposures. To obtain this class of result my own experience leads me to say very decidedly that nearly every maker (anxious, I suppose, to have his plates looked upon as the most sensitive obtainable) gives a proportion far too high of ammonia and too low of bromide. I have lately with considerable advantage altered the makers' formulæ in this direction, and produced better results than I had ever hitherto been able to average with the same plate when adopting the makers' formulæ. I have noticed, too, that the more thickly-coated plates will not, as a rule, stand without fogging anything like the quantity permissible with a more lightly-clothed sheet of glass.

Gelatine photography has long passed out of the realms of wonderland, and the best possible results of which a plate is capable must always be the aim of the artist who uses them. To obtain this, the alterations I have indicated have in my hands been successful to enable the experimentalist readily to know what he is doing in this respect, and to ascertain how his formula compares with others he will find Mr. Mayes' paper of considerable benefit.

G. WATMOUGH WEBSTER, F.C.S.

ENLARGEMENT FOR AMATEURS.

THE question of the best size of camera to employ is one that gives the tourist a good deal of trouble. Very few who are more than beginners are satisfied with quarter-plate pictures except lantern slides are required; and when even a good half-plate photograph is exhibited beside a 10 × 8 or 12 × 10 it seems more diminutive than the exhibitor anticipated.

It is certain, however, that when half-plate size is exceeded the difficulties of amateur photography increase rapidly. Weight, bulk, and cost all become prominent features in the pursuit. Two dozen half-plates weigh about seven pounds, one dozen whole-plates and about half-a-dozen 12 × 10; and while the former costs about eight shillings, the latter costs about nine shillings. All this means greater fatigue in working and more annoyance over failures, with fewer opportunities of securing good pictures. I have been for some time experimenting at enlarging, and after some trials I have fixed on 10 × 8 as the size to be aimed at, and have succeeded better than I anticipated.

Ten by eight makes a good picture, and the degree of enlargement from half-plate is so moderate that definition is not interfered with to any appreciable extent. This is, of course, almost equally true of 12 × 10, but the former is a more convenient size for several reasons. Amongst others, it permits of four prints being cut out of a sheet of sensitised paper, with power to avoid the margins, which are often defective.

The mode I have adopted has been as follows:—I first of all obtain a good half-plate transparency by contact. In my dark room I have a fixed spot at a definite distance from the gas burner, and I find that with an average negative three and a-half feet from a No. 3 gas burner (with a slit) four seconds is about the correct exposure. I develope fully, so as to get all detail, and it is surprising how much better the transparency sometimes appears than the original negative. The transparency obtained, after fixing and, if necessary, having received merely a provisional rinse, and drying between sheets of fine blotting-paper, it may be used moist to obtain the 10 × 8 negative, if time be precious.

In my dark-room shutter I have an aperture cut rather larger than half-plate size. In front of this a board five feet long projects into the room as a platform on which to operate. A frame fits into the camera, in which I place first the negative, *film* side inwards towards the lens (a Steinheil half-plate size), and a piece of finely-ground glass, with the ground side outward towards the shutter. The camera is then placed on the platform close up to the opening, with the lens pointing into the room, and a black cloth placed round it and attached to the window prevents the ingress of any light into the room except through the camera.

A perfectly-upright easel slides freely on the platform, and stands square to the camera. On this a piece of suitable white paper, smooth and moderately thick, 10 × 8 in size, is fastened with six drawing-pins. The picture thrown from the transparency through the lens is carefully focussed on the white paper, the first thing being to move the lens to or from the paper until the picture fully covers the latter, and then, having arranged the size, to focus by sliding the easel. I find that the whole apparatus is included within a space of three feet. No elaborate calculations are needed, as a few minutes' trial will show the relative positions of negative, lens, and paper. The nearer the lens is to the negative the larger the picture on the easel, and the further the latter must be away from the negative, and *vice versâ*.

If the frame in which the negative is placed be so arranged that the film side presses firmly against the rebate in same, one focussing will do for all the transparencies to be used so long as the whole transparency is to be enlarged to any given size. This is no slight advantage, as an especially clear transparency may be chosen for a preliminary attempt, and all the others will then be placed in the same position without any need for focussing.

The next matter is the sensitive surface, and here comes in the chief novelty in the proceedings, if novelty there be. I use gelatino-bromide paper. I have been for a long time thinking that, if the old paper negatives waxed—in which the negative was actually in the body of the paper—acted so well, modern gelatino-bromide paper, in which the picture is formed on the surface in a separate film of gelatine, ought to do very much better.

A sheet of gelatino-bromide paper will, like the sensitised paper, cut up into four pieces about 8¾ inches by 11, and a piece of this size is fastened to the easel in the place where the paper used for focussing had been fastened, and in the same manner, the paper being removed and the lens having been capped previously. I always use a small stop, so as to secure better definition. When the paper is fixed by the aid of the usual red light the cap is removed and the exposure given. This is the most difficult part of the proceedings. Last week at 4.45 in the afternoon, with the Steinheil above mentioned and stop $\frac{f}{28}$, I gave three minutes and ten seconds with perfect results, while earlier in the day under two minutes would have been ample. In this case the sun was shining full on the ground glass—a condition which greatly simplifies matters, as it makes an astonishing difference in the case of focussing.

I develope with soda developer—carbonate of soda, one ounce; water, ten ounces; bromide, eight grains; pyro, one grain, as recommended by Mr. A. F. Genlain last month. I soak the gelatino-bromide paper, after exposure, in clean water until it lies perfectly flat; and if I fear over-exposure I simply add water to the developer so as to weaken its action. The negative ought to come out slowly, and development be pushed until the shadows begin to discolour. It is now rinsed in water and soaked in alum solution to prevent blistering, then washed and fixed in hypo. It is now well washed, and allowed to dry. When it is *perfectly* dry it must be waxed. The best material is solid paraffine, which is melted and the negative drawn through it slowly, so that it may be thoroughly permeated. This paraffine solidifies instantly, and the negative is placed between two sheets of blotting-paper and carefully ironed with a hot smoothing iron to remove any excess of wax. When this process is completed there remains a horny, semi-transparent negative, which prints with extraordinary facility. I may mention that paraffine may be had at any grocer's in the shape of paraffine candles, a couple of which will wax a great many negatives.

If the original negative be sharp and properly exposed and developed, the transparency made without moving the frame while exposure is going on, and the final focussing done with care, the resulting negative or print will, as I have proved, not only be *apparently* as sharp as if taken direct, but it will be absolutely free from any granularity (owing to its being *on*, not *in*, the paper), and there will be many details visible which were not apparent in the original.

If any one try this process with the care it deserves I am satisfied that the result will be very gratifying. Every amateur has small negatives lying by—sharp, clear, and suitable; and, as all the materials employed are already in hand, there need be no hesitation on the score of preparation. H. NORWOOD ATKINS.

P.S.—It is quite possible that a great many persons who read the above will say that the whole story is as old as photography. The only answer is—try it, remembering that not *novelty*, but *success*, is what the writer claims.—H. N. A.

SULPHITE OF SODA.

I HAVE been much interested in reading the leader on sulphite of soda, and the remarks will go very far to explain many of the apparent contradictions that exist as to the benefit to be derived from its use. But although variations that may exist in different samples and the alteration the salt itself may undergo have been pointed out, there is, I think, another important factor to be taken into consideration before deciding as to its universal adoption in the developer, and that is the plate itself.

I know that one of its ardent supporters has said that any plate not giving good results with sulphite is not worth having. This may be true from his standpoint, but there are plates in the market that cannot be made to give satisfactory results with pyro. and sulphite, but which will give negatives of the highest quality when developed with dry pyro. and ammonium bromide—in the latter case developing free from all stain and fog, with clear shadows and ample density; and in the former giving flat images and films remarkable for their yellow tinge.

This fact has been brought very prominently before me recently. When Mr. H. B. Berkeley first introduced the use of sulphite I at once tried the formula, making up a solution according to his directions, and also obtaining a sample from the Platinotype Company. The plates I used were my own make and capable of giving good negatives either with ferrous oxalate or plain pyro.; but with the addition of sulphite they gave, after a slow development, yellow negatives of a very inferior quality. This, after trying several samples of sulphite in addition to the one sent out by the Platinotype Company, led me to condemn the addition of sulphite to the developer.

But such strong opinions were expressed in its favour by writers in whom I had every confidence that, two or three months ago, I was induced again to try it, and, having in the meantime altered my formula for making plates, to my surprise the results are everything that can be desired. Indeed, so good was the quality that a plate-maker of considerable standing who saw some of the results (although he had previously failed to obtain satisfaction from the use of sulphite) decided again to try it, merely to find that with his plates it was worse than useless, giving only yellow negatives of a very inferior quality. This took place not only with the solution he had made, but also with the solution with which the plates of my own make gave such good results; and yet his plates are equal to anything in the market when developed with pyro. without the addition of sulphite.

There are plates in the market of good quality and plates made by amateurs in accordance with recognised formulæ, both of which will give good results without sulphite and which are utterly ruined by its use. Why this is so I cannot tell, my knowledge of photographic chemistry not being sufficient to enable me to solve the difficulty. But the question is one worthy of the attention of those who are able to investigate it, and, along with the facts mentioned in the Journal, we will thus be enabled to understand more thoroughly the action produced by the introduction of sulphite of soda into the developer. T. W. T.

BOTTLES *VERSUS* GAS BAGS.*

OXYGEN-MAKING APPARATUS: ITS COST AND DANGERS.

THE requirements for making oxygen gas include the oxygen mixture, the retort in which the gas is generated, the source of heat, the wash-bottle, and the delivery tubes.

Oxygen Mixture.—This is usually compounded of commercial chlorate of potash and oxide of manganese. The oxygen is derived from the

* Continued from page 585.

chlorate of potash—the manganese acting mechanically, not chemically; for sand may be used in place thereof, and both, after washing away the refuse potash salt, may be used over and over again. Practically, one pound of chlorate of potash yields four cubic feet of oxygen, though chemical text-books would lead the manipulator to expect a yield of five cubic feet from that quantity. Manganese, sand, &c., is mixed with the chlorate of potash with the view of subduing the violent rush of oxygen which would occur on applying heat were the potash salt employed *per se.* Consequently the proportion is not a matter of exactitude; but one part of manganese to three of potash affords "a happy mixture," whereby the gas comes over neither too fast nor too slow. Some ten years ago chlorate of potash could not be got under 1s. 6d. per pound; now it is obtainable at one-third of that rate in wholesale quantities. The *cost* of obtaining six cubic feet of oxygen is, therefore, 1s., or ready mixed 1s. 6d., at the retail shops.

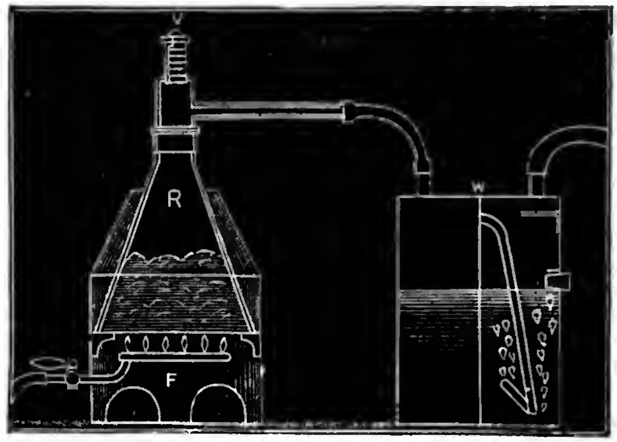
The dangers connected with oxygen mixture are through accidental contamination, producing explosive combinations on the application of flame, or using it in such a form as to lead to the blocking of the delivery tubes. As regards the first cause of accidents: it is within my knowledge that death has resulted through the ores of other metals getting mixed with the manganese in transit, and by soot and coal falling into the mixture during the process of drying on a kitchen hob. In one instance the worn-out end of a piece of vulcanised rubber tube fell into the hot mixture whilst being introduced into the retort, producing a slight explosion, which would have proved a big one had the retort head been screwed on and flame applied. Such accidents indicate the necessity for a careful inspection of the layer of mixture whilst spread out in the drying tray, and during the usual shaking and turning over of the materials. In some old books we were directed to pound the chlorate and use the manganese in fine powder. I soon found such instructions led to unpleasant results. The powdered manganese floats on the surface of the melted potash, and when the gas comes over it carries the powder forward into the delivery tubes and blocks them; then, if there be no valve, *something must give way*—probably with explosive force. If there be a valve of any practical value it will give way, and then a miniature volcano sets in and continues till all the fine black powder is blown off the surface of the gas-yielding potash, even after the source of heat has been removed or extinguished, and the laboratory becomes a sight gratifying to those who believe that "cleanliness is next to godliness." As blockage of the delivery tubes is a source of real danger, always select manganese in coarse grains, and only roughly break down the crystals of the chlorate of potash.

When you order chlorate of potash "see that you get it," as the advertisement says; for I have heard of cases where other white crystalline salts have been, through gross carelessness, delivered to the purchaser, which, if not detected, would have led to disastrous results.

The Oxygen Retort.—Taking the practical experiments of several active lantern workers on the question of cost of "wear and tear" as between copper and iron for retorts, all are in favour of iron. Sheet iron is best, for the reason that, should an explosion take place through blockage, suck-back of water from the wash-bottle owing to the oxygen being given off and a vacuum formed, introduction of organic or other out-of-place matter into the mixture, *wrought iron will only "rip;"* whereas if it be thick cast iron (veritable bomb-shells *have* been introduced for sale as "safety retorts"), *it will fracture and "fly!"* A conical shape is the best form for the body of the retort, with a gun-metal cap and head fitting by a coarse screw, which carries a short delivery tube of large bore, and a safety-valve. I believed in the closed tubular cap of vulcanised rubber as one of the cheapest and simplest of safety valves, till the accident occurred to which reference has already been made. The spring valve was subject to getting clogged with spurts from the melted mixture. The best and simplest proved to be a foot of brass tube of large bore, closed by a soft, sound cork wrapped in tinfoil, which was blown out in the event of the delivery tube becoming accidentally blocked, and also acted as "a tell-tale alarum." The cost of such a retort would be about sixteen shillings; but, as the conical bottoms can be replaced when worn out, in the long run they are not as expensive as the first cost indicates.

The Source of Heat.—In early days—before "the fifties"—the source of heat for oxygen making was the clumsy, clay-lined coke and charcoal furnace. Then house gas came into use in the laboratory. After this Dr. Lionel Beale pumped air from double bellows into a gas jet. He afterwards introduced the long tube, burning a mixture of gas and air on a surface of pumice for analyses crucibles enclosed in a jacket;* and as an outcrop came the neat, adjustable Bunsen burner. The best arrangement for heating the retort, R, is a gas ring, F, arranged to give a blue flame, both being enclosed in a sheet-iron jacket furnace, as shown in *fig.* 1. By this means we have entire control over the flow of the oxygen gas. If it come over with a rush, by a turn of the tap the rush is checked; if too slow, a fuller flame stimulates the delivery. The conical portion of the jacket keeps the upper surface of the mixture melted as well as that next to the flame, and so prevents jerky "bumpings." When house gas is not obtainable a large spirit lamp may be employed, the wick being adjusted by rack and pinion; or the lamp may be withdrawn should the gas come over too fiercely. A little circular grate for charcoal or wood can be placed within the furnace, in which case the furnace and retort must be lifted off should

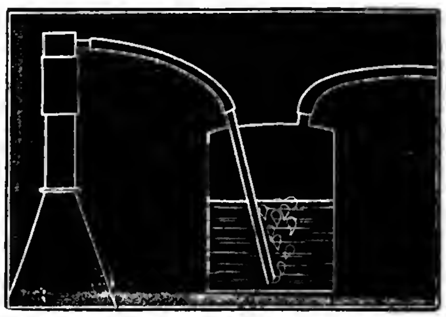
FIG. 1.



the gas come with a rush. The cost of such a "jacket-furnace" would be about twelve shillings and sixpence.

The Wash-Bottle.—The usual wash-bottle consists of a closed zinc can, with a tube passing through the top down to the bottom, and a short delivery tube, as in *fig.* 2. The dip-tube is connected by a short piece of rubber with the delivery tube of the retort, after the bottle has been two-thirds filled with water. The gas is thus forced to pass through the water, and in its passage is washed free from crude contaminations, and then is forced forward through the short delivery tube and a rubber tube connecting the wash-bottle with the gas bag or other receptacle. Some lanternists interpose "a drying-bottle" between the wash-bottle and the gas bag, whereby all moisture is removed from the gas before it passes into the bag, and this with advantage to the receptacle and the gas itself.

FIG. 2.



By this arrangement of the wash-bottle a train is laid for the danger previously specified, namely, the sucking back of the water from the wash-bottle into the retort upon the red-hot mass of exhausted mixture, when, being converted into steam, an explosion follows. To provide against any such accident I divided the wash-bottle into two compartments (W, *fig.* 1), and placed the tube by which the gas is forced through the wash-water in such a manner that direct connection between the delivery tubes from the retort and the water is intercepted. This will be understood by inspection of the right-hand figure in *fig.* 1. The cost of the old form is about 5s. 6d. My improvement was sold for 7s. 6d.

The Delivery Tubes should be of red or black rubber, as these materials, though dearer, are free from the very unpleasant sulphurous emanations which ordinary vulcanised rubber imparts to the hands. As long connecting tubes are not desirable a yard of red rubber is sufficient for connecting the retort to the wash-bottles; and these, with the gas bag and a yard of red rubber tubing, would cost about 2s. 6d.

We are now in a position to "tot up" the cost of oxygen generating materials and apparatus. Every six cubic feet of oxygen gas will cost for—

	£	s.	d.
Chlorate of potash and manganese	0	1	6
Plus a proportion of the cost of the generating "plant," as follows :—Retort, jacket furnace, wash-bottle, red rubber tubing, with case for apparatus	2	5	0

It is always well to have a duplicate retort bottom (to fit the "retort head") in store, especially if travelling. Professor Pepper informed me that for his provincial lectures he found my oxygen-generating outfit a great comfort, as he was never in fear of being placed *hors de combat*, all probable chances against a breakdown being provided for.

HYDROGEN-MAKING APPARATUS: ITS COST AND DANGERS.

House Gas (carburetted hydrogen = C_2H) is usually pure enough at the present day in London and in most country towns to allow of its

* See *Chemical Manipulation*, by C. Greville Williams, F.R.S., C.S., &c. 1856. Van Voorst.

being run off from a gas supply direct into a bag or other receptacle; though in some cases it may prove desirable to run it through a wash-bottle containing drying or purifying materials. When bags are used, house gas is consumed volume for volume when burnt in conjunction with oxygen for the production of the lime light, whereas hydrogen gas (H) is consumed in the proportion of two to one of oxygen. House gas only requires a bag of equal size to that employed for the oxygen, whereas two bags will be required if hydrogen be employed. Practically the house gas or hydrogen bag should be larger than the oxygen bag, as the inflammable gas is necessary for warming up the lime cylinders or keeping them warm, whilst the oxygen is being economised when a continuous run of pictures are not required upon the screen. Thus, if the oxygen bag measure 42 × 30 × 24 "in the wedge," the hydrogen bag or bags should measure 42 × 30 × 28 inches "in the wedge."

Hydrogen-Gas Generating Apparatus.—In a fixed laboratory or lecture theatre a generator made of lead, on the "Doebereiner's lamp" principle, is the most convenient, being always ready for use; and, if made to give sufficient water-pressure from the upper chamber, a gas bag may be dispensed with. For the lecturer travelling, where house gas is questionable as to amount of supply or quality, the "Wonlffe's bottle,"—made of sufficient size in sheet lead, with all seams carefully welded together and gun-metal fittings for inlet and delivery tube, with a companion lead wash-bottle—is the safest and most practical form of generator. *Clean* zinc cuttings are introduced through a wide mouth in the centre of the top, closed by a screw-cap, fitted with a lead washer. Strong commercial sulphuric acid, diluted with seven parts of water, is then introduced (by means of a lead funnel soldered into the top, the tube of which descends to within half-an-inch of the bottom of the closely-closed vessel) till this generator is about two-thirds full, further quantities of the acid being introduced whenever the action subsides and the gas comes over slowly. After passing from the wash-bottle it will prove to the advantage of the bag if the gas be passed through a drying vessel. Glass bottles present the advantage of allowing the manipulator to see what is going on. Earthenware jars are much less costly than lead, but the chances of fracture, while *en route*, are considerable, and so of the lecturer being "tree'd" at some place where duplicates are not obtainable.

The cost of producing pure hydrogen stands thus :—

	£	s.	d.
Clean zinc cuttings, per lb.	0	1	0
Sulphuric acid 1s. per 3 lbs..............................	0	1	0
Plus proportion of the cost of hydrogen generator and wash-bottle in lead, £2 2s.; capped lead bottle for acid, 6s. 6d.; red rubber tubing, 2s. 6d., with case	2	12	6

The dangers of house gas may be reckoned but slight as long as commonsense precautions are taken for not introducing it into a gas bag until that or any other receptacle has been completely emptied of previous contents, and for all practical purposes has been converted into a vacuum chamber. The same applies to hydrogen, with the very important proviso—that before a particle is stored care be taken to ascertain that hydrogen *per se*, and not hydrogen mixed with the atmospheric air that was above the surface of the liquid in the generator and wash-bottle or in the delivery tubes at the commencement of operations, is coming over. Some minutes must be allowed for the hydrogen generated to drive out all such extraneous air. This may be tested by thrusting the weighted end of the delivery-tube attached to the wash-bottle down to the bottom of a mug full of water, and then after a few minutes applying a lighted lucifer to the bubbles coming over. As long as the bubbles explode or snap on the surface of the water they are mixed with air. When this ceases connect with the bag or other receptacle—*not before*. All the serious explosions during the making of hydrogen have occurred through lights being applied to the end of the delivery-tube *to see* if what was coming over *was* explosive! or from not allowing sufficient time for freeing the apparatus from the atmospheric air locked up therein at starting.

SAMUEL HIGHLEY, F.C.S., &c.

PHOTOGRAPHY IN BELGIUM.

[FROM OUR SPECIAL CORRESPONDENT.]

PHOTOGRAPHY AT THE BRUSSELS MILITARY SCHOOL.

To carry on the work of the photo-engraving of the Belgian Ordnance maps, as described in my previous communications, a large staff and extensive ranges of premises are necessary. There, however, is ample accommodation at the Military School, in the commune of Ixelles, near Brussels, and in one part of the establishment is a large hall which the public are invited to visit, to inspect the numerous varieties of map engraving produced in all countries and at different epochs. Among the curiosities exhibited here is a relief map of Belgium, the elevations in which have been made by pasting pieces of paper one on the top of the other; 1100 layers of paper were used in the construction of this map, the execution of which occupied two men for seven months. In the same hall is the machine which was used for enlarging maps mechanically before the advent of photography. Its principle of action is the stretching of a rectangular sheet of caoutchouc evenly in all directions, and at the same time necessarily enlarging the design previously printed upon it. In another part of the building ten large lithographic presses are constantly at work in printing maps. The number of presses would be less, were it not that chromolithography requires several for the production of but a single map. Among the presses is an automatic cylinder chromolithographic machine, which will turn out nearly six hundred proofs per hour. There is also a machine for grinding and polishing lithographic stones. Several of the presses are worked by hand; the rest by steam. The engine is of the horizontal type, and of six-horse power, supplied with steam from a vertical boiler. This engine requires the use of no more fuel than is necessary to warm the room in which the printing operations are carried on. A shaft forty metres long runs from end to end of the printing-room to convey the power from the steam engine to the various presses, by means of drums and belting.

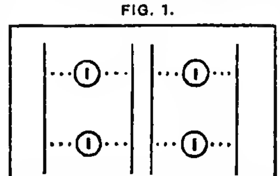
Major Hannot says that to damp a stone with a sponge and to rub its surface with an inking roller appear to be simple matters; but this apparent simplicity is an illusion, as a practical trial would soon prove. Sustained attention is necessary to work a lithographic press. The nature of the inks used must be continually studied, and those only selected which are adapted to the work to be done. Then the amount of pressure requires careful regulation, and only after long practice can the knack be acquired of giving the proper motion to the inking roller.

The work done in the establishment has been recognised to be of high quality in other countries than Belgium, and has received marks of distinction at various international and universal exhibitions, such as those at Paris in 1867 and 1878; the Vienna Exhibition in 1873; the exhibition at Santiago, Chili, in 1875-76; the Congress of the Geographical Sciences at Paris in 1875; and more recently at the exhibitions at Sydney and Melbourne.

Lieut. Massaux drew my attention to a camera which Lieut. J. J. Becker is about to take with him in an expedition on the Congo. It takes plates 6½ inches by 4¼ inches; plates of Monckhoven's of twice that size are cut in half for the purpose. Sixteen plates of the size required for use are stored away in thin, light, dark slides at the end of the camera, which in shape is not unlike a long cigar box. No stand is used with it, but it is held in the hand like a gun, and instantaneous "shots" are then taken with it. Over the slides is an opening on the top of the end of the long box. A bag is fixed over this opening and secured to the wood of the box round the opening by slips of brass, so that no light can get in. The slides are put in turn into their place and the plate exposed by handling them with the cloth of the bag between the fingers and the slides; the latter are so made that they can easily be handled in this way. One lens only is used with this camera. It is a rapid doublet, with a Sands and Hunter's shutter between the front and back glasses of the combination. The focus is adjusted by a plan, devised by Lieut. Massaux, of placing sheets of leather between the face of the camera and the wooden front carrying the flange of the lens. According to the distance of the object to be photographed so is the thickness of the piece of leather laid on. The various rectangles of leather are marked to indicate which of them should be used for any particular distance, so that actual focussing in the field is avoided. Lieut. Massaux has used this camera for a year, and finds it to work well. He is the inventor of a wet-plate camera, inside which plates can be both exposed and developed; its maker is Mons. L. Vanderperre. He also exhibited to me a tourists' camera for exposing and developing dry plates on the spot, invented by Captain Roselle. In this camera all the operations are conducted from the outside by means of an adjustable brass clip, which searches for a plate, grasps it, raises it to such a position that it is in focus, and finally deposits it in the developing trough.

To return for a moment to the subject of photogalvanographic operations described in my last: it may be well to state that several copper plates may be deposited by electricity in one sulphate of copper bath at the same time. For instance; *fig.* 1 represents four copper plates in the bath, and four zinc cells. The dotted lines show how the copper and zinc plates are joined up by the connecting wires. The best temperature for the electro-deposition of copper by the method described in my last communication is about 20° Centigrade.

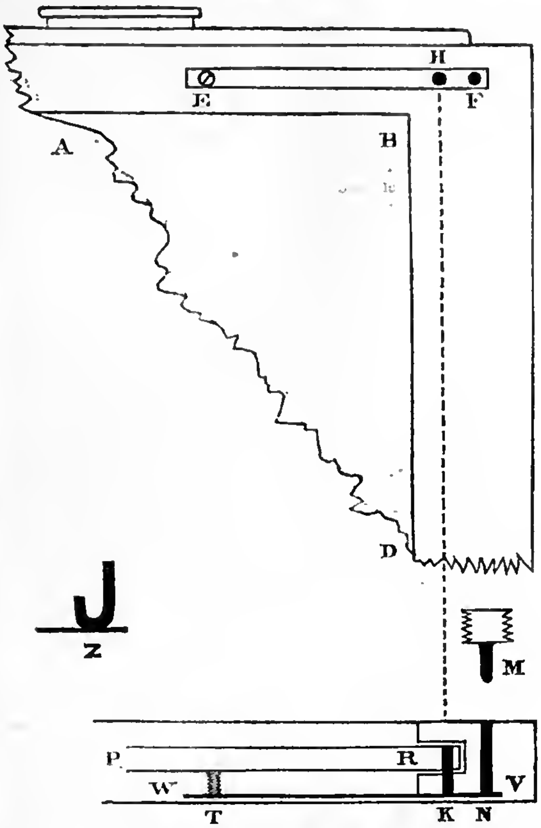
FIG. 1.



THE CAMERA OF THE FUTURE.

As an aid to the development of the camera of the future, which subject is now occupying long-needed public notice, it may be well to call attention to the ingenious plan by which M. A. de Blochous fastens the shutters of his slides, so that they cannot be pulled out except when they are in the camera unless by special means. The plan has another advantage, namely, that the operator cannot accidently pull out the wrong slide and thereby spoil a plate. The plan is represented in *fig.* 2, in which A B D is a portion of the frame of the slide viewed from the inside. E F is a steel spring let into a groove in the wood, and held in position by the screw E. This spring carries two little projecting copper pegs, the circular bases of which are represented at H and F. The same pegs are represented in elevation at K and N; one peg, it will be noticed, is longer than the other. W V is a side view of the spring

FIG. 2.



carrying them, and its screw is represented at T. A portion of the shutter is represented at P R, pinned by K, so that it cannot be withdrawn from the slide.

The camera is made on the American principle—that is to say, the slides do not slide at all but are pressed into position against the back of the camera, which is much the best plan. In the back of the camera of M. Blochous is a projecting pin M, which in the cut looks as if it would be liable to breakage, but the proportions are rather exaggerated in my diagram. This projecting pin pushes back N during the act of putting the slide in its place; N carries back the peg K with it, and the shutter P R is thereby unlocked. By reversal of this action the shutter is automatically locked during the act of removing the slide from the camera. There is nothing in this likely to get out of order. M. Blochous, who is an engineer as well as a photographer, has had this device in use for years. Sometimes he has made the two copper pegs simply by bending a piece of copper wire of the requisite thickness, and attaching it to the end of the steel spring, as represented at Z. By a little ingenuity a plan might be devised for the application of the principle of this invention to ordinary English slides; but the better course would be to abolish the latter and adopt the American system.

BRITISH ASSOCIATION.

The Connection of Sun Spots with Terrestrial Phenomena.

In Section A., on Monday, the 1st instant, the above subject was introduced by

Professor Schuster, who, after introducing his subject in a few humorous remarks, stated that the connection between terrestrial phenomena and sun spots was established beyond doubt; also that the magnetic needle is never stationary. Carrington first observed bright spots on the sun's surface. At the same time magnetic storms were observed simultaneously at Kew and Stonyhurst. There is no doubt as to the connection between terrestrial magnetism and sun spots. From 1810 to 1860 there has been a remarkable coincidence between temperature and sun spots. A strong proof is found on the Rhine, where the good wine years are coincident with the least number of sun spots. The connection between atmospheric pressure and sun spots has not been fully worked out; but observations show that the greatest number of most destructive cyclones occur coincidentally with maximum sun spots. Small comets are most numerous also at the same time.

Professor Archibald said that they could not attempt at present to decide the question at issue by observations taken only over very limited areas. False conclusions by these inadequate means had been reached. He mentioned the trade winds and his work in India, showing that different results had been obtained in different places. He explained the different actions of the winds in India by diagrams on the black board. He referred to a number of observations of his own accounting for the rainfall at various points.

Professor Rowlands showed that the variations in the sun's heat was due more to errors in observation than true change.

Solar and Terrestrial Phenomena.

Professor Balfour Stewart and W. Lant Carpenter followed with a paper *On Certain Short Periods Common to Solar and Terrestrial Phenomena.* Mr. W. Lant Carpenter said the coincidence of maxima and minima of magnetic disturbances, auroral displays, average rainfall, &c., with sun spots, in a period of 11 1·10 years had long been observed, and was admitted generally. The influence on terrestrial phenomena was very great, and the object was at present to discover if there were any close connection between the two sets of phenomena. The magnetic and temperature alterations followed the solar changes very rapidly, magnetic changes taking about 1·6 day to travel to Europe, the temperature changes taking eight days; hence the Kew weather followed the Kew magnetic weather at an interval of from six to seven days.

Rev. S. J. Perry considered it to be an established fact that there existed a decided connection between solar and magnetic phenomena. Along with magnetic disturbances we had great disturbances in our atmosphere, which gave rise to the aurora borealis.

The Measurement of Solar Radiation.

Professor Schuster read the report of the Committee, consisting of Professor Balfour Stewart (Secretary), Professor Stokes, Mr. G. Johnstone Stoney, Professor Roscoe, Professor Schuster, Captain Abney, and Mr. G. J. Symons, appointed for the purpose of considering the best methods of recording the direct intensity of solar radiation.

The Solar Spectrum.

Professor H. A. Rowlands read a very interesting paper on *Recent Progress in Photographing the Solar Spectrum*, and showed a number of photographs taken by him. His paper was the subject of much favourable comment and discussion.

Observations of the Red End of the Spectra of Solar Spots.

Rev. Father Perry read an elaborate paper on this subject, which excited much interest.

ON THINGS IN GENERAL.

A thorough-going aëronaut must be the most enthusiastic man in the world. It has long ago been proved to be impossible to navigate balloons; though it was also proved years ago that railway trains could not travel more than about a dozen miles an hour, and that it would be impossible for a steamship to cross the Atlantic; and, possibly, therefore, this remembrance serves to keep up the spirits of the members of the various aëronautical societies. But whatever the cause, and in the face of all obstacles and of the most disappointing drawbacks—mortal hurts and maimed limbs—still fresh experiments are carried out, and more money is sunk. One's hopes were raised a month or so ago as to what photography might do in the air at some near period by the reports of the experiments at Meudon—performed, though they were, with such secrecy—but, alas, another *fiasco!* The "self-directing" balloon went up, and — had to be brought back on a cart. M. Tissandier gives a full account of the ascent. He went over hedge and ditch, following on the earth the flight of the monster in the air; but it is clear that failure was already discounted. The ascent took place before sunrise. That gentleman's account of the exploit had to be lengthened out by a description of the extraordinary appearance of the rising sun as the "melancholy *cortège*" wended their way to Meudon wiser, yet, I do believe, not sadder men; such is the aëronaut's enthusiasm!

I much fear that photography from balloons—except such as are "captive"—will be nothing but toy hunting, and the heights of tall mountains will still be a much more frequent standpoint for the camera than the edge of the balloon car.

I was interested in reading Mr. C. E. Abney's description to the Derby Photographic Society of his visit to Snowdon and the neighbourhood, to which a melancholy interest just now attaches, owing to a sad accident that occurred a few days ago, a tourist having met his death through the effects of the lightning while sheltering, during a terrific storm, in a hut upon the summit.

Lofty as Snowdon is it can be most easily ascended in one direction; in fact, all but the last few hundred yards, which *are* stiff, may be done seated in one's carriage. If it happen to be fine when you get there, and there should be no mist, and the distance clear, you can see the traditional score or two of counties always shown to visitors by the inhabitants of any rising ground; but, as to their being worth photographing, that I should not like to assert.

Mr. Abney's experience of a smashed camera leads me to the subject that has been discussed in such an instructive manner during the last few weeks in these columns—the construction of tourists' cameras. Though we may be near to the advent of the "camera of the future," I do not think we have yet arrived at it. Now, though there is no one whose opinion about "camera and lens" I should esteem more highly than Mr. G. Smith's, yet I am bound to say I differ from him strongly when I find him stating, as he did in The British Journal of Photography for the 5th inst., when speaking of the makers of cameras, that "every important hint of increased efficiency is eagerly watched for and instantly adopted." How can this be, when a leading manufacturer can tell you, in answer to a query "what have you new?" replies—"nothing; and my orders are six months behind?" The truth is that when a manufacturer of repute has his workshops arranged for turning out a certain class of instruments it is but reasonable to suppose that he would never make money if he were to be constantly altering and re-arranging; or, if he did so alter, &c., that he would have to charge an exorbitant price. Everyone who has dabbled in inventions knows how much he has to pay for a very simple piece of apparatus when made for the first time, though when repeated many times the same thing may be cheap enough; and so I take it to be with cameras. A man must make a number of a definite pattern before he can see a profit. My own experience is that when a manufacturer has once completed a design for a camera, and begun to manufacture it, it is next to impossible to get a similar one with any material alterations within a reasonable time, if at all. I do not blame him; a camera-maker, though he may be fond of his art, still engages in it as a means of livelihood, and not to try experiments; at the same time it is quite possible to be too conservative. I think it probable that Mr. Smith's words cannot have been correctly "set up," for a little farther on in the same article he, apparently contradicting himself, almost entirely adopts my view in saying—"The trade, as I have before said, are very unwilling to adopt any new method of construction involving, as it does in this case, the change of an entire system."

Monotony of any kind is always in danger of palling upon the artistic mind in whatever form presented, and from this cause, no doubt, we are given the reports from the Manchester Photographic Society (which numbers many really artistic workers in its ranks) of April and May in the month of September. It may, however, be a question whether monotony in this instance is not superior to the alternative of staleness.

There have been several discussions lately—notably one at the London and Provincial Photographic Association—*anent* the slowing of the developer by the addition of acid. I should very much like to learn the name of the acid which, upon being added to the ammonio-pyro. developer, would not slow it; for a portion of the ammonia must be neutralised when the addition is made. The effect produced is then equivalent to a diminution of the ammonia *plus* the presence of an ammoniacal salt of the added acid. It is preposterous to imagine that anything but slowing could result; and to talk of the *effect* of certain acids in the pyro. developer is—well—not logical, to say the least.

I notice in the letter of the Philadelphia correspondent the statement that upon a photographic enlargement—"The artistic work is not done here (America) as it is in England with the crayon points." This is an assumption that is not borne out by facts. Some of the best work of the kind I have seen in this country is not done with the point of the crayons at all, but with stump and crayon powder produced in a better manner than the making of a stumping sauce; and, if any of my readers care to try the experiment, I can assure them that a piece of crumb of bread brought to a point will be far better than india-rubber for obtaining their effects. I am quite one, however, in the view taken in the same communication of Mr. Muybridge's experiments. Mr. Muybridge deserves the utmost credit for his perseverance in overcoming difficulties; but I must say I also fail to see what are the results aimed at in producing those highly-unpleasant pictures described.

Free Lance.

WHERE TO GO WITH THE CAMERA.

[It is hoped that this series of articles will be continued at regular and frequent intervals during the vacation months, and we shall be glad to receive contributions to the series from any friends able to treat of new and interesting ground.]

DUNKELD, MELROSE, AND ABBOTSFORD.

It is a "far cry" to Dunkeld, even should you go by the tourist express to Scotland; and especially is this the case if the night be made hideous by two babies who "continually do cry," and resist all the inane blandishments of those who have them in charge. The law of compensation, however, still works, and your sleepless vigil is rewarded by the sight of a sunrise which you might otherwise have lost; for, at the time of which I write (mid-August), the train reaches Berwick about half-past four, just as the pearly-grey in the east marks the advent of the dawn. As you watch, the grey brightens into orange, and the few purple clouds array themselves in gold-edged livery to attend the arrival of the Sun. As he lifts his head out of the waters of the North Sea the hoofs of Aurora's horses

"Beat the twilight into flakes of fire,"

and another day is born. Man goes forth—the photographer with him—to his work and to his labour until the evening.

You are in Scotland now, and reach Edinburgh about eight o'clock. If you please you may break your journey there, and it is well to do so if you have never seen the "Queen of Cities" before. I need not describe the glorious view from Arthur's Seat or the Calton Hill. Is it not written in the guide books? But the photographer may find ample "food" if he be disposed to avail himself of it, although the field has been closely gleaned. The art should thrive there; for, of eleven houses contiguous to one another, I counted six occupied wholly or in part by photographers. May they continue to prosper and increase!

From Edinburgh to Dunkeld is a matter of about two hours' journey, and we will not linger on the way, though Perth and Stirling are in it. Dunkeld is hardly surpassed in Scotland for the beauty of its situation. Seated in a hollow, through which the clear and sparkling Tweed runs under a noble bridge, girdled around with hills topped with firs, you look and admire. Nor is it without a certain sense of awe you learn that to the east of you is Birnam Wood, which, it is said, has never recovered from its forced march to Dunsinane; for the trees are thin and scanty, although planting has made good much of the deficiency. A camera placed on the stone coping of the bridge will embrace a lovely view, including the old cathedral, the "cottage" (as it is modestly called), of the Dowager Duchess of Athole, and many pretty houses peeping from out their emerald surroundings. There is no lack of subjects to photograph—the Rumbling Bridge, and Falls of the Braun (the scene of one of Millais' choicest landscapes), the cathedral, and many "bits" which meet you if you seek them, for they are too modest to obtrude. Best of all, however, are the Hermitage Bridge and Falls, situate in the park. You enter by the door, pay two shillings, and are placed in charge of a guide, who "personally conducts" you over the grounds. But if you are wise you evade his company, and by a mild and forgiven trespass you climb a gate which will be pointed out to you by someone who knows, and walk along a path sheltered by glorious trees till you reach the spot. There is no fear of passing it. The grand old bridge spans your path, and as you unlimber your camera you are lost in admiration of its wondrous beauty. The delicate hues of the grey stone, the trembling ringlets of birch and ash which caress its base and sides, and the boulders on the river bed tinted with moss and lichens—all reflected on your focussing-screen—make you sigh to think how poorly your best results in browns or purples will represent it all. Having exposed your plates (over-exposed, alas! by me), you go forward and upward a space till you are on a level with the top of the bridge, and in front of you is the "roar of waters" rushing madly over the fall—white in the sunlight, as they leap into the black pool beneath. You gaze your fill, put up your traps, and turn again by the way you came. The river runs merrily at your side as if glad of human companionship; quiet in its depths, and now fretting itself into foam and bubbles as it breaks upon some obstructive boulder, fearful it should be left behind. Here and there as you walk some stone, crowned with a mossy cap, tempts you "to rest and be thankful;" and the heart must be sadly wanting in its best feelings, if it be not lifted in grateful praise for existence in such a fair and beautiful world.

Out of Paradise into the common world! The sun beats on your head while you tramp along the white and dusty road, "carrying weight" in the shape of your belongings. As, like Falstaff, you "lard the lean earth" with your dripping perspiration, the never-resting question of lighter cameras comes to your mind. Yours, like mine, may be the best of its kind; a thing of beauty—and of weight. What is to be done? Why does not Mr. A. Cowan give his attention to the subject? He could scarcely increase his well-earned fame for ingenious contrivances; but could he not turn Willesden paper or ferrotype plate to this useful purpose? It would put "siller in his purse," and the blessings of many photographers would brighten the future of his life. It is no use to talk of taking small views and enlarging them. Amateurs like myself, with whom photography is mainly a holiday amusement, have no enlarging cameras or time to use them if they had; nor is our work (I speak for myself and many others) worth the expense and the trouble. We can scarcely look for much saving in the weight of plates. As Mr. George Smith has pointed out, diminished thickness means greatly-increased expense and added risk of breakage. It is to the camera we must look for increased lightness. "More power to the elbow" of those who are working in this direction.

From Dunkeld to Blair Athole is a journey of an hour or so by rail, and the grounds of Blair Castle, the residence of the Duke of Athole, are worth visiting, but offer little to the photographer save the Falls of the Fender, which are very fine and present the usual characteristics. It is from thence you start through Glen Tilt for Braemar, and I must leave those who have passed through this earthly Inferno—which seems never to have emerged from original chaos—to describe it. Not for me is it given to pay half-a-crown a bottle for Bass's pale ale at Braemar! You take the train back to Killiecrankie, and visit the famous pass, whose steep sides seem as if rent asunder by contending giants. They are clothed now with ash, birch, oak, and fir, whose various tints are lovely to look upon. The river which rushes below is shadowed by the heights frowning above it; but some good pictures may be got if one takes the trouble to descend the slippery and awkward path to the water. Here was fought the famous battle in 1689, in which Claverhouse fell; and here, too, is shown the place leaped by a soldier, and called "The Soldier's Leap." Unbelievers looking at it, and measuring the distance by their own powers pronounce it impossible. But to be pursued by a great hairy Scotchman, with a head of flame, intent on splitting your skull with his claymore, might make a very Mercury out of Mr. Wardle's fat boy. Some idea of the value of the district to photographers may be formed from a little circumstance which occurred to me. An old man who sells views and scraps in the pass told me he had paid Wilson, of Aberdeen, £1,500 for photographs. He did not say in how long a time, but it must make a respectable average.

The sun is setting over the hills as the train takes me back to Dunkeld. His level rays find admission to many a wood and copse denied to his noonday efforts, and the straight stems of the firs are transfigured into pillars of fire. As I gaze and wonder the splendour falls, the glory fades, and the sun sinks to his rest.

> "Look! the world's comforter with weary feet
> His day's hot task has ended in the west."

The day is dead—and dinner waits.

I must not linger over the journey back to Edinburgh and on to Melrose Abbey, which you will probably reach in the evening; and if you put up at the Abbey Hotel you look from the windows into the Abbey grounds. The waning light only permits a general view of wonder and admiration, which closer inspection in the morning seems to deepen and increase. Founded in 1136, by David I., it was three times wrecked and destroyed by English hatred, till it finally rose in all its stately grace under King Robert Bruce. But its worst foes were among its own countrymen; for James Douglas actually used part of its sacred stones to build a house for himself, and so closely was his bad example followed that it is said there is not an old house in the town but has in its walls a stone from the Abbey. However, if much has been taken much remains, and it requires no strong imagination to complete "the slender shafts of shapely stone," and fill in the delicate tracery with its coloured glass, till the intervening centuries fall away and its east oriel stands before the mind as when in all its glorious beauty it fronted the morning sun. Permission to photograph is given as a matter of course. The early morning will be selected for the east window, and late in the afternoon for the south side, as otherwise both sides are bathed in sunlight and the needful shadows are wanting. Some beautiful effects may be had from the interior, but a wide-angle lens is needful. The camera, however, is soon placed aside, for you are on classic ground, and every step recals the past. Here is the grave of the wizard, Michael Scott, from whose arms Sir William of Deloraine rifled his Book of Might: dark and empty now. Here rests the heart of the Bruce, in the place and among the people he loved so well, and for whom he did so much. And here, too, on the ground, is a name, and a name alone—"the Douglases." So much, and no more. The long list of mighty warriors who bore that title, whose fame was in many lands, ends in this—"the Douglases."

> "Here lie the great. False marble! where?
> Nothing but mouldering dust lies here."

The spirit of a mightier wizard haunts the spot, although his only weapon was a pen; and the name of Walter Scott will be linked with Melrose Abbey while a stone of it remains.

From the Abbey to Abbotsford is a natural transition, and a pleasant drive takes you thither past the Eildon Hills, which the industrious, familiar spirit of Michael Scott is said to have rent in three in a single night. A fine view of Abbotsford may be had from the entrance gate, with its delicate background of distant hills. I need not describe a place so familiar to every reader. From the home to the burial place of the poet in Dryburgh Abbey is part of the same drive. It is a beautiful ruin; and the teeming brain—which, were it not that we of this later day are so much the richer for it, would seem to have come into existence three centuries too late—rests here in quiet peace. From every land come pilgrims to this shrine; and Scotland may well be proud that she guards such noble dust.

I must end. I am afraid I have said little of photography, but I can scarcely excuse my shortcoming. It is much to take good views; it is more to become, like Ulysses, "a part of that which we have seen"—to recal quiet resting-places, and thoughts that the fever and the fret of business life are too apt to banish from the mind. But if "the meanest flower that blows" could give Wordsworth "thoughts too deep for tears," much more may our truthful pictures of places and people we have seen and met give rise to pleasant memories when summer days are gone. F. H. Carter.

WARWICK, LEAMINGTON, STRATFORD-ON-AVON, AND KENILWORTH.

On Tuesday, August 26th, a friend and myself started by the 3.15 train from Manchester, bound for Leamington, where we proposed to establish our headquarters for a two-days' photographic trip in that neighbourhood. After a pleasant run through Crewe, Nuneaton, and Coventry, we arrived at our destination, the Manor House Hotel, about seven o'clock, just in time for *table d'hôte*, to which we did ample justice, a band playing in the garden during the time.

Wednesday morning was very wet, dull, and disagreeable; but as our time was limited we proceeded to Warwick by tram-car, where we inspected the ancient building, founded by the Earl of Leicester in 1517 for the benefit of twelve army and navy pensioners from the adjoining towns. Although raining in torrents we each exposed two plates—one on the front of the building from the church wall, the other being the master's house. Both on development turned out very fair, although we gave an exposure of forty seconds with the $\frac{f}{}$ stop of Suter's 3B aplanatic.

We next walked to the castle, but, the lodge-keeper refusing us admission with our cameras, we were directed to the house of Major Fosbery, the agent for the property, for permission. Not finding this gentleman at home we were beginning to despair, when we were redirected to the house of the sub-agent, residing near the castle gates, who, on being interviewed, gave us the required permission. To save this trouble and waste of time intending photographers should write beforehand to Major Fosbery. In the castle grounds we exposed eight plates, the best views being obtained from the meadows near the river, comprising the old Castle Mill, ferry boat, and the celebrated cedar trees. Photography finished, we were shown the interior of the castle, which we enjoyed very much, the pictures, inlaid tables, and armour being very fine.

The weather still being very unfavourable, we returned to Leamington, hoping for better luck on the morrow. On Thursday morning we were up at 6.30, and were much pleased to see a change for the better, the day being all that could be desired. After a hearty breakfast we caught the eight o'clock train to Stratford-on-Avon, where we arrived in about thirty minutes. We immediately proceeded to Shakespeare's house, which was, of course, photographed, although from an artistic point of view we were disappointed, and then without loss of time we turned our faces toward the church. The best point of view we found was from the meadows on the other side of the mill. The picture here composed very well—an old lock and the river in the foreground, with the church in the distance. Being pressed for time we hurried down the line to the station, just in time to catch the ten o'clock train to Warwick, intending to finish there what we had not been able to do the day before.

Arrived at the station, we walked to Guy's Cliffe (about one mile), and there photographed the fine avenue of trees, the old mill, and the house. Thence we proceeded by tram to Leamington for lunch, and then by train to Kenilworth, where we arrived about two o'clock. Having ordered tea for five o'clock we strolled up to the castle; but here, also, the gatekeeper refused admission to our cameras, stating that photography was only allowed in the morning. However, by the transfer of some current coins of the realm he allowed us to have half-an-hour, which, it is needless to state, we took upon ourselves to extend. We only exposed two plates in the interior, the walls being much disfigured with placards, but found more scope for the camera outside in the meadows below the castle, which gives a very good idea of the great extent of this ruin. Here we exposed all our plates. My friend, having only three double backs, had, through the kindness of the photographer at Leamington, been enabled to change his plates there.

We then hastened back to the hotel, had tea, and having caught the 6.20 train to Nuneaton, and thence *viâ* Crewe to Manchester, arrived home about ten o'clock after a very pleasant but rather hurried tour.

A Member of the P.P.S.

RECENT PATENTS.

PATENT SEALED, September 16, 1884.

No. 7,678.—"Improvements in Apparatus for Washing Unmounted Photographs." Abel McDonald, Penrith, and Thomas W. Kendall, Cockermouth.—*Dated May* 14, 1884.

Improvements in Photographic Shutters.

By Frederick Woodward Branson, Leeds.

My invention has reference to improvements in photographic shutters, for which letters patent were granted to Richard Reynolds and myself, dated April 2nd, 1883, No. 1,650.

According to my present invention, on the end of the spindle which carries the flap I mount a lever having thereon a suitable adjustable weight. By altering the position of the weight upon the lever the flap may be actuated at different velocities, and the time of exposure be thereby varied.

The lever may be moved and fixed at any desired angle or position on the flap spindle, so that it may be applied in some cases for opening the flap to allow the drop to fall; or, when required, by throwing the lever over to the opposite side of the centre of the flap spindle and fixing it there, to retain the flap closed until it is raised by a movement imparted to the flap spindle by the attendant.

Instead of the weight being placed on the adjustable lever, in some cases it may be found preferable to attach a cord or its equivalent to such lever at any suitable point, such cord or its equivalent being passed over a pulley on the upper part of the shutter, the required weight being suspended to the other end. Other parts of the photographic shutter are similar to those described in the specification of the above-named letters patent.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
September 30 ..	Bolton Club	The Studio, Chancery-lane.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

At the technical meeting of this Society, held on the 23rd inst., the chair was occupied by Mr. T. Sebastian Davis.

Mr W. England showed a double dark slide for dry plates, fitted with a groove, into which was slid a holder containing two plates back to back, with a stout piece of blackened card between them. For use with this slide was a plate-box furnished with six grooves, each groove containing one of the holders fitted with a pair of plates. It was intended to change the plates from the box to the slide, and *vice versâ*, by working with a black twill bag, furnished with sleeves. The plates were to be changed by feeling merely, and this was much facilitated by their being ready arranged back to back in the holders.

Mr. W. Brooks had found a changing-box to work very satisfactorily, but it was necessary to dust it out carefully each time it was filled, as fragments of glass were apt to be left from the friction of the plates in working. It was also desirable to use only plates that moved very freely in the grooves, and reject others.

The Chairman thought that with plate-carriers, which of necessity must move freely in the dark slide, there would be a certain amount of play that would prevent the focus from being accurately obtained, unless there were some means of bringing the frame always home true to the side of the slide that was to face the lens.

Mr. A. Cowan considered the amount of side play was so small that it might be disregarded.

The Chairman referred to a formula for a developer that had recently been published in The British Journal of Photography, which, when reduced to the proportions for one ounce in order to facilitate comparison with other developers, came out thus:—

Pyro.	4 grains.
Sulphite of soda	4 "
Citric acid	4 "
Washing soda	20 "
Bromide of potassium	¼ grain.
Water	1 ounce.

He said that he found, with this mixture and ordinary exposure, only the highest lights came out, and that, to render it effective, he had to add one minim of liquid ammonia to the ounce of developer. The image then came up with considerable power, but there was green fog, which he attributed to the sulphite of soda. There was also a tendency to frill and blister, which he ascribed to the use of washing soda. He inquired whether there was any satisfactory substratum that would prevent frilling.

Mr. Brooks had never found a plate which soda would not cause to frill. The developing formula that had been mentioned was, he believed, published as a complete one, and yet it required a certain addition of ammonia to render it effective.

Mr. Cowan believed that if the citric acid had been omitted the developer would have worked in as many seconds as it appeared to require minutes.

Mr. W. E. Debenham said that when the use of a citrate in the developer was introduced by Mr. G. Watmough Webster it was as a remedy for over-exposure, and plates many times over-exposed were stated to come out as if normally exposed. The use of a developer containing a large quantity of citrate would, therefore, presumably necessitate greatly-increased exposure of the image. Was there any special good quality in the negative produced by this developer to counterbalance the slowing effect upon the plate?

The Chairman thought not. There was certainly green fog, no doubt due to the sulphite of soda.

Mr. Brooks thought that, in hot weather, sulphite of soda was best omitted from the developer altogether; but it might safely be used in cold weather, and he then liked the effect it produced.

Mr. W. England had discarded the use of sulphite for the last two months.

Mr. F. W. Donkin said that sulphite of soda soon changed into sulphate, and then was a restrainer. This change took place even in closed vessels.

Mr. Cowan had discarded the use of sulphite for a long time past.

Mr. Ashman inquired whether the fog that had been complained of had been positively traced to the use of sulphite of soda.

Mr. England replied that it had. He had cut a plate in two, and, treating the halves in precisely the same manner in other respects, had found that the one developed in presence of sulphite was fogged and the other one clear.

The Chairman said that sulphite kept the developing solution clean, but the plate itself was not so clean as without it.

Mr. Brooks did not think that the discolouring of the developing solution was injurious. On the contrary, he found that he got the brightest results by using the same developing solution over and over again, until it was the colour of bottled stout. It must not, however, be kept, but used for all the plates immediately one after the other—adding a little more ammonia as the development became slower, and a little more pyro as they appeared to require it for density. Working in this way one ounce of pyro. would go as far as ten or fifteen if fresh were used for each plate, and he preferred the negatives resulting from this treatment.

Mr. Arnold Spiller remarked that with this method the developer was continually acquiring more bromide, from the decomposition of the sensitive compound in the film.

The discussion then turned upon frilling, and Mr. Cowan said that he had found that the maximum of chrome alum that could be worked in emulsion was a-quarter of a grain to the ounce. With this proportion the emulsion had to be heated to 150° for coating, but the plates set immediately, even in hot weather, when the coating-room stood at 80°; and emulsion without chrome alum did not set at all, but remained liquid on the plate all day.

The Chairman said that he had used silicate of soda as a substratum, laying a three-per-cent. solution on the plate with a brush. He had found this gave a tendency to prevent frilling and to cause smooth and easy flowing of the emulsion, but the effect could only be called a tendency and was not complete in either direction.

Mr. T. Bolas said that the use of silicate without subsequent washing left an alkaline deposit on the glass which might be injurious to the emulsion. He thought that the best method of using silicate of soda was to employ it mixed with albumen, to allow the coating to dry, then to wash away the alkali with water, and dry again before coating.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on Thursday, the 18th instant, the chair was taken by Mr. William Ackland, F.C.S.

Mr. A. Cowan, referring again to the difference between the results obtained by himself and Mr. Ashman when using Monroe's developer, brought with him some plates that had at the previous meeting been given to him by Mr. Ashman to develope. As in his previous trials, the image came yellow. The only difference that he was aware of between his working and Mr. Ashman's was that the latter gentleman used ordinary washing soda to develope with, whilst he employed the crystallised carbonate from the operative chemist's.

Mr. Ashman showed some negatives on extremely-rapid plates. They had received an exposure after five o'clock, in the studio, of one-third and one-quarter of a second respectively with a lens stopped down to $\frac{f}{16}$. A wet collodion plate had required with similar light an exposure of thirty seconds with the full aperture of the lens.

An extract from a letter was read, in which the writer stated that he had been told that when using dry plates the length of focus of the lens need not be taken into account in calculating the exposure, as they were so sensitive that the difference between the time of acting of long- and short-focus lenses was not noticeable when using them.

Mr. W. E. Debenham remembered seeing an article some years since in which the writer stated that a great difference existed in the ratio of the speed of a long-focus and a short-focus lens in the winter and summer. Notwithstanding that in the winter the long-focus lens required three times or more as long as the *carte* lens, in the summer they worked with nearly equal rapidity. This was, of course, merely an instance of inaccurate observation; but, unfortunately, in photography there were many instances of inaccurate observations put forward as facts.

Mr. W. K. Burton said that formerly there was an idea very prevalent that the ratio of speed between collodion and gelatine was very different in summer and winter, but experience had dissipated that notion.

Mr. H. C. Turner showed some engravings and negatives made from them by printing in contact on albumen paper; also prints from these negatives, some of which were made by the blue or iron printing process, and some on salted paper. The engraving had been rendered translucent in the first place by being coated with a mixture of one part of lard and three parts of turpentine, boiled together. He had formerly used the engravings without this treatment, but the result was not so good. He had been led to try this mixture from reading the account of an inquest after a fire at a tracing-paper factory, when it was mentioned that lard and turpentine were being heated in a pan.

A Member thought that the preparation of such a compound in a private way was very likely to result in an inquest.

Mr. Burton, remarking that there had been inquiries for silver gauze through which to squeeze emulsion, asked whether any member had found injury to accrue to emulsion from the use of copper gauze. He had not found any ill result himself.

Mr. J. B. B. Wellington's experience was similar to that of Mr. Burton.

Mr. H. S. Starnes showed a tray which he used when coating plates. The tray was of the same length as the width of the plate to be coated. The bottom of the tray and one of the vertical sides were not quite in contact, but allowed a stream of emulsion to flow when the tray was tilted with that edge downwards. The plate was laid upon a level table, and the tray tilted and drawn over it. A slip of wood close to the slit, and about half the depth of the tray, kept the emulsion from flowing into the slit when the tray was not being tilted.

Some plates were exhibited having a dense mark along the edge, and then a rather insensitive mark next it. In answer to inquiries, it was elicited that the emulsion had been treated with bichromate of potash and that the drying had been slow.

Mr. Burton suggested that decomposition of the gelatine might account for the peculiarity observable.

Mr. A. Haddon thought it was due to accumulation of the salts imperfectly removed by washing. He remembered seeing similar marks on plates that had been coated with unwashed emulsion.

Correspondence.

EXPOSURES.

To the EDITORS.

GENTLEMEN,—I take the liberty of addressing you a few remarks on the above subject, with the condition that if the ideas herein expressed have already been suggested in your columns you consign this to the waste-paper basket.

In dry-plate work we have the clearest instructions how to produce a picture with one exception—*the exposure*. All the treatises, guides, companions, &c., dismiss the subject with—"*As to exposure, no definite rules can be laid down.*"

Amateurs (as myself) purchase plates labelled 10, 20, and 30 times more rapid than wet collodion; but as the great body of amateurs have had no experience in the wet process it follows that the label is a perfect puzzle, the consequence being over-exposure, under-exposure, and in many cases so much disgust that the *paraphernalia* is got rid of at any price.

But a little perseverance will surmount the difficulties—such is my experience. My *modus operandi* is as follows:—I take a plate (I use $6\frac{1}{2} \times 8\frac{1}{2}$), and in the dark room carefully cut it with a glazier's diamond into six or seven pieces lengthwise. Each piece is placed in a separate dark slide on a bright summer's day. I focus a subject, and then proceed to expose as follows, being careful to keep a record of the number of each slide:—

No. 1. Drop shutter.
,, 2. Uncap and cap as quickly as possible.
,, 3. Uncap and expose one second.
,, 4. ,, ,, two seconds.
,, 5. ,, ,, three ,,
,, 6. ,, ,, four ,, and so on.

I develope the whole at one time, being careful to scratch on each fraction of plate when taken out of the slide the number of the record kept. After development and fixing I can decide which is the proper exposure. This can be repeated as often as there is a modification of light (say during the different seasons), and thus by the loss (?) of *one* plate the amateur is able to arrive at a proper exposure, and save dozens of plates, time, and patience.

There may be nothing original in the above, but the Editors must remember that amateurs—at least, many of them—have not the opportunity of reading up what has been published in years gone by.

In conclusion: I would suggest to amateurs the advisability of learning, by comparison with a clock or watch, the exactness of a *second* of time.—I am, yours, &c., R. H. MURRAY.

Buenos Ayres, August 20, 1884.

THE SODA DEVELOPER.

To the EDITORS.

GENTLEMEN,—Mr. W. M. Ashman thinks I ought to have been aware of the fact that Mr. Munroe's formula has been largely employed since its publication. I am perfectly aware that the soda developer has been in common use; but, whether it is owing to my not being gifted with such a retentive memory as Mr. Ashman, or to my not being within the magic circle of the "profession," that I have failed to recognise the origin of the formula in question I know not.

Mr. Ashman finds fault with me for limiting its use to interiors and copying. I would merely remark that in these cases more especially I found it certain and reliable. I shall, as he suggests, give it a further trial as a universal developer and "report progress."

Mr. Ashman says he can obtain the black image without the alum bath. All I can say is that I get a sickly-looking, yellowish negative if I omit it, while with it I secure a sparkling, blue-black image.

It would be interesting to know whether Mr. Cowan at the last meeting of the London and Provincial Photographic Association used the alum bath when he failed to obtain the black image that Mr. Ashman obtained with Mr. Munroe's formula.—I am, yours, &c., L. MACDONA.

Cheadle Rectory, Cheshire, September 22, 1884.

Notes and Queries.

"CAN you inform me of a brilliant yellow pigment of a slightly orange character, regarding the permanency of which there is no doubt?—SYNTAX."——In reply: *Cadmium yellow* will fulfil this requirement better than any other pigment with which we are acquainted. Had "Syntax" mentioned the use to which he intended putting this pigment we might, perhaps, have been able to advise further.

"ANXIOUS" asks if it be possible to learn to photograph in three lessons.——In reply: We do not see the impossibility of doing so, provided "Anxious" makes use of gelatine plates. If he fall into the hands of a skilful, painstaking Mentor he will acquire, at least, the *elements* of a mastery of making a negative in one lesson. A second lesson would be devoted to printing, and the third to a recapitulation of points overlooked, or cognate to those two branches.

X. and Z. say—"At an early date we purpose sending a photographer to London to take for us a series of negatives representing life in the lowest social stratum of the great metropolis. To what part of the city should his attention be directed in order to secure the class of pictures we require?"——In reply: The "slums" to the immediate west of Lincoln's Inn Fields and east of Drury Lane will furnish everything that can be required or desired in depicting "low life" in London. White Horse-yard and its immediate surroundings north and south should prove a veritable *El Dorado* to any photographer who is quick to see and prompt to act.

"CAN moonlight photographs be taken? I have seen what purported to be a moonlight photograph taken in the Isle of Wight, showing breaking waves, reproduced in the most charming manner.—R. F. SCOTT."——In reply: The photograph referred to was taken by sunlight, but had been printed darkly in order to show a moonlight effect. By employing a sensitive gelatine plate, however, and a quick-working lens, a genuine moonlight view may be obtained by giving a protracted exposure—say an exposure varying from one hour to six hours, according to the nature of the subject.

M. D. inquires—"Are there any means by which I can fix a crayon or chalk drawing so as to render it adhesive to the paper to which the crayon is applied? I have tried floating the drawing upon milk and then drying it, and I have also tried the application of resinous solutions by sponging them upon the back of the drawing, but in both cases the picture is degraded in an appreciable degree. Your kind aid is requested."——In reply: Let our correspondent obtain one of those toilet toys known as a "spray producer" or "atomiser," and apply the spray of a weak alcoholic solution of bleached lac and sugar candy to the drawing. This will fix the picture without discolouration.

GEORGE C. BARKER says:—"I am informed that there exist means by which a tint may be imparted to a silver print on albumenised paper or, at anyrate, to the albumenised surface of the paper, after the print has been toned, fixed, and washed. In other words, that any of the tones peculiar to a print having been produced on tinted albumenised paper may be obtained when plain or untinted paper is employed. If this be the case I will be glad of any information on the subject."——In reply: After washing the print place it in a vessel of water to which has been added a few drops of any liquid aniline dye that may be preferred. Avoid the employment of too strong a solution, as the albumenised surface of the paper is very readily affected by the action of the pigment.

T. inquires—"Is there any similarity between the 'elephantinon' process and the 'Grecian' method of colouring photographs? The former was in use many years ago, but I have not heard of it for a long period. I greatly admired the photographs bearing this designation, and have one framed which is admired by all who see it."——In reply: The term "elephantinon" was applied by a clever colourist, Madame Una Howard (now deceased), to a species of colouring of which she made a speciality. The photograph was rendered transparent in only a slight degree. It was tinted lightly in front and still more strongly behind, a peculiarly-delicate, ivory-like effect being the result. In the "Grecian" process the photograph is made very thin by having the paper rubbed away; it is then rendered as transparent as possible, and the colour is applied entirely from behind.

WE are asked to state whether two photographs of landscapes can be taken by different individuals, at various times, which shall be so like to each other as to defy any point of dissimilarity being discovered by the keenest vision, with the sole difference of dimensions, one being larger than the other. It is contended, we understand, that one of the pictures has been copied from the other.——We are of opinion that two photographs could *not* be taken under the circumstances mentioned which would be similar in the sense referred to, for there would be so many points of difference between them as to be readily distinguished by an expert. Even in such an unchangeable object (in its physical aspects) as the moon, it is quite easy to distinguish between the photographic representation of the satellite by two individuals, although operating with telescopes of similar power. A noted—if not notorious—case in connection with this branch of photography, and one strictly to the point, was brought prominently before the scientific public twenty years ago.

DAVID H. SIMPSON writes expressing his opinion that it is to be regretted the triple achromatic lens has fallen into disuse. It had, he says, so many points of excellence, and the photographs taken by its agency were usually so soft and delicate, that he feels certain of a successful future being in store for it, provided it were again manufactured.——That the triple lens was useful and excellent we readily admit; but, so far as we are able to ascertain from a careful comparison of a good example of this special optical production, it is no better—even in the slightest degree—than more modern objectives which contain fewer lenses and, therefore, fewer reflecting surfaces, and which can be manufactured at a smaller cost. The doublet lenses of the rapid class work in less time and are more generally useful than the triple; hence the latter has been superseded. But we would not advise anyone possessing a good triple lens to part with it on the mere chance of acquiring another which may possess the advantages hinted at, because for groups and copying it is a very useful photographic appliance.

Exchange Column.

I will exchange 143 numbers of THE BRITISH JOURNAL OF PHOTOGRAPHY, gem camera, nine lenses, good as new, and the *Newcastle Weekly Chronicle* from March, 1883. Wanted, whole-plate bellows-body camera.—Address, PHOTO., 121, Carlton-road, Attercliffe.

I will exchange a fifty-inch special express bicycle, with lamp and odometer, cost £8 11s. 6d., for a Victoria camera and lens; also a fifty-two-inch tourist bicycle, cost £7 10s., for a standing head-rest, cameo press, and dies for *cartes*.—Address, W. W. EVERS, Rose Cottage, Wath, near Rotherham.

I have duplicate volumes of many years of the *Photographic News* and some of THE BRITISH JOURNAL OF PHOTOGRAPHY. Wanted, the *News* for 1861-62, 1873-74, and the Journal for 1857-58-59 and 1866, in exchange volume for volume or give or take other useful exchange.—Address, W. E. DEBENHAM, Massingham House, Haverstock-hill, London.

I will exchange a 16 × 12 and a 12 × 10 porcelain dipping-bath, quantity of opal glass, tripod-stand, about two years' numbers of THE BRITISH JOURNAL OF PHOTOGRAPHY for 1883-84 and Hardwich's *Manual of Photographic Chemistry*, for embossing-press with cabinet and *carte* dies, half-plate portable dry-plate camera with dark slides, Bigelow's *Album on Lighting*, or Fallowfield's 10 × 8 new patent burnisher; difference adjusted.—Address, E. HALL, photographer, Malton, Yorkshire.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPHS REGISTERED.—

John Edmund Cracknell, 6, Wightmans-road, Hornsey, London.—*Photograph of Royal Autographs.*

John Owen, Newtown, North Wales.—*Two Photographs of Miss M. C. Phillips and Two Photographs of Miss R. Davies—the Welsh Evangelists.*

The Burnley Photographic Company, 25, Bridge-street, Burnley.—*Photographs of the Barnoldswick 1st Eleven Cricket Club; The Burnley 2nd Eleven Cricket Club; The Burnley 1st Football Team.*

PHOTO. (London).—Received as we were going to press.

JOSEPH J. GRANT.—We do not supply apparatus of any kind. Consult our advertising columns.

H. W.—The tests employed reveal a state of matters that we think will account for the formation of the spots.

R. G. A.—The Photographic Exhibition will be opened to the public on Monday, October 6th. The Health Exhibition will not be closed till the end of October.

S. A. WOLLETT.—If your dark-room window will successfully stand but half the test to which you have subjected it, it will answer quite well for all practical purposes.

A. SEEMAN.—The prints are very good of their kind; but you must bear in mind that the process itself is incapable of yielding results equal to prints on albumenised paper.

E. J. HOLMES.—We believe the light is used by some professional photographers; so are other systems of artificial lighting. If expense be not an object the electric light would, perhaps, answer your requirements best.

I. I. I. I.—It is evident the chemical and actinic focus of the lens does not coincide. From your description of the instrument we strongly suspect one or more of the glasses have been changed since it was issued from the manufacturer.

S. S.—There is no real advantage in using bleached lac instead of the yellow variety, except its freedom from colour. Practically in the thin film, such as exists on the negative, the slight tint conferred by the orange lac is no disadvantage whatever.

B. P.—It is pretty clear that the solution was put into a dirty bottle. As the chemist supplied the bottle you will be quite justified in expecting him to send you a fresh solution. Of course you will return the old one, so that he may recover the gold.

A. BOYES.—The process by which the red pictures referred to were produced is the carbon. By this process it is manifest that pictures of any colour may be produced at will simply by the admixture of a suitable pigment with the gelatine with which the paper is coated in the first instance.

G. M. J. B.—So far as we are aware the apparatus is not an article of commerce. You had better write to the inventor again. Your former letter may have miscarried. The society has been in vacation for some months past. Possibly this may account for your former communication not having received attention.

PATENTEE.—You had better get a copy of the New Patent Act. This you can do for a few pence at the Sale Department, Patent Office, Curzitor-street, Chancery-lane. It will give you the necessary information. To learn if your invention is already patented you will have to search the records of the Patent Office. You can do this, without charge, any time between ten and four o'clock.

AMATEUR (Wilts.).—In all probability the sulphite of soda—or, rather, what you purchased from your local chemist under that name—was not sulphite of soda at all, but the sulphate. If so, it will fully account for your failure. You had better procure a fresh sample from some photographic chemist. Few country druggists keep sulphite of soda that can be relied upon, if they supply it at all.

G. R. FLUDDER.—If you cannot succeed with any of the numerous intensifiers that have from time to time been recommended we are afraid we cannot assist you further. The commercial intensifiers mentioned are highly spoken of by most workers. You should bear in mind that the only "royal road" to success is experience. From what you say, we fear it is this you lack, and not that the different intensifiers you have tried are at fault.

WARWICK.—Your sudden success, after several weeks of failure, is probably due to the change in temperature. You were somewhat unfortunate in commencing experiments at a time when the heat was so excessive. Experienced workers have met with the greatest difficulty in carrying on their operations in collotype printing when the weather was extremely hot, as it was at the time you met with your failures.

Z. Z.—There is no difficulty in obtaining brilliant results by the carbon process on opal glass; but you will have to employ as vigorous negatives as for paper. A strong negative means a thick film of pigmented gelatine in the shadows of the prints, and if this be coloured, and highly "gummed up" in doing so, there is some little risk of the film splitting up should the picture be made abnormally dry. Hence, carbon prints on opal are usually made from rather weak and delicate negatives, so as to avoid the risk.

W. W. EVERS.—1. You will find many good formulæ for dry plates in the ALMANAC for the present and the past two or three years. Commercial plate-makers do not publish the formulæ by which they work.—2. Yes, if you can uncover and cover the lens sufficiently rapid.—3. Use one or other of the numerous clearing solutions.—4. To preserve the solution.—5. There is no harm in using the fixing solution saturated, except that it will not fix so quickly.—6. Better use them separately; there is no advantage in employing them mixed.

RECEIVED.—W. Brooks; W. Coles; J. Harris; S. Fry; Kenneth Bean; Lyons; Hypo.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—In accordance with a resolution passed at the June meeting of this Society, a special meeting will be held at the House of the Society of Arts on Thursday next, October 2nd, at eight o'clock, to consider the future of the Society, after which Mr. W. Ackland will read a paper *On Furnell's Lens.*

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, October 1, the subject for discussion will be *On Artificial Lighting.* At 9 p.m. the meeting will be resolved into a special general meeting. The Saturday afternoon outing will be at Blackwall—train leaving Liverpool-street Station at 2 p.m.

THE NEW YORK SOCIETY OF PHOTOGRAPHIC AMATEURS.—On the evening of the 9th instant a large body of the New York Photographic Amateurs assembled in the rooms of the Society, 1,260, Broadway, to listen to an address by Mr. A. L. Henderson, of London, on the preparation of gelatine plates by cold emulsification. Knowing the experience of Mr. Henderson in this department of photography, his lecture was heard with great attention. At the close an opportunity was afforded for asking questions, and many of those present availed themselves of this privilege. Numerous experiments were made and demonstrations given during the lecture, at the conclusion of which the thanks of the Society were unanimously awarded to Mr. Henderson.

AËRONAUTIC PHOTOGRAPHY.—From that intrepid aërial navigator, Mr. Cecil V. Shadbolt, we have received a set of his latest balloon photographs, taken from the car of the "Monarch," on the occasion of a special trip on August 13th last. These comprise *Woolwich*, as seen from an altitude of 500 feet over Silvertown; *Royal Albert Dock and Thames*, at an altitude of 600 feet; *The Crystal Palace*, at 1,100 feet; and *Blackheath*, at 2,700 feet. Speak of a "bird's-eye view" of any locality! What can possibly equal in accuracy the view of a scene on *terra firma* depicted by the finger of science when working in upper air? Mr. Shadbolt is to be congratulated on his success.——From Mr. James H. Hare we have also received interesting mementoes of the recently-celebrated "Balloon Centenary," in the form of a series of cabinet views of the balloons "Robin Hood," the "Colonel," and the "Monarch," taken at various stages of their progress—from their inflation to their ascent and disappearance in the distance. The groups present are successfully delineated.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician,
For the Week ending September 24, 1884.
THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1274. Vol. XXXI.—OCTOBER 3, 1884.

ANOMALIES IN DEVELOPING FORMULÆ.

We have frequently called attention to the strange anomalies which exist in the developing formulæ issued with the different commercial plates as well as in those frequently published in these columns and in the Almanac, and have pointed out how difficult it is for those operators who do not confine themselves to one make of plate to follow out instructions without having a distinct set of solutions for each separate brand. In view of the numerous fresh departures in the direction of other alkalies than ammonia, and the consequent increase in the number of new formulæ, these difficulties do not promise to be lessened; and as the subject has been once more raised by Mr. G. Watmough Webster in our last issue, and by Mr. W. F. Mayes in the previous one, we may be allowed to call attention to one or two points which have hitherto escaped general notice.

In the first place, referring to Mr. Mayes's carefully-compiled table for the reduction of different formulæ to common terms, we must point out the fact that it fails in complete accuracy from the neglect of one important element in the working out of the formulæ. We allude to the necessary increase or decrease in the volume of the solutions consequent on the solution of certain solids or the mixture of water and ammonia. Thus, if one ounce of potassium bromide be dissolved in two ounces of water the volume of solution formed will not be so low as two ounces nor so high as three, but will be between the two, the exact bulk being beyond the powers of calculation of the ordinary operator to discover *on paper*. On the other hand, when water and ammonia are mixed at normal temperatures a decrease in the combined volume ensues, so that it will be evident that to attempt accurately to calculate the respective proportions or quantities of material included in different formulæ is impossible without actually working out the formula and noting carefully the bulk of solution which results.

The amount of error thus caused in the generality of formulæ is probably not great, though in those which contain a large proportion of bromide—as, for instance, Swan's—it may be sufficient to cause trouble. But if our readers will take the trouble to practically compare a few of the better-known formulæ with the figures in Mr. Mayes's table they will find that, with the exception of, perhaps, one—of which more anon—none of them agree.

Taking three haphazard we have made them up carefully, using an analytical test mixer to accurately determine the volume. We find Swan's formula—to which allusion has been made, and which consists of strong ammonia and bromide of each one ounce, and water half-an-ounce—makes up to 840 minims or one ounce and three-quarters. In order then to estimate the equivalent of one minim of ammonia we are compelled to measure by some method or other one and three-quarter minims—a rather difficult job; or if we desire to proceed on the standard of a grain of bromide we are reduced to the still more difficult computation of 1·92 of a minim. In like manner Wratten's formula for their instantaneous plates contains one minim of strong ammonia in each three and three-quarter minims of solution, and one grain of bromide in each half-drachm; and Nelson's one minim of ammonia in about 1⅝ minims of solution, and a grain of bromide in a little under seven.

As we have remarked, the discrepancies are, perhaps, not particularly vital, but are sufficiently bewildering to puzzle those who desire to compound their developing solutions from separate standard solutions; and, as the remedy for such extremely awkward figures is so simple, it seems a pity it should not be generally adopted. Referring to the one solitary case in which it is, perhaps, possible to calculate with accuracy, the solutions are not made by mixing together certain definite quantities of the ingredients, but by taking definite quantities of the important constituents and making a definite bulk of solution. In other words, as the dispensing chemist would say, "Liquor ammonia one ounce, bromide of potassium one ounce, water *ad* two ounces"—that is to say, water *to make up* two ounces. If the formula quoted were compounded in that way, each two minims would represent one of strong ammonia; and, if troy weight were substituted for avoirdupois, the same quantity of solution would also contain one grain of bromide.

In the case of the soda developer, in which a far larger proportion of solid matter is contained, the importance of care in the direction suggested is still greater; and it is eminently desirable, if only for the sake of facilitating calculations, that some exactitude should be observed with regard to the constituent parts of the developer.

As regards the suggestion of Mr. Webster—that manufacturers should frame their formulæ in such a manner as to permit a ready comparison of the proportion of pyro. to ammonia or of bromide to ammonia—we quite agree that there is ample room for reform; but if they would first carry out the proposal we have made the user of the plates would at least be able to perform his calculations without the necessity for making a quantity of solution which he may probably never use.

And now a word upon another subject intimately connected with development, and possessing most decidedly the character of an anomaly, though, in this case, it is the operator and not the manufacturer who is at fault. We find most photographers exercise considerable care in the purchase of pyro. of good reputation, of bromide and sulphite of soda of acknowledged quality, and if anything go wrong the pyro., the sulphite, and the bromide generally suffer the odium. But is it not somewhat anomalous that the ammonia, which plays at least as important a part in the function of development and which is quite as difficult to preserve in proper condition as the other three put together, is accepted, without guarantee or warranty, as being *liquor ammoniæ fortis* of s. g. ·880? We venture to say that not one in twenty samples taken haphazard from commercial sources will be found, upon trial, to come up to that description. It is true the majority may not vary to a very great extent, though we had submitted to us a short time since a sample obtained from a first-class chemist as "s. g. ·880," but which on testing we found to be between ·940 and ·950, and contained *less than one-half the percentage of real ammonia*. The result of its employment had been the spoiling of a batch of important negatives from sheer ignorance of its deficiency in strength; but had that circumstance been known and allowed for the faulty sample would have answered as well as the best.

We would therefore counsel all users of dry plates to either have their ammonia guaranteed of a certain strength—not necessarily ·880—or preferably to test its specific gravity for themselves. A specific gravity bottle will cost but two or three shillings, and will pay for itself in a short time. The *modus operandi* is simple enough, and a method we described some years ago will secure all the accuracy the photographer requires. It consists in filling the specific gravity bottle with the liquid to be tested, plunging it for a quarter of an hour (without its stopper) in a basin of cold distilled or rain water. It is then stoppered, wiped and weighed, emptied, washed out, refilled with water from the basin, again weighed, and the weight of its contents on the first weighing divided by the weight of the weight of water on the second. Reference to the table at page 254 of this year's ALMANAC will show its percentage value in real ammonia, and a simple calculation will enable the operator to adjust its strength to suit any formula written in terms of ·880 ammonia.

DENSITY IN COLLODION IMAGES.

IN making copies of engravings the negative must, of course, be of as intense a character as possible. We lately tried a very old sample of collodion originally prepared for engravings, and which, when nearly new, or at most only a few months' old, gave negatives having a degree of intensity greater than we remember to have seen before or since. After remaining untouched for a few years we had the curiosity to try this once-excellent engraving collodion for the same purpose as that for which it had been originally prepared. Its virtue had, however, departed. While it yielded negatives that were clean, they possessed scarcely any density. A change, too, had taken place in the solubility of the film; for, whereas in its palmy days it resisted the strongest alcohol, it now succumbed to all alcoholic varnishes, even when their strength had been reduced by the addition of water.

For the benefit of those whose collodion may have become disintegrated in a manner similar to that to which we have referred, we shall describe by what means it may be rendered serviceable.

First of all, it will be necessary to add a small proportion of an iodide, such as that of ammonium. To strengthen the negative: make use of an admixture of solutions of nitrate of uranium and ferridcyanide of potassium, the proportions being nearly equal parts, although this does not appear to be of much consequence. When this solution is applied to the thin negative it immediately acquires a dark brown colour, and the intensity goes on gradually increasing in force, until eventually what was at first a thin, feeble negative becomes one possessing great vigour, which is still further increased upon drying.

If the operation terminated here all would be well; but it is unfortunate that the application of varnish quite destroys the intensity, leaving the image thin and poor. In cases where a solvent action is exercised on the film itself, this may be prevented by the substitution of a benzole varnish for one in which the solvent is alcohol; but in this case the reduction of the strength of the image takes place in quite as great a degree as before.

To prevent this it is only necessary to make a thin solution of gum arabic and apply it as a varnish to the negative. This does not act in a deleterious manner as regards reducing the intensity. The strength should be such as to fill up the interstices of the collodion film, which is now spongy and porous to a very considerable extent. When dried, any varnish, whether alcoholic or benzole, may be applied for the final protection of the film, and without the slightest reduction of intensity being experienced.

VIGNETTING.

AMONGST the various fashions in photography, some of which come and go, the practice of printing portraits in what is known as the vignette style is one that has held its ground from the period of its first introduction, and is at the present time at least as popular as ever. This general and enduring consensus of opinion shows that there is an inherent attractiveness in the results of the process that render it independent of the fickleness of mere fashion or fancy. The clearness with which the outline of the head is delineated against the light ground, and the absence of anything to distract the attention in the picture, are no doubt the main causes of the popularity of the vignette style.

It is, however, not of the advantages of vignetting that we wish now to speak, but of the different methods by which the effects have been, and are, produced. The softening of the edge has been effected in two distinct ways, and perhaps more generally by methods in which these two plans are united. One distinctive method of softening is to place in contact with the negative a mask of some kind, the inner edge of which is graduated to give the intermediate or softening tones. The best-known example of this method is the vignetting glass of silver-flashed orange, the vignetting colour in the centre of which is ground or dissolved away. The other distinctive method is that in which distance is employed to produce the gradations required, and may be exemplified by a card with a hole in it supported at a certain distance in front of the negative. This latter method is so simple, and lends itself so easily to variations both of form and of degree of softening away, that it has come into very general use. There are also plans of vignetting in which both principles come into play. Of these methods we may instance the use of several layers of tissue paper, each a little larger than the next one. This combined set of papers is held between two glasses, and laid either directly upon the negative or kept at a certain distance if it be desired to make the vignetting more gradual.

One objection to the use of the simple opening in the vignetting form, and to the dependence upon distance for the effect of softening a gradation, is that, unless suitable precautions be taken, the light may strike under the "form" more in one direction than another, and so cause the shade on the background to show more on one side than upon the other; or may cause the top of the head either to be lightened itself, or, on the other hand, to have too much dark shade over it.

To overcome this difficulty some printers use a revolving table, kept in motion by a roasting jack; but this motor is scarcely powerful enough for a large board capable of holding many pressure-frames. In one establishment that we have visited, where the printing for several branches is carried on, a large circular table or board is suspended by three cords joined together at the top like the strings of a scale-pan, and an occasional twist by the person who has to examine the presses, in order to decide when the printing is deep enough, keeps the whole in motion. In another establishment we have seen the printing of vignettes conducted under a sash glazed with ground glass, and it is a rule each time that a press is looked at to give it a quarter turn in one direction. Both these plans are found to work well in practice, and to give a print with the head and figure in the part of the general printed image where it was desired to be, when placed in the frame.

A manner of fitting up and arranging printing-frames which we have seen employed with good effect may be new to some of our readers. We will, therefore, briefly describe it. At the establishment where we saw it in action the size known as half-plate was in use for both cabinet and *carte* negatives, and it will suffice to explain how the method referred to is carried into effect for these two popular sizes. Taking the *carte* size first: Two pieces of millboard are cut to be of the dimensions of the frame itself. In these millboards are cut two holes of about three inches long and two and a-quarter broad, side by side, like the prints in a stereoscopic picture. One of these millboards is glued on to the front of the frame, and then strips of thinner card of about half-an-inch wide are glued on to the surface of the millboard round three of the sides—two of the short and one long side. The second sheet of millboard is now glued on to these strips, and a few tacks for additional security are driven in through the two thicknesses of millboard and the one of card into the woodwork of the frame itself. There is thus a double thickness of millboard with holes in them corresponding to the two *carte* portraits upon the half-plate. The two folds forming this double thickness are separated by the card round three sides sufficiently to allow a card to lie between them, and close enough to keep this card without shifting unless it be intentionally done with the fingers.

To complete the vignetting "form" a number of cards are provided all of the same size, and about half-an-inch longer and broader than the openings that have been described in the millboards. These cards have openings of various sizes, and in order that the same negative may always have the same-sized opening, and for convenience of reference, the movable cards are numbered. The system of numbering adopted is by eighths of an inch. Thus, an opening one inch long is numbered 8, one of an inch and a-quarter is numbered 10, and so on. There are also some with openings of extra width and some with extra narrow openings proportionate to the length, and these are lettered W or N, in addition to the number specifying the length. When the negative is placed in the frame, one of these loose cards is slipped between the two thicknesses of millboard through the space which has been left along the side, where they are not attached by means of the intermediate strips of card running along the other three sides. The card is adjusted to the right place over the negative by the fingers, and it is found that it does not slip, but will remain in place, kept there by the pressure of the millboard on both sides.

In the case of *carte* vignettes of ordinary size it is found that the thickness of the wood composing the front of the frame keeps the vignetting card at a sufficient distance to ensure the necessary softness. With portraits of larger size—those of the cabinet, for instance—it is considered better that the softening round the head should be diffused over a larger surface, and that towards the lower portion of the figure the vignetting should be still more gradual. In order to effect this, strips of wood are attached to the front of the frame before the millboards are glued on. These strips are arranged in the following manner:—On one end of the frame there is a strip of about three-eighths of an inch in thickness, and on two of the sides are strips, one end of which meets and is of equal thickness with the end strip, whilst the other ends of these side strips are flush with the surface of the frame itself. One end of the millboards, and, consequently, of the card enclosed between them, is thus raised higher from the negative than the other end, and the negative is placed so that the lower part of the figure comes where this end is raised to the greater distance.

Concerning a variation on the plan just described, especially contrived for carbon printing and suitable for that purpose, as well as for the production of vignettes with tinted margins by any method of printing, we may speak upon another occasion.

NEGATIVE EVIDENCE REGARDING THE DETERIORATION OF GELATINE PLATES.

Having observed in one of the foreign journals that the deterioration of gelatine plates which have been packed with a thin slip of cardboard placed round their margins (so as to effect their separation) is owing to the presence of hyposulphite of soda in the cardboard of which these slips, or separating masks, are formed, we have subjected some of these masks to sensitive tests for the hyposulphite without being able to perceive the slightest indication of its presence.

It is well known that when the material of which paper is formed is subjected to the bleaching action of chlorine a subsequent treatment with hyposulphite of soda ensues, this salt being the recognised "antichlor" of the paper mill. But in one case, in which marginal deterioration of gelatine plates was well marked, the separating masks were formed of a rather thin, brown cardboard. The materials of which this was formed bore no appearance of having been bleached by chlorine or any other bleaching agent, and, therefore, concerning this it was reasoned, *à priori*, that no hyposulphite of soda would have been employed as an antichlor. Certainly with these slips, or masks, the iodine test, although most carefully employed, failed to indicate the presence of the antichlor, and yet the plates which were packed up in contact with them gave the indications of deterioration to which we have referred as a characteristic, not always present, of this mode of packing gelatine plates.

From this it appears evident that there are other agents than hyposulphite of soda which act in a deleterious manner upon the surface of the plate. We shall be glad to receive samples of paper or cardboard which are known to produce the deterioration mentioned, in order that we may have them properly tested.

THE QUALITY OF RECENT PRINTS.

In another page Mr. E. Dunmore asks a series of pertinent questions as to the character of the prints obtained or obtainable from gelatine negatives, and we draw attention to his communication as being one of considerable importance at the present moment, trusting that it may elicit such replies as will lead to a thorough knowledge of the views of practical men. The tenour of the replies to some parts of the queries will have been foreshadowed in previous articles we have written dealing with cognate topics; but a wide subject bearing upon many branches is herein opened, and we hope it may be thoroughly ventilated.

That a distinct difference — not necessarily indicating either superiority or inferiority—exists in the quality of the prints now produced may be fairly anticipated to be a portion of the verdict. What the character of that quality is, and to what extent it has been governed by the advent of gelatine, will be the question to be handled. Whether an artist works in water-colours, oils, fresco, enamel, or even mosaic, he obtains results beautiful according to his skill rather than the medium he works with; and though some may prefer one and some another mode, yet there are few critics who would venture to assert that one medium possessed greater actual excellence than another, different though may be the modes adopted and the vehicles employed for appealing to the mind through the eye. Similarly, though in a more modest degree, does photography speak with different voices, not one of which is necessarily more melodious than another. Since the days of Adam-Salomon—whose prints were forcible, brilliant, and powerful, yet not lacking in delicacy, and refined in the highest degree—down to the present time when negatives are printed from which, from their thinness, would have been rejected without further thought twenty years ago, every shade of quality has been represented and every style has had its votaries. It is not for us to say which is the best, though it is undoubtedly true that a better average has continually been arrived at from year to year. The public, too, are, as it needs no argument to prove, far better educated in art, and, as a matter of course, have become more exacting in their requirements in consequence. This also reacts upon the quality of the prints to their advantage. That photography has had a considerable share in aiding the cultivation of this taste there can be little doubt, and almost every year there may be perceived a distinct advance in the character of the work—more, perhaps, in the average of merit than in individual merit.

We thus see that Mr. Dunmore's questions will be complicated by considerations almost too powerful to be termed side issues; yet we may say that, notwithstanding the ever-recurring warning, *de gustibus non est disputandum*, there will always be certain standards —varying in nature, not in degree—which may be decided upon for comparison. They may include the two extremes of brilliancy combined with delicacy—typified, perhaps, by the work of some of the leading American portraitists on the one hand, and on the other the combination of fulness of detail and softness, with as much richness as can be obtained, such as is seen in the work of one or two of the leading London photographers. Between these two extremes there will be found every grade.

Without making any positive assertion, we incline to the belief that the former class of picture will be produced in the highest excellence from collodion negatives, while those from gelatine will be greatly superior for the latter. In the early days of gelatine the common cry was—"Insufficient density;" and there is no doubt that the plates then made were less amenable to intensification than such as are now procurable. On this account, probably, a mode of printing was adopted which was calculated to get the best effect out of thin negatives, and the influence of the plan thus drifted into may be still felt at the present moment. All practical printers know that they cannot get equally good results from every kind of negative upon a single brand of paper, nor even on one kind of paper by a similar mode of treatment.

Then, as to landscape *versus* portrait results: it must not be forgotten that there are many thousands of amateur landscapists who, though possessed of much talent, are yet but beginners, and it would not be fair to take an average of these tyros as against the few wet-plate veterans, who have brought their hard-gained experience in that direction into their working with gelatine. A poor wet-plate negative gives but sorry results; but from a poor dry plate only the most wretched prints imaginable can be obtained.

The character of prints from dry plates is governed by two most important factors—the colour, and the amount and character of the fog present. This latter quality is intimately connected with the composition of the developer, or perhaps we might say the proportion of ammonia it contains. For a long time plates were developed with such a predominant amount of ammonia present that almost every plate suffered more or less from a suspicion of fog. But that a reaction is setting in cannot be doubted; it is shown in the printed instructions of manufacturers, and the general tendency of the authorities of the day is in a similar direction. This we take to be a most important matter, and a factor of great importance in arriving at a satisfactory response to Mr. Dunmore's queries. The wonderful rapidity placed in our hands by gelatine ought not to warp us from the endeavour to attain the highest excellence. "Quality first and rapidity next" should be the motto of all photographers.

When everyone has fallen into a way of using a small quantity of ammonia in his developer we shall get still better results—more like wet plates through possessing the highest brilliancy, yet having all that delicate softness which we are inclined to attribute specially to gelatine work.

There is, however, fog and fog. As we write we have before us two prints—one really good, and the other poor and quite deficient in richness. On referring to the negatives we are almost astonished; the brilliant picture is from a negative that is completely fogged, while the negative from which the other was printed seems perfect—the shadows apparently quite clear, and the negative thoroughly exposed. Readers of photographic literature well know that more than one well-known artist has stated that green fog is not in any way injurious, while at least one has stated it to be an advantage. This particular subject is too wide, however, to treat at the end of an article, and we will refer to it fully on a future occasion.

Little need be said as to the colour of a negative, seeing that any objectionable yellowness can be removed by the acid alum bath at any time, if desired. There are printers, however, who assert that the yellow tone of a negative is of decided assistance in the production of good tones. It is upon such points that we hope to have the opinion of correspondents.

In conclusion: we may say that if Mr. Dunmore's queries meet with a hearty response matter of great interest will be elicited, and a thorough discussion, though opening sufficiently wide ground to lead to diffuseness, may show the way to a real improvement in results and to a forward movement in our art.

OUR contemporary, *La Nature*, gives an interesting description of the Simonoff photometer—a sort of telescope on a stand, with a series of diaphragms of graduated apertures inserted at the field end, with the purpose of diminishing the light till certain figures become invisible, the particular diaphragm required with the lighting under examination telling directly the necessary exposure without calculation. The instrument is merely a toy so far as photographers are concerned. The veriest tyro knows that the apparent illumination of an object affords of itself but a poor criterion of its photographic power, and the new photometer is really no more use than Crookes's beautiful instrument, the radiometer.

IN *Nature* is a description of a radiation measurer of another kind—a huge congeries of reflectors laid upon a frame shaped like a saucer with its centre cut away. These mirrors reflect the rays from the sun to a central heater of conical form acted upon by the reflected radiation in such a manner that each point of its surface receives an equal amount of radiant heat in a given time. Professor Langley has shown the extent to which the atmosphere absorbs the sun's rays, which but for the layer of air round the earth would present a blue appearance to the eyes; and Captain Ericsson, correcting his results by calculations founded upon such absorption, estimates by means of this new instrument the temperature of the sun's surface to be far above any degree hitherto put forward—that is, 3,060,727° F.—and this he terms "an under-rated computation."

BY calling in the aid of photography Dr. Norris asserted the discovery of a third kind of corpuscle in the blood of mammals, and Mr. G. S. Clair, F.G.S., lately communicated to the Birmingham Philosophical Society a note on a possible error in photographing blood corpuscles, in which he attempts to explain Dr. Norris's discovery as being due to an optical illusion. He suggests that the alleged bodies are due to an exactly similar cause to that of "flare" produced by the diaphragm of a landscape lens, for instance, when not suitably placed—a very distinct circular image being often found under such conditions. We fail to grasp the meaning of *Nature* when it says "if he had attempted to focus these ghosts and the real images at the same time, we venture to say the note would never have been written." The fact is, the definition of a possible ghost would alter according to the length of the telescope, the effect being more particularly one of reflection than refraction.

WE apprehend that our readers will be too busy enjoying the pleasures of the feast intellectual at the *conversazione* in Pall Mall, on Saturday evening next, to pay much attention to the eclipse of the moon. Nevertheless, to those so inclined the obtaining of a photograph of one stage of the phenomenon should present no considerable difficulties to the possessor of very ordinary optical appliances in these days of gelatino-bromide. The eclipse will be a total one, commencing at sixteen minutes past nine, and ending at twelve minutes to eleven. The middle of the eclipse will be at two minutes after ten. It will thus be seen that the duration of obscuration continues for a remarkable length of time.

A NEW bright comet has been discovered. The fortunate astronomer whose name, we suppose, will be handed down to posterity in connection with this "find" was Herr Wolf. Several observers also saw it, but priority belongs to the above-named gentleman. At the Earl of Crawford's observatory, at Dun Echt, it was independently discovered, examined by the spectroscope, and pronounced as a gaseous body, early on the morning of Tuesday, the 23rd ult.

IN a recent letter to *The Times* on "The Influence of Civilization upon the Eyesight," Dr. Brudenell Carter, F.R.C.S., has some remarks very interesting to photographers. Explaining the optical structure of the eye he shows how its adjustments are influenced by the kind, the extent, and the duration of the work they are subjected to, and proves that civilisation results in eyesight inferior to that of savage races. There is no doubt of the increased prevalence of near-sightedness at the present day; and with regard to it we may quote what he says as having a direct interest for all photographers, especially those who have much dark-room work. The term myopia is used by the occulists to define this condition of "short" or "near" sight. "The original cause" he says, "of myopia, on the other hand, seems to be the application of the eyes to near objects; in other words, the poring over books and handicrafts. When the eyes are directed to a near object they are turned in, or rendered convergent, so that the axis of vision meet upon it; and this position is maintained by a muscular effort which, if continued, alters the shape of the eye in the direction of elongation. Manifestly, the alteration will be most easily produced during youth, when the tissues of the body, including those of the eye, are comparatively lax and distensible; and it will also be most easily effected amongst those young people whose tissues are exceptionally weak by reason of inadequate food or of unhealthy descent or surroundings. Badly lighted schools are the great manufacture of myopia, the bad light compelling approximation of the books or other materials of study." Retouchers and dark-room workers should lay these remarks to heart, and much trouble will be avoided by reading them in conjunction with previous remarks by ourselves on a similar question.

TOURISTS' AND OTHER CAMERAS, &c.

SOME good should result from the discussion which has been lately going on in the columns of the Journal on this subject, and it might be advisable to let it embrace photographic apparatus generally. In the matter of tourists' cameras—that is, those carried merely to give additional interest to a trip—I think the tendency is to try and get rather more into them than is practicable; but where a few ounces more or less do not make much difference we might reasonably ask for things to be a little more perfect.

Taking, first, the camera front: how many are there which admit of more than a very little movement of the lens, either up or down? Yet it is sometimes requisite to use a lens raised nearly to the top of the camera or dropped down almost about level with the bottom. I had occasion not long ago to use a whole-plate camera (made by a firm of some repute living not many miles from Holborn), the maximum rise of the front of which provided for by the makers was about one inch. No arrangement at all was made for lowering it, and to do so would necessitate cutting the woodwork away. Yet I required it for a street view taken from a third-storey window. The only way out of the difficulty was to turn it on its side and make the horizontal movement do duty for the falling front; but it being made square, with a reversing frame, there was no means when on its side of fastening it to anything. It had a folding tailboard, but when this was let down there was nothing except its own weight to keep it from folding up again; so that when turned on its side, after focussing, the bellows had to be kept from collapsing by propping open with a piece of wood. It may be thought that this was an antiquated piece of apparatus, but it was nearly new, and, I daresay, cost £8 or £9 a few months ago.

Some time ago I bought a second-hand pocket camera by noted makers which had only conical bellows, and, consequently, no provision for altering the position of the lens. This I took to an apparatus dealer to get square bellows and front put on, impressing upon him that the front was to fall as well as rise. "Why! whenever do you want to lower the lens?" was his query; and this was from one who considered himself in the van of photographic progress! I pointed out to him that nowadays it is not unusual to take street views from a greater height than the level of the road.

Studio cameras also are not always perfection. One which I use has the focussing-screen hinged at the top, the camera drawing out by means of a screw placed just below the screen. The makers did not notice when constructing this that the handle of the screw, as often as not, comes above the level of the lower part of the screen, so that, to raise the glass and push the dark slide along, the screw has to be turned round a little and then put back by guess, thus running a risk of displacing the focus.

The fronts of studio cameras should likewise be made to drop a little below the centre. They are usually made so that the lens is central or raised; but, when taking a full-length portrait of a child standing or sitting on the floor, unless the camera stand be very low it is well to lower the lens a little, or the image will not occupy its proper position on the screen without a great deal of tilting, which, while throwing the feet much out of focus in a standing figure, would, in a sitting one, dwarf the neck down to nothing.

Many people prefer using one large camera for studio work, and employ carriers for plates smaller than the largest size they are in the habit of using. When the wet process was in vogue it was a necessity that the plates should be supported only by the corners; but now that gelatine has almost ousted collodion there is no reason why slides and carriers should not be made so as to support the plate all round the edge.

If anyone will take the trouble to put (say) a 10 × 8 piece of stout plate glass in a dark slide and test it for correct register with the focussing-screen, and then substitute for plate glass a thin glass taken at random from the negative shelf and compare the register again, he will, if the spring of the dark slide be at all strong, probably find a considerable difference. If the thin glass happen to be at all curved inwards the difference will be still more noticeable. By making carriers with a rebate all round bending of the plate would be to a great extent prevented.

Large cameras might with advantage have slides pushed in at the back instead of sliding in from the top or side, though for convenience the shutters should pull out sideways and fold over. I recollect a 15 × 12 apparatus I formerly worked with in which the shutter pulled out, and when the camera was raised a good height for taking a half-length picture of a tall sitter, a short operator I knew had almost to get on tiptoe to draw the shutter properly. This brings up the question of folding-back or pulling-out shutters for outdoor work. It appears to me a matter more for individual preference than any hard-and-fast rule. In a small size I have used both, and for convenience and ease of working prefer the shutters which fold back; though I always feel safer with the solid slides, with which there is no fear of the slide itself opening accidentally. It takes me longer to replace the loose shutter than to push in the folding one, and for larger sizes one would certainly require the special pockets suggested by Mr. A. Pringle. I fancy an operator with a 12 × 10 piece of board between his knees waiting for a gleam of sunshine would not present a very dignified appearance to a crowd of small boys either in a London street or on the almost extinct village green. It must, however, be admitted that markings on the plates have been produced by something in the leather used to form the hinges of the folding shutters—the pull-out ones, of course, being free from this defect.

Frequently an expensive, elaborately-made piece of apparatus is rendered imperfect through some little detail not being properly looked after. I saw the other day two new 12 × 10 double slides just received from the makers, costing somewhere about 30s. each, much of the workmanship being all that could be desired. When in use, however, the greatest care has to be taken not to touch the little buttons which keep the shutters from opening; in fact, they sometimes slip out of their place even with careful handling. Surely it would not be difficult to devise some fastening which will keep in its place till moved intentionally.

Referring for a moment to the remarks of the Editors in the Journal for the 19th ultimo: I do not see how the tail-board can well be dispensed with in outdoor cameras. If the base-board be placed in front it cuts off a portion of the field when a wide-angle lens is used; and even with a longer-focus lens, unless this come quite to the end of the base-board a drop-shutter cannot be used or, at anyrate, one with a long opening. Whether the base-board be in front or behind it is generally hinged once so as to fold up, and, if hinged again a short distance from the hinges, as they generally exist, but in the reverse way so as to fall down when not required, I imagine the desired end might be attained. I experienced only the other day, when taking an interior, the inconvenience, alluded to by the Editors, of a long tail-board, it being difficult to get near enough to the focussing-screen to see well.

It would be a good thing if manufacturers made the different parts of various-sized cameras interchangeable. Screws for rising fronts, tripods, &c., need not vary for ½, 10 × 8, and 12 × 10 apparatus; and the front for a ½ size might be made to slide into an adapter for a 12 × 10 camera without having a separate flange cut. For studio work, too, it is often requisite to quickly change a cabinet for *carte* lens, or *vice versâ*. With some of our modern universal cameras it is now the custom to have the lenses screwed on to square pieces of wood which slip up under a strip of brass on the camera front, and are kept in place by a tongue at the bottom. Makers might well agree among themselves on a standard size for these square blocks.

I do not know that I have seen the American camera alluded to by the Editors in the Journal of last week, in which the rackwork can be thrown out of gear when it is desired to extend or shorten the bellows; but, if I have, I forget what the pattern is. In my opinion the ordinary arrangement in front of the camera, in which two upright rods pass from the base-board up the front, and are tightened by screw nuts, would answer better if the front could always be bept square to the ground glass. When working quickly there is a risk of fixing it a little out of the square unless lines are ruled on the board.

WILLIAM COLES.

PHOSPHORESCENT TABLETS FOR SENSITOMETER PURPOSES.

A LETTER in our correspondence column is a sample of many similar queries that reach us from time to time; and, as a general feeling of the necessity in modern work for the possession of a sensitometer of some kind seems to be growing, we propose to give simple directions for the manufacture of the light tablet, which, all things considered, appears to be the most suitable form of illumination for general purposes.

We may say, first of all, that the phosphorescent tablet is not a reliable guide under all conditions, as has been fully shown in these columns. The different ratios of sensitiveness of the several haloids to its influence render its readings valueless when a plain bromide plate has to be compared with a bromo-iodide film, though it is sufficiently reliable when one kind of plate only is used. Further than this: the preparation of the violet phosphorescent sulphide is so uncertain an operation that no two batches can be guaranteed of the same actinic value; hence for standard reference purposes—except in the case of the Warnerke instrument, in the manufacture of which special care is employed to secure a sulphide of uniform value—it is hopeless for the amateur or others to attempt to form a standard.

But to proceed to the description of the manufacture of the tablet. The graduated screen we have nothing to do with, since each individual must adopt whatever form that may to him be most convenient. The phosphorescent sulphide of calcium is obtainable from most of the leading operative chemists of tolerably, though not of absolutely, uniform character, the price being about four shillings per ounce. The only other material required for the phosphorescent surface is paraffine wax, and, of course, the necessary glass. Failing other sources of supply a paraffine candle will afford the necessary vehicle for carrying the powder. One ounce of the sulphide and a similar quantity of paraffine will suffice for eight tablets of quarter-plate size, so that, although the price of the sulphide may appear high, the tablet is really not a costly article.

One plan of procedure is to weigh out the requisite quantity of sulphide and of paraffine for a quarter-plate—one drachm of each—and, having melted the paraffine over a Bunsen burner or, preferably, the water bath, the powder is stirred in so as to form a homogeneous mixture. Having previously cleaned a plate and made arrangements for laying it in a perfectly horizontal position, it is warmed and the melted mixture poured on to it. It will be noticed that the sulphide exhibits a strong tendency to subside—so much so that the mixture must be stirred up to the instant of transferring it to the glass plate, where it will again prove somewhat refractory. With a spirit lamp or Bunsen burner at hand, however, it may be coaxed over the plate by means of a warm glass rod, and when spread pretty evenly up to the corners an even layer may be produced by taking the plate in the fingers and holding it in as nearly level a position as possible over the source of heat, when a sharp, lateral movement or shake will gradually bring about the desired end. This secured, the plate is placed once more on the level and allowed to set.

A better plan—easier in execution, though not so economical unless more than a single tablet is to be prepared—is to mix the sulphide and paraffine as thickly as possible, and in larger quantity than is immediately required; the solidified mixture will keep far better in this state than will the powder. Taking a plate larger than the tablet requires a thick coating of the melted mixture is poured, the larger quantity of material rendering the coating operation far easier. The wax having been allowed to harden thoroughly the surplus may be scraped or planed off with a piece of glass, a very thin film being all that is requisite. The plate is then cut to size with a diamond, and the edges trimmed.

To finish off the tablet a piece of opal glass of the same size as the tablet is heated to a sufficient temperature to cause the wax to melt. This is pressed in contact with the layer of wax and sulphide, and the tablet then laid down on a cold, level surface. No attempt should be made to warm the tablet itself, or the wax will run in irregular lines. If the opal glass be heated to about 170° Fahr., placed in contact with the wax surface, and the whole then laid, as described, upon a cold surface, opal glass upwards, the latter will adhere to the wax without causing it to melt. All that is now required is to bind the two glasses together in the same manner as a lantern slide with strips of paper or ribbon.

Such a tablet will be found a very useful adjunct to the amateur's, or, indeed, to the professional's, laboratory. Though not forming a standard for comparison with other operators, it will be found a reliable guide for private use—at least in comparing plates of the same make one with another. It will be an easy matter, where plates of various makes are used, to establish a standard for each.

PRINTS FROM GELATINE NEGATIVES.

It would be interesting to know, now that gelatine negatives are almost universally in use, the average *quality* of prints therefrom. If every commercial printer would reply to the following queries, a good estimate might be obtained of the improvement or deterioration in the general work:—

Given (say) one hundred average negatives, is the average of good prints greater, or less, than with wet plates?

If better, in what does the improvement consist?

If worse, where is the falling off?

Can as great a number of good impressions be obtained in a specified time from gelatine negatives as from wet-plate negatives?

Do the averages differ with portrait and landscape work?

I think if the above questions are fairly answered by a number of persons representing the printing interest, the direction to which we are to look for improvement in our work would be clearly indicated.

EDWD. DUNMORE.

PHOTOGRAPHERS AND PHOTOGRAPHY IN AMERICA.

No. II.

When in Chicago I visited Mr. C. Gentilé, editor of the photographic *Eye*, also Mr. F. H. Davies, editor of the lately-defunct journal *Photography*, and underwent that much-dreaded ordeal of being interviewed. I then visited the veteran photographer, Mr. A. Hesler, 96, State-street, where I saw a fine collection of daguerreotypes, taken in 1851. Mr. Hesler, it would appear, took a number of instantaneous drop-shutter daguerreotypes half-plate size with a Harrison lens, about that period, from the deck of a steamer on the Mississippi between Galena and St. Paul. He found that by electrolysing the plates by friction he could reduce the exposures to one-fifteenth, and by further keeping the plates prepared a still greater increase in sensitiveness was attained. They were taken for *Harper's Illustrated Guide*.

My next visit was to Mr. C. D. Mosher, 125, State Street. This gentleman has a magnificently-appointed studio. He has conceived and is carrying out a grand idea of presenting a memorial offering to Chicago, consisting of cabinet photographs of great men of all countries. These are to be hermetically sealed and placed in fire-proof safes to be opened in 1976. Although the portraits are to be printed in silver, Mr. Mosher is sanguine that with the precautions named they will be in good condition in that year. Mr. Mosher has a very clever artist in his employment (Louis Marxsen) who is working on gold—that is, engraving portraits on watch domes. The gold is rendered matt, and then with a pointer he polishes the surface, which, when viewed in certain lights, looks darker than the matt portion, and in appearance very much like a daguerreotype. I suggested that the gold might be coated with platinum, nickel, or aluminium, and when engraved on the surface cut would give greater contrast.

Chicago has also a firm of stock-dealers, Messrs. Douglass and Thompson, in whose rooms the Chicago Association of Photography hold their meetings. A studio, dark room, and other conveniences are at the service of the members without charge, and I have no doubt that such liberality tends greatly to increase the popularity and business of the firm. Their stock of photographic requisites certainly are second to none in the States.

I had the pleasure of spending a very happy day and evening with Mr. and Mrs. Joshua Smith, of Chicago (of baby renown), accompanied by Mr. and Mrs. Armstrong, of Milwaukee, and Mr. Gentilé. They kindly drove us over the stock-yards; and after visiting the pigs we visited the "lions," and they are not a few. Chicago, considering it was in ruins a few years since, is the most marvellous city I have seen.

I attended a meeting of the Chicago Photographic Association, over which Dr. Garrison presides, and demonstrated a method of making emulsion. An animated discussion took place, which I have no doubt will be fully published.

My next resting-place was Rochester (the market and home of dry-plate workers), on the earnest invitation of Mr. James Inglis, who not only insisted on my being his guest while there, but allowed me to visit his factory for the production of the "insoluble dry plates." I may mention that that gentleman, like myself, has no secrets. I have carefully taken measurements and plans of his works, and these will be a subject for future publication. Suffice it to say that the arrangements are as perfect as human skill can make them. For example: several batches of ten gallons of emulsion are made at a time in the morning, coated, and in a little over two hours the plates are in the packers' hands.

I called on several other plate-makers in Rochester—notably Eastman, and my old friend, Peter Mawdsley, who is now a maker on his own account. Mr. Eastman seemed somewhat stiff with me at first, which led me to think he imagined me to be either a spy or a process-monger. I cautioned him that whatever he said would be taken down in writing, &c. He told me he would show me over all his premises except one room. Of course I immediately came to the conclusion that the room in question would be the coating-room, but this illusion was dispelled when I witnessed three girls coating somewhat slowly with the "teapot" coater. This, above all, astonished me, seeing that Mr. Eastman was the inventor of the roller coating machine. By-the-bye, rumour says that Mr. Eastman returned the £400 paid to him by an English firm for the patent coater in consideration of his being allowed to inspect the said English plate-makers' works. What the aforesaid room contains must remain a mystery to me. One thing I did learn, namely, that Mr. Eastman is very anxious to get a method of coating paper for negatives and positives. I had presented to me an interesting picture showing an exposure through a cardboard shutter, and printed on the sky of the landscape was the word "exposed." This is printed in large type on the shutter, so that when the exposures are made the shutter is reversed. Mr. Eastman is having copies of this picture sent to all the stock-dealers, to show that this form of dark slide is useless.

Rochester has also its Optical Company and Camera Manufactory (W. F. Carlton, proprietor). From floor to ceiling are piled cameras and printing-frames, but where they are all to go is the question. Every man, woman, and child will soon be their own photographers, and then where are to be the professionals? This company have in their service a very clever engineer, who showed me a coating machine, certainly a little complicated, but when finished may answer admirably. Here ended an enjoyable visit.

My next trip was to Niagara Falls. I feel certain that of all places in the world no place has been more photographed than the Falls. There are good, bad, and indifferent photographs, each representing peculiar phases. There is no doubt that the photographers on the spot have the best chance. I was not so fortunate as I would have desired. The light was hazy; yet with a very rapid shutter and plates giving 20 on Warnerke's sensitometer, lens stopped to $\frac{f}{8}$, I have secured some well-exposed views.

I was fortunate enough to drop in on a wayside photographer, Mr. Norris, who not only allowed me to change my plates, but insisted on supplying me with the materials to develope, &c. Mr. Norris makes all his own dry plates, and I saw some of fine quality, but too rapid to put into the hands of Tom, Dick, and Harry. Mr. Norris thinks of going into plate-making commercially. My advice to him was "don't!"—to let well alone and stick to a certainty, notwithstanding the extraordinary reports that Cramer, of St. Louis, had netted $650,000 (£130,000) last year at plate-making; on which, when I heard it, I remarked that we had "cram-mers" in England also.

The finest views I have seen were taken by Mr. Neilson, of the size 20×17 inches. This gentleman, although not a very good photo.-chemist, has done some grand work. He has noticed a peculiarity regarding the permanence of gelatine negatives; that is, that after printing some time they lose their sparkle—so much so, that the varnish has to be removed and intensification resorted to. I closely questioned him with the view of eliciting an explanation, but I have failed. As a matter of course I presumed intensification; but—No! Then I suggested that the negatives were yellow and that the light had bleached them. The answer to this was—that they were not yellow at first. He puts all his negatives in alum before fixing. Does the liberation of sulphur from gelatine tend to destroy the keeping quality of gelatine plates? The matter to me seems so extraordinary that I have promised to bring the subject before a London society.

My next halting-place was Toronto, Canada. There I called upon Mr. Notman's successor, Mr. Fraser. This gentleman produces fine work and has a very large studio, which I very much envied. He does not make his own plates, and those I saw developed could not be very rapid, as the light in the dark room slightly fogged some of my plates. I believe the maker of the plates used by Mr. Fraser is a townsman (Mr. Hunter). I nearly missed a gentleman—Mr. Dixon, an Englishman—who "spotted" me from his buggy, he having met me at the convention at Cincinnati.

Mr. Dixon seems to be "setting the lake on fire" (Ontario) by the amount of business he is doing, reminding me of my own heydays. The plates he uses are English make—"Britannias." Some lovely "bits" might be secured between Toronto and Montreal, through the Thousand Isles and the St. Lawrence. I fully intended exposing a dozen or two plates, but the ship was so crowded that I had no room to walk; and, moreover, the thermometer was at 95°, with a light wind blowing astern.

In Montreal I "made tracks" for my namesake, Mr. Alexander Henderson, but he was enjoying a holiday at the seaside. Mr. Notman (whom I found at home), whose name is intimately associated with composition photography, showed me some of his pictures of the Ice Palace, tobogganing, &c., which are wonderfully fine. He makes all his own dry plates, and seems to prefer slow cooking. He has presented me with several examples of his work, which I will exhibit at a meeting of the London and Provincial Photographic Association.

At Montreal I met, by appointment, Mr. and Mrs. F. York, of London. They were of the party who came out by the steamer "Parisian" to attend the meetings of the British Association. His photographs of the members and their wives, taken in mid-Atlantic, are certainly very good, and should be historical pictures. I was told that the success of the groups is largely due to the indefatigable amateur, Mr. H. Trueman Wood, Secretary of the Society of Arts, who arranged the figures.

A few "shots" at the icebergs were successes also, and I daresay Mr. York will exhibit all of them when he returns to England. He intends to stay about a year in the States, and is going to the far west to take negatives for lantern transparencies.

I have not said anything about the meetings of the British Association, as nothing of interest to photographers took place.

My next halting-places were Saratoga, Albany, and New York. At the latter city I saw Mr. Sarony. He seems to have lost some of his vivacity. "Old Father Time" is also beginning to leave his mark on him as well as on the writer. I did not notice any falling off in the quality of his work. He is a great advertiser. At nearly all the hotels I visited large, handsomely-bound albums containing photographs by Sarony are placed on the tables.

The Americans are much more pushing than the English. At Mr. Rockwood's, of Union-square, I saw a number of *souvenir* photographs being finished to distribute gratuitously to all the ladies who might witness the one hundred and fiftieth representation of a certain play. Mr. Rockwood had an order for 1,500 of these *souvenirs*, and only about ten days in which to finish the whole. They are two cabinet photographs bound together. A large number of photographs of the steamship "America" were being finished, also, which were originally got up on speculation, and which have turned out successes. Mr. Rockwood has more than "one string to his bow;" he is a publisher of views and a commercial plate-maker.

I did not call upon any other photographers in New York.

The heat was so excessive (98° in the shade) that it was with difficulty I managed to exist. In spite of this state of things I attended a meeting of the New York Society of Amateurs, where I had the pleasure of meeting a great many gentlemen whom I had often heard and read of, and who gave me a hearty welcome, electing me an honorary member of the Association. A very animated discussion took place on cold emulsification (precipitated). Thus ended a most enjoyable tour. If I have omitted to give credit to whom credit is due it must be taken as a "sin of omission," for I have got dreadfully "mixed."

A. L. HENDERSON.

TOURISTS' CAMERAS.

I HAVE read with much interest the series of articles on this subject which have appeared in the Journal during the last few weeks.

Mr. W. H. Harrison begins by complaining of the time the camera takes to put up. On this point I surprised myself the other day by the shortness of the time between two exposures. We were walking up the River Almond from the small village of Cramond at its foot, and I find entered on my camera:—"Old Spade Mill, $\frac{f}{33}$, 11.30, light B, 17 seconds;" and next—"Old Iron Works, $\frac{f}{44}$, 11.45, light B, 25 seconds."* That is to say, a quarter of an hour—or, speaking loosely, twenty minutes—from exposure to exposure.

Now considering that I was not timing myself, that I had to cross the river (which ended in wading), and that the Spade Mill and Ironworks, as I find from referring to the map, are about a quarter of a mile apart, I think this shows pretty good time. In fact, I remember mentioning it as sharp work to my friend when I noticed it after exposing the second plate.

The camera which I was using was a 9×7, of French make, having a plate-box underneath. It exends to nineteen inches, and when closed measures $5 \times 17'' \times 11''$—plate-box, holding one dozen plates, included.

I use a light case similar to that which Mr. Andrew Pringle described in one of his articles. My stand is one of the folding pattern, which I simply strap together, and find very useful as a walking-stick or alpenstock. I use the lens mount which Mr. Pringle described in his first article, and find that it works admirably—no loss of either temper or time, and, above all, no fear of letting the lens drop out of your fingers while trying to catch the thread of the screw.

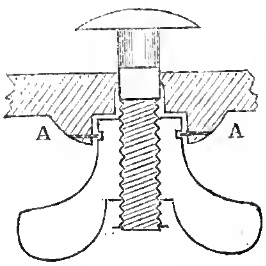
With regard to this I see that Mr. George Smith suggests that there should be three studs instead of two. I thought of that in designing it, but deemed the advantage gained was out-balanced by the increased difficulty in fitting.

The only difficulty I find in rigging up the camera is the screw for fixing it on the head. I always put an extra one in my pocket since the spring, when I lost one and was left high and dry. It sometimes comes in useful. I know I worked away with one and could not get it to catch. Of course I lost my temper with it, and at every trial was less likely to succeed than the one before; so

* We believe that Mr. Gifford means by "light B" a good diffused light, but not of the very best quality, which would be represented by "A."—EDS.

I took it out and tried the other, and hit it at the first trial. I imagined that I had cooled down in getting it out of my pocket. I should say that that screw was responsible for a "power" of language!

I think this screw should be banished as soon as possible, and I should propose to put in its place something of this description:—



On the foot of the camera a brass plate is screwed with a slot cut in it, similar to the slot cut in a soldier's "button-stick." On the head is fixed something of this description:—A brass button having a shank rounded for about a-quarter of an inch, then square for about the same distance, and below that a screw having about three-eighths of an inch pitch. This passes through a square hole in the head (fitting the square part on the shank), which widens out so as to embrace a thumb-nut. This thumb-nut has a groove cut round it near the top, so that small pins, A A, may be inserted in the head to prevent it from falling down. A pin is passed through the button shank on the lower side of the nut, which prevents the nut from getting unscrewed too far.

The camera is placed on the head with a motion similar to that by which buttons are put on a "button-stick," which brings the button head behind the brass plate. Then, when you get your camera pointing in the proper direction, give the thumb-nut a turn, and the whole thing is clamped and fast. H. J. GIFFORD.

P.S.—I notice that in your last issue (26th ult.) Mr. Smith proposes this contrivance for fixing the camera on the stand.—H. J. G.

BLEACHING OF RUBY PAPER.

AT the present time, when manufacturers of dry plates are competing with each other in the production of films of the utmost sensitiveness and capable of reproducing the most instantaneous effects, fog on development is still a common complaint, in spite of every care in manipulation, and notwithstanding the apparent safety of the double thickness of ruby paper which protects the windows of the dark room.

Certain observations have lately led me to believe that in some cases the ruby paper, although perfectly non-actinic in the first instance, may in course of time undergo sufficient change to render it doubtful whether it can any longer be considered safe. Colours of all kinds are extremely susceptible of change under the influence of light and air, and bleaching is almost certain to take place in proportion to the intensity of the light to which the colouring matter may be exposed.

I have tested the permanency of the colouring matter of ruby paper by exposing a small quantity for two years in a window, and comparing it afterwards with a portion which had previously been cut from it, and kept in darkness during the whole time. Scarcely any appreciable difference could be detected, and the inference might be drawn that ruby paper, in a dry state, is *per se* unacted upon by light to any serious extent.

It must be remembered, however, that it is the usual custom to make the ruby paper more transparent by oiling it. It is also not uncommon to find that either gum, starch, or some other adhesive substance is used for pasting the paper on to the window. Lastly, windows are liable to be not perfectly free from damp, especially if wind and rain have free access to the imperfectly-fitting joints. Usually, therefore, there are present all the conditions necessary for promoting rapid alteration of the colouring matter, namely, light, moisture, and the presence of decomposing organic matter. Oils are especially liable to oxidation and change, and the presence of this agent, in intimate contact with the particles of colouring matter, may exert a powerful influence in its decomposition.

Whether or not the above agencies do promote bleaching of the ruby colour, I have lately had occasion to examine a window which, two years ago, was safely covered with the usual ruby paper of commerce. This paper has now scarcely a particle of its original colour remaining, the whole having been changed to a light canary-yellow, with the exception of small portions which happened to be screened somewhat from the light.

Fortunately for the success of the photographic operations in this room a second thickness of paper had been placed loosely over the window, and the defect beneath was only noticed by the accidental removal of this second covering. Had it not been for this precaution there would, doubtless, have been a time (the bleaching of the paper being perhaps as yet only in an incipient stage, not to be detected by the eye) when the quality of the light transmitted would be no longer safe, and a most mysterious source of fogging would ensue. Those, therefore, who have not examined the condition of their windows for some considerable time would do well to see if the colour of their paper has faded to any extent, in order that the necessary steps may be taken before any serious mischief results. It is, of course, chiefly to workers with plates of the highest degree of sensitiveness that these remarks apply; but many of these avoid this source of failure through developing only by artificial light—a far safer plan than the most perfectly-constructed window. But, if a window must be used, probably the stained glass will prove a more satisfactory material to deal with than oiled paper; for, although most specimens of glass are influenced by light, the result is in most cases an acquisition of colour rather than bleaching. J. VINCENT ELSDEN, B.Sc.

THE CAMERA OF THE FUTURE.

ANY philosophical apparatus maker or other adept in the manufacture of instruments of precision who may carefully read the utterances made in these pages during the last two months or thereabouts, since I started the discussion, will find ample materials in the shape of ideas to aid him in designing the tourists' camera of the future. The following are a few of the leading points which demand attention.

The primary fault at present is the excessive waste of the time of the users of the existing cameras in unpacking, fixing, and adjusting them; then in unfixing and packing them away again over each view. Whenever I read in the journals of new tourists' cameras I feel no interest whatever in the descriptions except where they relate to the saving of the time of the user over mere mechanical operations, for that is the chief thing lacking. It would be a good thing if every camera-maker who presents himself before a photographic society with a new instrument were to be invited to go through the following operations with it himself there and then, subject to being timed by the watches of the observers:—

CAMERA-MAKERS' DRILL.

1. To stand at "attention," with his camera in one hand and the legs in the other, carried packed in their cases or straps as when travelling. [*Time taken by observers.*]
2. To unlimber and fix camera on stand in position for taking a view.
3. To extend camera to its full length.
4. To get two lenses in succession in position on the camera front.
5. To take apparatus, lenses, and stand down again, pack them up in their straps or cases, and stand again at "attention" as when prepared for travelling. [*Time again taken by observers.*]

Probably very few makers with their own instruments in their hands, if asked to perform these operations before a photographic society, will get through the drill in less than seven or ten minutes, and in some cases the time may be longer, representing a dead loss of an hour or an hour and a-half over the exposure of but six plates; and all this time consumed in connection with mere mechanical operations of not the slightest educational or other benefit to the user of the camera.

Two points will present themselves to the camera-maker of the future, by attention to which time can chiefly be economised. Firstly, that the camera shall be ready for use inside its case, with one lens already in position, so that all is as nearly as possible ready for work when it is fixed on the stand. Secondly, that some device is necessary for rapidly changing the lenses. Mr. Pringle's plan seems to be very valuable in this respect; also the plan of having the lenses on a rotating disc, as described some months ago by the Editors. Attention to the merits of these two points only will go far towards solving the whole difficulty of the present waste of time, incurred chiefly in fixing and adjusting the camera, unfixing the same, and fixing and changing the lenses. A man might make it a special branch of business to adapt Mr. Pringle's apparatus to cameras of the past sent for the purpose; for the box cameras of the future, the rotating disc front seems to be best for bringing the lenses into position with expedition.

Next to the question of time, that of the nature of the case of the camera is of importance to the tourist. Most makers, perhaps, now sell their cameras without cases, and the purchaser at once finds that he must either put them in some kind of bag or thin satchel, or in a proper case possessing more rigidity, and that to get the latter specially made adds considerably to the cost of the camera. The latter and more expensive plan is necessary to the practical tourist who carries his apparatus about for many months at a stretch. The friction and strain upon the parts of a camera carried in a loose bag may not be of practical importance to a photographic dweller in towns who uses his apparatus out of doors only once a week, or less frequently. With a tourist on regular travel the conditions are different; and he also has the aggravation of knowing that, with more intelligently-made apparatus, portions of the case might have been made to serve the purpose of portions of the camera, thereby economising weight. The camera-maker who sells his apparatus in a case will always have a great advantage over the one who does not, because he will be able to point out to the purchaser that he is relieved from the expense of having a rigid case specially constructed. Home-made devices of cardboard, as sometimes recommended for cheapness and lightness, are useless for prolonged work and real travel; the outside of the case must in such instance be of good leather, or some thoroughly serviceable stuff which will stand long wear and tear, and keep out rain and dust. A lock is also absolutely necessary to keep out unauthorised fingers; otherwise the tourist is never happy in mind after the apparatus has been out of his care for half-an-hour, and consequently he clings to it for the whole day as tenaciously as the grand old man of the sea clung to Sinbad the sailor.

At Zurich I had a special case made of the best white leather, with compartments inside lined with soft material; thus each slide, the camera, the stand-head, and so on has a special compartment, in which it is gently held without friction when travelling. To get stiffness without much weight the skeleton of the case was built up of pasteboard by a bookbinder, and was lined by him; the leather work as well as a good lock was then added by a saddler. The cost of this case was thirty shillings. Those who understand leather work tell me it would have cost at least two pounds in England, which is a difference to be expected considering the relative ruling prices.

The minor objection on the score of dust to the use of a tied or strapped bag rather than a case tells with greater force during tourists' work abroad than during work in the exceptionally humid climate of England. Captain Abney spoke of this in relation to certain roads in Switzerland, and named an excellent and simple palliative, namely, to rub glycerine over the grooves and movable parts of the slides, let it soak in a little, and then wipe it off superficially with a cloth. The grooves afterwards trap the fine, penetrating dust, which would otherwise reach the plates. Another palliative is due to the fact that in those parts the people have an extraordinary superstition that Switzerland belongs to the Swiss, so will not allow private individuals to fence off portions of land to any great extent. As a general rule, the tourist can leave the dusty roads, when they do not border a precipice, and can go right ahead through field and fen and forest, and over mountain and moor, without any let or hindrance being in that case made and provided. Notwithstanding, moreover and nevertheless, the understanding is that on cultivated lands the traveller must not walk over growing crops, but keep to the footpaths; if he damage the crops he is liable to a fine. To save delay and trouble over litigation in a country in which judges on circuit are paid a few shillings a day for their services, the amount of the fine is sometimes painted upon a board on a post at the entrance to the field. For instance, in the Alpine valley of Andermat are notices in some of the fields that anyone trespassing is liable to a fine of sevenpence-halfpenny, or whatever the amount may be. If a Briton choose, nevertheless, to walk on the owner's crops he can pay the latter sevenpence-halfpenny on the spot, and the matter is amicably settled without adjournment to a police court. This freedom of traversing the land in all directions is a great boon to the photographic tourist. Strange people are these Swiss! If a photographer build a studio on another man's land, under a lease from the latter, the Swiss actually think that the studio belongs to the photographer who built and paid for it, and he is allowed to take it away at the end of his lease, just as if he had a moral right to its possession. Photographic studios and temporary builders' sheds are sometimes erected on land held under a few years' tenancy; but a substantial dwelling is never erected on another man's land—at least in those parts of Switzerland I have traversed. If a man did build a house in that way, the pitying populace would probably touch their foreheads significantly as he passed, and recommend his friends to look after him; but then, it must be remembered, the Swiss are such an eccentric people! More English photographers should go there to get these notions out of their heads, and to teach them the blessings of a greater freedom and a higher civilisation. The natives would probably feel interested in being shown photographs of streets of jerry buildings in the act of falling down at the end of a lease. Such pictures would, no doubt, make them open their eyes. The amateur British missionary might also take out with him some beads, paints, bits of looking-glass, and remnants of coloured cloth to barter with the simple aborigines.

To return from this digression: has anyone ever considered whether in tourists' cameras metal cannot be in some parts substituted for wood with advantage? The claim is already sometimes made that metallic slides are better than wooden ones, more especially in the matter of economising space. What are the merits of such slides as compared with those made of paper across the Atlantic? and where in London can the American paper slides be seen? When engineers want strength and lightness they use angle or tubular iron and lattice work. What would be the merits and demerits of a camera case with its skeleton built up of angle-bars of steel more rigid than those of umbrellas, and of uniting the longer bars by means of light steel lattice work, then covering the skeleton framework with thin cork, like that used for hats, with a final outer coating of good leather? To what extent can aluminium be advantageously used in tourists' cameras, now that an easier method of soldering it has been discovered? These questions are merely put to elicit information upon a subject on which I possess none, and a philosophical instrument maker would be the person to answer them. A saddler would argue that there is nothing like leather, and a cabinet-maker that there is nothing like wood; a maker of scientific instruments of precision might be allowed to have his say in the matter. It is to be hoped that those manufacturers, of whatever class, who intend to do anything to meet the public want, will make a close study of every suggestion made by writers within the last two months, to see how nearly they can incorporate in one camera everything that is really good. Attention to little points, small in themselves, may prove a great boon in the aggregate. A few fractions of an ounce saved here and there in the weights of parts, without sacrificing efficiency, might as a whole prove a substantial benefit.

Sooner or later, though the time may not be yet, the parts of model cameras will be turned out in great part by machinery, and then fitted together by hand. The most successful men of commerce in England and America are those who have spent much in thought and in money in the erection of machinery before commencing the actual manufacture of their goods. This principle can be acted upon also by makers in a small way. I know one ingenious man who, when orders are slack, employs his men in making new labour-saving tools devised by himself to expedite the future manufacture of his goods, so that when a run of new orders comes in the speed with which he executes them astonishes his competitors. His profits are also necessarily higher.

To steady a tourist's camera in a high wind, a mackintosh bag to hold some stones should have one of those spring links which fasten chains to dogs' collars fixed at the end of its string, so that it can be sprung in an instant into the hole in the camera screw. This will save time and trouble in tying and untying, and the annoyance sometimes caused by bad knots. An exceedingly large piece of mackintosh will fold into remarkably small space; it is also light-tight, and so is the best stuff in the world for a focussing-cloth. It also serves as a temporary table-cloth at hotels, where it is not desirable to damage the furniture with spilt chemicals. In Scotland it is considered partisanship to have much to do with mackintosh. Who has not heard of the photographer who returned to his compartment in a train on the Highland railway, saying "Did I leave a black mackintosh here?" The reply from the assembled "chiels" was—"Nae. We're a' Red Macgregors!"

Mr. George Smith, in his article some weeks ago, misquoted me several times, and then proceeded to overthrow the statements he had put into my mouth. Among the instances I remember are that he stated, either in substance or by implication, that I had said that my camera took ten minutes and upwards to fix; that I recommended that a camera which would extend to three times the length of its plate should have a gigantic case, inside which to carry it while so extended; and that I had said that the use of a spirit level on the camera was desirable when the straight line of a building was in sight in a mountainous landscape.

W. H. Harrison.

REDUCING THE DENSITY OF NEGATIVES, AND THEIR IMPROVEMENT.

There have been a very great many methods put forward for the reduction of intensity in gelatine negatives since their introduction; but, so far as I can learn, I don't think any of them have been of much use, being too risky, especially with negatives of any great value. In the most experienced hands, at times, a negative will, when finished, prove a little too intense, and when this does occur it is a good thing to be able to reduce the density, without having a shadow of a doubt in one's mind as to the spoiling of it.

It will be remembered that some twelve months since I wrote an article in these pages upon the intensification of gelatine negatives, and by the numerous letters that I have received it has been of great service to many—at any rate it has to myself. If I had been able to put this part of the question forward with the intensification portion it would have been complete as a whole, and not in parts like the franchise bill and redistribution; but in scientific matters inventions follow one another, and we must be content to take them in that way, and read them together whenever they do come. Not only is it very convenient to have a reliable method of reducing negatives, but it is also good to have a method of improving them in certain parts—not on the retouching system, which has been overdone in portraiture. For myself I would sooner have a lithographic portrait than many of the photographic portraits of the present day. I am well aware that photography pure and simple, in many instances, is not true to nature by any means, especially in rendering gradations of colour. I hold it to be perfectly legitimate to make up for such shortcoming, *and no more*, so as to get as near to nature as possible without being untruthful, and I fully believe that artists will agree with me on this point. In landscape photography there is very little retouching done, for in this instance the subject never finds fault.

It will be remembered that some long time since Holmes's ozone bleach was introduced for reducing the intensity of negatives. In my hands it was of service with certain emulsions made from moderately-soft gelatines, but with harder samples it was of no use whatever. Then, again, the risk was great; but I have seen some good effects produced by its use, and, on the other hand, I have seen negatives utterly spoiled by it. Another method was reduction by means of a dilute solution of hydrochloric acid, and another with iodine in solution, followed by either hyposulphite of soda solution or weak cyanide, or cyanide solution alone. Chloride of copper has also been used, followed by hypo., &c.

All these, as will be seen, acted generally over the whole image except the Holmes's ozone bleach, which could be applied locally. I have given up these for a considerable period, and have contented myself with altering the colour of the negative as much as possible, making it of a grey colour by using a strong solution of alum and citric acid, and leaving the negative in the solution for hours sometimes.

Some months since there was published in these pages a small paragraph on the use of methylated spirit for the reduction of negatives. As I have not heard any comments upon it I suppose it was too small to be noticed, so it was overlooked. When reading it it brought to my mind that a few months before I had some negatives lying on the table, and was pouring some methylated spirit from one bottle to another, when the bottle slipped and sent some splashes of spirit over the negatives. I instantly took up one of the negatives and rubbed it over with a clean duster until it was dry; but I spoiled the negative by making it thin in the part where the spirit had been.

Not wanting the negative it was put on one side, and I never thought any more about it until I saw the small paragraph before alluded to. I then at once set to work on some old and useless negatives to see what could be done with methylated spirit (?) and if it was of any value, when I soon found it was of very great service. I discovered that I could with ease reduce the intensity all over the negative, if required, without the slightest risk.

I went to work in this way:—I took an old worn-out cambric pocket handkerchief, wetted it with strong methylated spirit, and began rubbing it all over the negatives, rubbing briskly. I found there was not the slightest fear of damaging the film, unless there was any grit on the rubber. After a little time I found the white cambric was covered with black, like fine blacklead, and as this gradually came away the intensity became reduced, and by continuing I found the image could be rubbed nearly all away. I then tried reducing the intense parts of a negative and experienced no difficulty whatever, and the beauty of it was that I found it came away so gradually that there was no risk of spoiling a good negative. As these experiments proved so successful I now use methylated spirit, whenever I require it, with perfect confidence.

In using the spirit I need not say that the negative should be perfectly dry, and the spirit must be strong. The strength of methylated spirit, as sold, is about ·825 or ·830 sp.gr.

In portraiture this method has its uses. Very often the lighting may not be quite perfect, the light being rather too strong on one side of the face, which throws the other side too much in shadow; but by reducing the intensity matters are greatly improved. As regards the backgrounds a very great deal may be done. A plain background that prints too light can be reduced by the same means, and not only reduced but graduated to suit the subject, which very much enhances the picture.

In many figure studies certain parts of the picture are roughly masked, while other parts are exposed to the light. Instead of having this to do with every print, there is no reason why it should not be done on the negative once and for all, as it can be done with such certainty. There are also other classes of subjects worth mentioning, namely, ladies in white or very light dress, in either satin or silk. These materials, when properly photographed, are very beautiful; but at times the development has to be carried on to such an extent as to entirely bury the beautiful details and gradations, on account of the face, which makes the dress print too high in tone, and makes the face appear dirty. All this is remediable in the way described. Another defect is the drawing in collars, &c., of white lace, which can also be reduced by rubbing with the spirit. The dress can also be manipulated to secure a truthful effect.

All this I own to be perfectly legitimate, if truth is to be aimed at, and we have a perfect right to use any means in our power to give the correct rendering of any subject. Photographs, as we all know, are pictures or representations in monochrome, the shadows and half-tones forming by far the greatest part of the picture, and the high lights (or the parts rendered by the pure white of the paper) a very small part indeed. If we take, for comparison, a water-colour drawing, place it beside a good photograph, and examine them both closely we shall find that the paper on which the picture has been painted has, before commencing, been toned down to cover the white paper, and the extreme high lights, which are probably just small points, have been scraped out with the knife, or sometimes (but very seldom) they are made of pure white pigment. In the photograph we find much more white paper in comparison than we have in the water-colour drawing. This white does not exist in nature to such an extent, and with skill can be modified to represent nature better.

Again we go to nature. Take (say) a landscape, and we find little of pure white. If we wish to represent nature truthfully it is only the *extreme* high lights must be pure, and if this be done the lights are like diamonds of the first water in a rich setting, and give great brilliancy to the whole. In a photographic landscape, say, for sake of illustration: with some broken ground there is some yellow sand, or nearly white, showing when photographed. This will show dead white, and no one could say, taking gradation of tone, that if left so it would be true to nature—not only true, but would spoil the picture. Such a blemish can be overcome and made more perfect by the means that I have here named. I have seen hundreds and thousands of photographs that would have been greatly improved, and in some cases made works of art, if a little knowledge, skill, and taste had been brought to bear on them in their production. But with many—and it always will be so—the camera is only a machine, and will only produce crude, mechanical representations perfectly meaningless in themselves, and painful to a cultured mind and taste to look upon; therefore nothing should be left undone to get the most faithful representation of nature.

Wm. Brooks.

ON THE TREATMENT OF HUSNIK'S PHOTOLITHOGRAPHIC TRANSFER PAPER.*

Blackening of the Print.

For this may be used a fatty transfer ink which I prepare commercially, dissolved in oil of turpentine; or anyone may prepare such an ink for himself from ordinary lithographic transfer ink by adding to eight parts of that ink one part of wax, melting them by heat, mixing them well, and then thinning with rectified oil of turpentine until a cold sample is of the consistency of syrup. This solution is then poured into stoppered bottles and closed. It must, however, be borne in mind that such dissolved ink changes with keeping, and must be well stirred with a brush each time before being used (the brush being left sticking in a bottle during the time it is in use, and having been inserted when the bottle was opened), because, though the fatty ink remains perfectly dissolved in the turpentine, the wax is insoluble; so that if the upper part of the solution be always poured off there would at last remain nothing but wax at the bottom, and then the colour would become so hard that it would no longer allow itself to be transferred to either zinc or stone. In such a case add five to ten drops of olive oil to the residue of the ink; that should make it work well again.

It is necessary to use as solid an ink as possible; hence the addition of wax to harden it, as the harder the ink the sharper the impression. Too fatty and soft an ink becomes squeezed out under pressure and gives thick lines and black shadows; but if there be too little of the grease then the colour is not transferred at all, but remains on the print.

Stone requires a much greasier ink than zinc, because, though an ink may allow itself to be transferred to stone, yet if it be not fatty enough the stone cannot absorb any fat from it and the transfer cannot bear to be etched. A very fatty ink must therefore be used for stone, and it is obtained by the addition of more olive oil. We have to do with a different state of matters when zinc is used. Here nothing sinks into the metal, and, therefore, wax or varnish is sufficient of itself to protect the metal from the action of acid, so that a harder, waxier ink may be used. The print to be transferred is laid flat upon a zinc or glass plate and coated with ink, the drops of ink lifted out of the bottle and placed by the brush on the print being spread by means of a tuft of cotton wool—first by equal strokes in all directions, and smoothed down until there is only a mere film of the ink remaining over the print. The ink so distributed is left exposed to the air for a

* Concluded from page 585.

few minutes to allow the turpentine to evaporate. The print is next laid in a zinc trough partly filled with cold water. In half-an-hour the picture may be developed, but the development can be postponed, if so desired, by leaving the print lying in the water for a few days.

The development of the picture depends most upon the proper exposures of the print. After the print has soaked about half-an-hour—completely covered on both sides and at all parts by water, yet free from air-bubbles—then the colour may be wiped off the whites by gentle rubbing with a sponge, so that the design alone retains the ink. The developing tray is then placed so that one end is canted up until the bottom of the upper end is no longer covered with water, and the print laid upon this raised end. The surface of the raised end is then rubbed with a sponge with a circular motion, until the whites are quite freed from all dirtiness and the shadows appear quite open.

If the print be over-exposed the shadows remain closed, all the lines appear broader, and the background will not easily part with the colour. The last-mentioned behaviour also occurs with weak negatives. If the paper had been sensitised for three or four days, or if light had had access to it, the colour would in these cases also not readily leave the whites. If the paper was under-exposed the colour would be more easily removed, but the finest lines and dots would also be washed off along with it.

Only prints that have been pretty correctly exposed can be perfectly and faultlessly developed; still the limits lie pretty far asunder, especially in the case of good negatives, which may be considerably over-printed without the picture becoming too black. The kind of tissue used also makes a difference both to the development and the printing. Too soft a gelatine or a thicker film requires long printing; too hard a gelatine or a thin film requires a short exposure. It has been proposed to add a little alum to the gelatine to render the tissue harder and less sticky; but I found that this addition gave rise to many difficulties in the development, and that the print was more injured by the greater pressure which had to be exerted on the sponge to remove the colour than when the latter could be wiped off without any particular pressure. As the swollen-up print forms a relief, so that the design appears sunk (in intaglio), each line and all the five dots are better protected than when one has to rub hard until the ground of each line is reached. Care should be taken to use cold water always, even in summer, as warm water not only dissolves the gelatine but renders the ink also soluble and smeary. Almost any water may be used if it do not contain too much iron.

Prints so developed should be well rinsed with clean water in order to remove all fatty ink that may be merely adherent, and then they should be laid upon clean blotting-paper. One print after another is placed alongside of each other and covered with clean blotting-paper. Then the paper is all smoothed and pressed out in every part by the palm of the hand in order to bring it in contact everywhere with the print, and so dry up all adherent water. The prints are then placed near a stove, which must be heated all day, so that the drying may be thoroughly completed.

If one, however, desire to transfer at once and cannot spare time to let the print dry thoroughly, it must be previously laid for two or three minutes in a solution of one part of alum to fifty parts of water. This bath hardens the gelatine, so that it cannot adhere so firmly to the gelatine, and is not so easily crushed when being transferred. Yet the gelatine should not be too hard; otherwise it will not stick to the zinc, which causes the impression to appear double.

It is best, however, to allow the prints to become quite dry, as then they are simply laid against any window and exposed for half-an-hour or longer to the light, which also causes the gelatine to harden. In spite of the washing there still remains a trace of chrome salt, which is only just sufficient to produce the necessary hardness in the light parts of the picture. If there be no longer any light at one's disposal the print must be placed in the above alum bath, and then, after being sufficiently dried with blotting-paper, transferred.

The dried prints only keep about two days, after which the ink dries in and can no longer be transferred. If it be desired to keep the print longer in a state fit for transference it must be allowed to lie in water, or the ink must be adapted to that purpose by adding from six to ten drops of olive oil to a bottleful of ink. This is very often useful, especially when the prints have to be sent to another place to be transferred. To send them: place a sheet of tissue paper upon each print, then roll all the prints together and place them in a cylinder made of strong pasteboard.

I used to prepare a tissue, to the gelatine of which alum was already added, so doing away with the subsequent alum bath or exposure to light of the print after development. But, as the results obtained with the more adhesive gelatine were much better, and as they were also much more easily developed, the tissue is now only prepared with the purest extra-white gelatine and the hardening only takes place when the print is ready to be transferred to zinc.

The Transference.

If the print is to be transferred to stone it then requires to be hardened neither by alum nor by exposure, as it must be sticky, otherwise it will not adhere to the stone. The stone is moist, and a hard gelatine will not adhere to it. Except in this particular case the transference to stone and to zinc are alike, and the same lithographic press may be used for both, or an autographic roller press may be used for the zinc plate.

The print is laid, with the picture side down, upon clean paper, and the back of it moistened and smoothed with the sponge until the tissue has become soft and supple and the front appears somewhat sticky. The print is then laid upon the zinc or stone and a sheet of paper laid over it, after which they are passed through the press under a slight pressure, which is gradually increased, the plate or stone bearing the print and its protecting paper being passed through it after each increase of pressure. Then the back of the print is moistened again, and one recommences passing it through the press—with a slight pressure at first and gradually increasing the pressure. Then the print is again moistened and drawn off from the support, when all the ink should have been transferred from the paper to the zinc plate or stone, so that the drawing appears perfect upon the latter. The design is then strengthened and gummed as usual—an operation which is generally left to a professional.

If the pressure be much too great then the gelatine would be crushed, and it is on that account that some practical men prefer but slightly gelatinised tissue. Others, again, favour that containing a great deal of gelatine, because it has a flatter surface and should give finer results. A medium thickness of film is, however, best, as the surface may be made as smooth as one can wish by burnishing before printing.

Every new process or method requires experience before one can obtain perfect results, and the short step from what is good to what is best is often more difficult than the long road that leads to mediocrity. Here I have collected the result of all the experience I have gained during a ten-years' use of photolithographic paper, so that anyone may use it with confidence, and work so as to obtain the best results.

—*Notizen.* J. Husnik.

WHERE TO GO WITH THE CAMERA.

[It is hoped that this series of articles will be continued at regular and frequent intervals during the vacation months, and we shall be glad to receive contributions to the series from any friends able to treat of new and interesting ground.]

CYCLING AND PHOTOGRAPHY IN CHESHIRE.

As we are now approaching the end of the summer, and have only a few remaining days to air our favourite hobby, a short description of a "wheel run" in search of autumn "bits," taken about this time last year, may be of some guidance to other photographic "wheelmen," or the photographic pedestrian (the latter, of course, would be unable to cover the distance the day's run embraces).

Leaving Chester about eight in the morning on our tricycles, with bags well stocked with camera slides and portable tripod, we made our way through Hoole to Tarvin, where a couple of plates were exposed, including the main street of the village and the church—an old edifice dedicated to St. Andrew. Tarvin was the scene of numerous skirmishes during the civil wars between the royalists and parliamentary troops.

Our next halt was at Delamere Forest, where, leaving our machines at a cottage, we enjoyed a quiet ramble through the woods, here and there transferring to our slides many a gnarled trunk and "bit" of underwood. How we longed for photography in colours! The varied tints of russet brown, yellow, and purple, contrasted with the dark green shades among the trees, the long vista down the open pads, with rabbits skipping about in the sunshine—all combined to make us long for an entire day for this beautiful spot at least.

Remounting our "steeds" we ran on to Tabley, where we dined at a wayside inn. We called at Holford Hall, the ancient seat of the Cholmondeley's, now a farm house—a specimen in fair preservation of a timber and plaster house. One side projects over the courtyard and rests on wooden pillars. This house is a favourite with artists from Manchester, as we were informed by the farmer's good lady. The hall is a short distance to the right of the high road, almost level with Plumley Station. At Tabley we paid a visit to the old hall, the remains of another timbered mansion, situated on an island on the Mere. It contains some ancient oak furniture, wainscotting, pictures, &c.

Leaving Tabley Park, and being directed on our way by a friendly gamekeeper, we reached the gates of Tatton Park, the seat of Lord Egerton. Turning sharp to the left ran through Rostherne village to the church gates. Here, leaving our machines, we went down a steep incline to the margin of the Mere—a beautiful sheet of water. Just below the church is the fisherman's boat-house. Looking to the left is a beautiful view. In the foreground are rushes and reeds, with a row of pailings running out into the water and overhanging trees; in the middle distance a boat-house thatched with rushes, a small landing jetty of piles driven into the bed of the lake, and a few yards from this is a sailing boat moored to a buoy. In the distance the rising ground on the far bank is well wooded and almost gives an impression of distant hills. Occasionally there are a pair of swans sailing about, and the fisherman setting his nets from a broad, flat-bottomed punt. Turning round and facing up the brae is the venerable church surrounded with lofty trees, the *beau-idéal* of a sequestered country church. Ascending from the lake and mounting a few steps, we are in the churchyard. To our right is a genuine old Lychgate—a picture in itself. The best view of this is obtained by passing through the gate, down the steps leading into the lane, and facing about with the church in the background. Of the church itself, the best view, in our opinion, was from the east end outside the churchyard on the rising ground. The interior is plain and old-fashioned, the only object of interest being an ancient stone coffin, carved on the lid of which is a knight recumbent with crossed arms, sword at his side, and his feet resting on a dog. The Egerton chapel at the south side of the chancel contains a monument, by Westmacott, to Charlotte Beatrix Egerton, who died at the early age of twenty-one years. The inscription was as follows:—

"Softly she slept in that last hour;
God's angel hovered nigh;
He raised with love that fragile flower
To wake in bliss on high."

There was nothing of further interest in the village; so leaving this we pushed on to the Tatton Gates again, turning to the left to Ashley Mill—another spot favoured by painters, &c., situate on the banks of the river Bollin, and now in ruins, the business of the mill having been removed to Broadheath. The bridge across the river, with the overhanging trees and moss-grown roof, form a pleasing picture. We noticed, just at about a-quarter of a mile before reaching the mill, a timbered barn covered with a Virginian creeper. The brown and red leaves, with the moss-and-lichen covered woodwork, would be well worthy of a plate.

The day being now well advanced we "made tracks" for Broadheath Station and took train to Liverpool, after passing some of the most picturesque localities in Cheshire. We had intended a visit to Dunham Park, with its haunted mill and beautiful lake, but our time was limited, and having covered about forty odd miles and exposed nearly two dozen plates we were fain to say "enough!" KENNETH BEAN.

HERNE BAY.

It will be generally conceded that all the old frowning castles (and it will be interesting to learn at what stage of their development the "frown" was evolved), all the old bridges which span the still older rivers, all the old cathedrals, stately mansions, and village churches have been duly photographed from every point of view by every conceivable lens by amateur and professional talent all over the country, so that the question "Where to Go with the Camera," if new views are the object, becomes almost as much of a puzzle as the *pons asinorum* was to the baronet of B.K. when he suggested its possible location in the island of the saints. Most of us, even when we take a photographic holiday, would prefer a slight *honorarium* as the reward of merit, and Windsor from the Clewer Meadows, Tintern Abbey, or Conway Castle are not likely to possess the claim of novelty; so suppose we go out of the beaten track, and try Herne Bay.

There comes another question—Why do the Kentish maidens invariably designate this place as "*the Bay?*" Is it because its conformation so slightly resembles a bay, or is it that their travels are so little extended they know no other bay save that of Herne? Anyhow we are in search of the picturesque, and so turn our back sharply on the stormy beach and the soft ooze which does duty for "sands," where the same nurse girls sit poring over the pages of the same cheap novels day after day, while the same bare-legged children paddle at the water's edge, and the same young men in the same light tweeds smoke the same cheap cigars, and the same fathers of families lounge through the hours engaged in the intellectual pastime of throwing pebbles in the sea.

There are no noted public buildings in "the Bay." Its architecture is at an extremely low ebb, best described as local,—*n'importe*. Ramble along the main Canterbury road, and a few yards past the cemetery on the right is a small wicket gate which, passed through, only requires a suitable figure or figures to tell its story. The trees, either at the fall of the leaf or in early spring, and the rich undergrowth are all at hand to make a perfect picture. On the other side of the main road, and opposite this gate, is a shady pool, with a background of fine old trees—the very spot where a thirsty soul would lie on the ground and slake his thirst, or where the village children after school would swim their tiny craft.

We take the road once more. Still on the left, opposite Prescott Park, is a stile leading to a footway across the meadow. This footway literally teems with "bits"— the overhanging branches, the gnarled trunks in all manner of fantastic shapes, wanting only the returning cows from milking, or the boys birdnesting, or the waggoner's team to make subjects tempting indeed to him imbued with the true art feeling.

Out again on the road, through the village of Herne-street, past the old church—which, however venerable and however much surrounded by tombstones, is not a subject for high art—on past the workhouse, where the paupers tending the inside grounds seem afraid to lift their heads lest they commit a breach of discipline, and bearing with the track to the left we come sharply, on the left again, to a wood, which small in extent, makes up in richness of undergrowth and moss-covered banks for any shortcomings as to size. There the artist may positively revel while the glades re-echo the spirit he inspires in his models.

Back to the Canterbury Road, and beyond the "Halfway House" on the left, are two magnificent old oaks, where the wayfarer might stretch his weary limbs or where the village festival might be held; where the lassie might keep her tryst or the gleaner rest from her labour. Many memories of the past could these knotted trees unfold; many aspirations of the future may be sheltered beneath their spreading branches, while author and artist drink their fill of inspiration from the beautiful around.

Continuing the ramble to within a short distance of Sturry, studies without number may be made in a dense mass of foliage and hill and dale on the right. It is here at every point that a fresh beauty meets the cultured eye, and a constant succession of change may be made by a simple turn of the instrument and a variation of the models. It would be presumption to suggest the titles when the field is so rich, and when the inception that would be the creation of one mind would be out of harmony with the aspirations of another. These tangled thickets are so many settings for pictures, and by their beauty they invite us to make them speak—to tell to others the varied emotions they have instilled in ourselves; and it is in scenes such as these lies the great future of our art.

The mere delineation of tracts of country—however beautiful, however romantic they may be—call forth but slight creative power. The selection of the best point of view, the introduction of figures, the arrangement of certain details, and the choice of light will distinguish the artist from the mere slipshod worker; and when all is done, the combined whole will be a pleasing effect—a harmonious reproduction of nature. But there is no great *creation*. There is no theme originated and developed to a point which strikes the beholder as a story most effectively told; but, when the models form the picture and the tangled bushes become only a suitable background against which they are taken, it is then that the *same* creative power is called forth from the artist with the camera as from the artist with the brush. The expression and the pose of each model must be a study beforehand, so that when the moment arrives the result must be perfect in composition, in spirit, and in *technique*. JOSEPH HARRIS.

FOREIGN NOTES AND NEWS.

DR. LOHSE'S ISOCHROMATIC GELATINE PLATES.—A NEW USE FOR ALBUMENISED PAPER.—A VARIATION IN CRYSTOLEUM PAINTING.—HINTS FOR THE ASPHALTE PROCESS.—DR. VOGEL ON CHRYSANILINE AND ISOCHROMATIC PLATES.

IN the *Archiv* Dr. O. Lohse writes, regarding isochromatic gelatine plates, that he has made a further series of experiments on the modification of the sensitiveness of bromide of silver to colour, and used as sensitisers the following yellow dyes:—Orthonitrophenol, orthonitraniline, paranitraniline, metanitraniline, thymokinone, phenatrenkinone, chrysophanacid, tropæolin, quercitrin, aloes, diamidoazobenzol, diamidoazobenzol hydrochlorate, amidoazobenzol, amidoazobenzol hydrochlorate, nitrosodimethylaniline, nitrosodimethylanilin aniline, picraminic acid, phosphin, aurantia, chrysoidin, Martin's yellow, diamond yellow, chrysanilin, nitric chrysaniline, and tropæoline iodide. Each of these dyes was treated in the same way, namely, 0·02 of a gramme of the dye was dissolved in 100 c.c. of water containing ten per cent. of ammonia, and filtered. If requisite the substance was dissolved in a little absolute alcohol before being added to the water. All the plates used in the experiment were Nelsons' "extra-rapid" plates, which were soaked for two minutes in the above staining fluid and then dried. Without entering into details of the series of experiments it may be remarked that, amongst all the substances used, there were two that distinguished themselves, namely, diamidoazo benzol hydrochlorate and nitric chrysaniline; while of the others some seemed to affect the sensitiveness injuriously, others to exercise no action at all, and others again to produce a slight effect. The diamidoazo benzol hydrochlorate increased the sensitiveness of bromide of silver to green and yellow considerably, so that when the sun's spectrum was photographed a second maximum appeared between the Fraunhöfer lines D and *b*. In the neighbourhood of F, a little towards G, there was a spot of diminished action like that which occurs in the case of eosine. Nitric chrysaniline in combination with ammonia increased the general sensitiveness of bromide of silver, in consequence of which the sensitiveness to colour also appeared to be raised. With a normal exposure of twenty-five seconds the photographed spectrum extended upon the experimental plates from the ultra-violet on the one side to well beyond D on the other side. An accelerating action also occurred, after which both the chrysaniline contents of the solution and the addition of ammonia were diminished. He then prepared a solution containing only 0·004 of a gramme of nitric chrysaniline and two c.c. of liquid ammonia to 100 c.c. of water, and exposed a plate prepared with this stain along with an unstained one to suitable light, under a paper scale of sixteen graduated folds. The result showed that the stained plate was considerably the more sensitive, as upon it No. 9 of the scale could be distinguished, while the unstained plate only went as far as No. 4. Dr. Lohse, therefore, thinks himself justified in recommending the addition of a slight trace of nitric chrysaniline along with ammonia to bromide of silver emulsion, in order to increase the sensitiveness of the latter.

A new use for albumenised paper has been spoken of in French papers. It is said that butter rolled in albumenised paper will keep fresh for months. This sounds all very well, but we should be very unwilling to roll good butter in some of the samples of albumenised paper that have passed through our hands lately, since it is well known that butter, like all sorts of fat and grease, absorbs with great readiness the *perfume* of anything that may be placed near it, though not necessarily in contact with it. This danger may, however, be avoided by preparing the albumenised paper for one's self, since, as perfect equality and smoothness of surface are not indispensable to the butter-preserving housekeeper as they are to the photographer, the former may turn amateur albumeniser. She will add from one to two grammes of saltpetre to the white of one egg and apply to her paper. The butter is to be provided with an inner covering of linen, and the albumenised paper placed outermost.

The *Archiv* informs us that a Mrs. Nelson Decker has discovered a way of dispensing with the second convex glass for coloured photographs —presumably those coloured by the crystoleum process. This discovery consists simply in dipping the print at different stages of its colouration into the wax and paraffine solution.

The same journal supplies some short hints for working the asphalte process:—A solution of asphalte in oil of lavender or oil of turpentine is spread, by means of a leather roller, upon metal plates and dried in the dark. Old asphalte films furnish much firmer prints than new ones, which separate from each other; even some months after preparation the films are still quite useable. The film should not be too thick, as that would cause the development to be too prolonged, and there would also be a danger of some parts not being sufficiently washed at development. For contact copies of engravings it is advisable to soften the engraving in a mixture of glycerine and water and then to apply it with the squeegee to the dry asphalte film. In this way extraordinary sharpness is obtained. The exposure may last a quarter of an hour in the sunlight and about an hour in diffused daylight! It is better to expose too long than too short a time, as over-exposure may be avoided by the use of stronger solvents. If the plate be exposed in sunlight it should be allowed to become cold before being developed. Oil of turpentine, or a mixture of oil of turpentine and olive oil, are used as developers. Benzine alone has too energetic an action; it is better when asphalte is dissolved in it. Petroleum makes the unexposed parts soft and swollen. Before being etched the film is washed with water, dried, and exposed to sunlight or daylight in order to harden it. Steel may be very beautifully etched with a golden-yellow (not orange-yellow) solution of iodine, renewed every ten minutes; or, if it be preferred, an asphalte solution, consisting of 30 grammes of asphalte dissolved in a mixture of 10 c.c. oil of citron and 600 c.c. benzine, may be used. Quite lately, instead of asphalte, marine glue has been employed, which resists the etching to a very great extent and requires all the longer exposure.

With regard to Dr. O. Lohse's experiments with chrysaniline and other dyes, Dr. H. W. Vogel writes in the *Mittheilungen* that, according to his book on practical spectral analysis, chrysaniline absorbs the blue side of the spectrum and shows a weak streak of absorption from F to F 2/3 *b* in the blue-green. Accordingly, going upon the principle of optical sensitisation, an increase of the sensitiveness to blue and blue-green was to be expected. Dr. Lohse's experiments on the colour scale with plates stained with chrysaniline quite confirmed this view, as they actually showed a considerable increase in the sensitiveness to ultramarine blue and pale green, which not only reflect blue but also blue-green. An increase of sensitiveness to Naples yellow and chromic yellow, on the other hand, was not observed. Azaline plates laid in a bath of chrysaniline and exposed behind a yellow glass reproduced ultramarine considerably more brightly than pure azaline plates; indeed, almost as distinctly as chrome yellow. On the other hand, their sensitiveness to yellow and orange was distinctly less than that of the latter. It was the same with their general sensitiveness, for they appeared in the developer more slowly than the azaline plates. This does not contradict Dr. Lohse's results, since the increase of sensitiveness observed by him only took place in the blue light, which, in Dr. Vogel's experiments with chrysaniline plates, was to a great extent absorbed by the yellow glass. Chrysaniline, then, Dr. Vogel thinks is valuable for increasing the sensitiveness of *common* gelatine plates; but, on the other hand, it is valueless for plates sensitised for colour, in so far as that the increase of sensitiveness produced by it takes place principally in the case of the most strongly-absorbed blue, while the sensitiveness to yellow remains far behind. (Another substance, the optical properties of which were examined by Dr. Vogel, and the action of which he considers to equal or even to exceed that of chrysaniline, is the substance discovered by Witt, and which he called "chrysoidin." Dr. Vogel, has, however, only tested it optically, not yet photographically.) With plates stained for colours, he has obtained great sensitiveness to yellow and a slighter one for blue. The task of colour photography is not to produce a so-called isochromatic plate—that is, a plate equally sensitive to all colours—but a plate the sensitiveness of which shall approach as nearly as possible to that of the human eye. "That, however, is far from being isochromatic, being most sensitive to yellow, next to green-yellow, less so to the dark blue, and least of all to violet. Dr. Vogel would, therefore, wholly reject the word 'isochromatic'" as applied to plates, this use of the word being of French origin.

PHOTOGRAPHY IN COURT.

USING THE ROYAL ARMS WITHOUT AUTHORITY.

Messrs. A. and G. Taylor were summoned before Mr. Newton, at the Marlborough-street Police Court, on Tuesday last, the 30th ult., "for unlawfully and without authority of her Majesty using, in connection with their trade, the royal arms, or arms so nearly resembling them as to be calculated to deceive or mislead persons to believe they were carrying on the business or profession under such authority." Mr. Bateson appeared for the prosecution, and Mr. St. John Wontner for the defence.

Evidence from the Lord Chamberlain's office was adduced, showing that the names of the defendants were not among those who were empowered to make use of the royal arms as photograpers to the Queen; and a canvasser lately in their employment put in papers as evidence which bore the royal arms, and which had been entrusted to him to use for the purposes of canvassing for the defendants' club portraits. Evidence was also given to show that the royal arms were publicly displayed at the defendants' places of business. The prosecution, it was stated, had been undertaken in the interests of the photographic profession. In defence, it was urged that when the defendants commenced business as photographers in 1866 one of them, who had previously been employed at Balmoral in another capacity, returned there and took some photographs, among which were portraits of certain members of the royal family; that in consequence of this he applied for permission to use the royal arms; and that he had subsequently used them, although without written permission.

The Judge said that, while on the evidence adduced it was shown that the firm of A. and G. Taylor made use of the royal arms without legal right to do so, he would adjourn the case for a week in order to afford the defendants an opportunity of bringing proof that they had authority for making use of the royal arms. The further hearing of the case was, therefore, adjourned until Tuesday next, the 7th instant.

[From inquiry it appears that there are only three photographic firms in London who have a legal right to use the royal arms as photographers to the Queen.]

RECENT PATENTS.

APPLICATIONS FOR PATENTS.

No. 12,772.—"Increasing the Usefulness of Photographic Cameras." F. Shew.—*Dated September* 24, 1884.

No. 12,855.—"Camera Tripods or Supports." W. Watts.—*Dated September* 27, 1884.

PATENT SEALED, September 23, 1884.

No. 8,643.—"Improved Apparatus for Coating Photographic Plates or Paper with Gelatine Emulsion." B. J. Edwards.—*Dated June* 5, 1884.

SPECIFICATION PUBLISHED DURING THE WEEK.

No. 10,950.—"Certain Improvements in Photographic Cameras."

This invention is a communication from Calvin Rae Smith, of New York, artist. It relates to a method of transferring plates from a receptacle to the camera, which we think would not prove of sufficient interest to our readers to warrant us in printing it.

" 9	Glossop Dale	Glossop Coffee Palace, High-street.
" 10	Ireland	Royal College of Science, Dublin.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on Thursday, the 25th ult., the chair was taken by Mr. A. Haddon.

Mr. A. L. Henderson described some of his experiences during his recent visit to Canada and the United States, but more particularly as to the results of his observations at some of the dry-plate manufactories he had visited, and notably that of the Inglis insoluble plate factory, which he had been most courteously allowed to inspect throughout. He showed a machine for packing plates in use at this establishment, and demonstrated the method of using it. The machine consisted of a board and frame for holding firmly the box into which the plates were to be packed, and a traversing bar through holes in which string passed. The string was by this bar drawn backwards and forwards as each fresh plate or pair of plates was placed in the box. It was necessary that the plates should fit into the box with very little play, or the string might not be retained between the plates. When the box was filled it was covered with a deep lid, and this, again, by another lid put on as though the intermediate lid were a box. This effectually prevented light from being reflected on to the edges of the plates. At the Inglis factory the plates were dried by a blast fan driven by steam power. The air as it entered the drying-room was filtered from dust by a canvas bag which was tied over the air inlet, and the drying was complete in about two hours. The emulsion was made at six o'clock in the morning, and the dried plates were in the hands of the packers by one o'clock in the afternoon. The glass was cleaned very rapidly by being held between the ends of two revolving cylinders composed of blotting-paper wound round. As the paper became worn away with use the cylinders were approached so as still to press against the surfaces of the glass held between them.

The CHAIRMAN showed some negatives from an emulsion giving green fog. One of these plates had been left in the hypo. all night, and the fog which in the other plates had been red by transmitted light was thereby changed to a bright indigo-blue colour. Another plate from the same batch treated with the Monroe developer came out without fog.

Mr. HENDERSON said that the less gelatine employed to emulsify with the less green fog there would be.

A MEMBER inquired what was the state of photography in America, as shown in the exhibition of the Convention at Cincinatti.

Mr. HENDERSON thought that, whether owing to the superiority of the light or not, the Americans were ahead of the English in instantaneous photography in the studio, and instanced a photograph of large size of a child riding on his father's foot.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE ordinary meeting of the above Association was held on Thursday, the 25th ult., at the Free Library,—Mr. J. H. Day, Vice-President, in the chair.

The minutes of the June, July, and August meetings having been read and confirmed, Mr. J. Eaglesfield was elected a member of the Association.

Mr. W. H. KIRKBY introduced a resolution on the subject of the July and August outdoor meetings, and said that he thought it would better conduce to the welfare of the Association if these meetings were held, as usual, in the city.

Mr. O. R. GREEN suggested that notice of these outdoor meetings should be given annually in the ALMANAC. He had wished to attend the last meeting, and found to his disappointment that there was no assembly at the Free Library.

The Rev. H. J. PALMER reminded Mr. Kirkby that his resolution amounted to a new rule, and could only be introduced after due notice had been given. He (Mr. Palmer) had gone through the minutes of the last ten years and found that in nine of the ten no meetings of the Association had been held in Liverpool in July and August.

Mr. J. H. T. ELLERBECK said that if Mr. Kirkby would give notice now the matter could be discussed at the next meeting.

Mr. KIRKBY adopted Mr. Ellerbeck's suggestion, and said he would propose a new rule at the next meeting, and after this the subject dropped.

The CHAIRMAN announced donations to the print collection of the Society, by Messrs. Watts, Williams, Hartley, and Wharmby.

Mr. H. N. ATKINS gave some account of his success in the production of paper enlargements, and passed round some very fine specimens of his work. [Mr. Atkins's views were fully described in the Journal of last week, p. 615].

Mr. J. H. DAY said he had obtained good results with Morgan's paper, and showed a print from a waxed negative, which was perfectly sharp, and could not be distinguished from an ordinary glass negative.

A MEMBER exhibited an excellent enlargement, 16 × 12, made in this way on gelatino-bromide paper from a quarter-plate.

The Rev. H. J. PALMER read an important resolution passed at the last meeting of the Executive Committee of the Associated *Soirée*:—"That a certificate of merit be awarded by the *Soirée* Executive Committee to the best series of six photographs, taken by an amateur, of subjects within a radius of ten miles from Liverpool," and urged the members of the Association to join in this useful competition. Mr. Palmer further reminded those present of the number of interesting negatives of subjects connected with the Liverpool of the past which had been taken by members of the Society. He hoped that these would all be printed afresh, that members would produce numerous other pictures of scenes which were now fast disappearing, and thus that a really useful and valuable collection of views connected with Liverpool might be available for exhibition at the coming *soirée*.

Mr. J. A. FORREST remarked that one wall of the old slave market of Liverpool was still standing.

The CHAIRMAN spoke in cordial approval of the competition and of its objects, and thought that the Association should assist the project by giving a prize.

Mr. R. CROWE proposed that the Association assign two of its presentation prints, properly mounted and framed, as a first prize for the best series of six prints of Liverpool, &c., and one such print, also mounted and framed, as a second prize.

Mr. ELLERBECK seconded the resolution, and it was carried unanimously.

Mr. H. A. WHARMBY gave notice that he should, at the next meeting, move the following addition to the rules:—"Each member shall send in to the Secretary, at or before the meeting following his election, his *carte* portrait for insertion in the Society's album."

Mr. O. R. GREEN gave an interesting account of his mode of collodionising and developing plates 24 × 18, and remarked that negatives taken by him with his large camera at Melrose, Furness, Conway, and other places, and varnished twenty-five years ago, were now just as bright and good as ever.

Mr. Forrest exhibited three views taken at Rivington, two at Tal-y-Cafn and one at Bidston at the last excursion; Mr. Baker, a clever instantaneous picture of *A Cat in the Act of Springing on a Bird;* Mr. Day, some very fine negatives of Carnarvon and Amlwch Coast, with prints; Mr Wharmby, views at Sefton, Walton, and Bidston; and Messrs. Hartley Watts, and Haworth, some prints from their negatives taken at Condover Pitchford, and Wenlock.

The meeting was then adjourned.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE usual monthly summer excursion of this Society took place on Friday the 29th August. Amongst those present were Mr. T. Davey (President), Colonel Playfair (Vice-President), and Mr. H. A. H. Daniel (Hon. Secretary). The locality fixed upon comprised the very romantic districts of Moorend and Glen Froom, and that portion of the latter beautiful scenery enclosed in the grounds of Mr. Vassall the Association was permitted access to by the courteous permission of the proprietor.

Leaving Clifton Down Station and St. Philip's by Midland trains about eleven o'clock, the party found on arrival at Fishponds that the thoughtful care of the worthy Secretary had provided ample accommodation in the shape of horseflesh and carriages, and a short drive landed them at the new country residence of Mr. Daniel, who, though having moved thereto but a very short time previously, had evidently managed to get "fixed up," to use an Americanism, as though he had been settled there for years.

After an inspection of the house and grounds, at which admiration was expressed, a very substantial and delicious luncheon was sat down to, and very ample justice done to it. Then followed the start for work; and, as a matter of course, the weather, which for many weeks had been unintermittingly fine, at once began to storm at the little party. Nothing daunted, however, and with the shelter afforded by focussing-cloths and other impromptu devices, the Old Mill at Moorend was reached without mishap, unless the minor accident of the Vice-President having nearly swallowed a live wasp, and the Secretary finding himself minus a vital part of his camera stand, might be considered to be mishaps.

At the Old Mill a rush was made to the blacksmith's forge for shelter, which, fortunately, was not required for long.

Here a long and patient halt was made, for the wind it blew and the leaves they shivered. However, at last a few "shots" were made despite the movement of the foliage, and a move made for Frenchay and Glen Froom, distant about two miles. Near the entrance to Oldbury Court Park, but on the wrong side of the river, stood a very enchanting-looking cottage. All agreed that it might make a good picture, so a formal request was made to the lady in charge that we might be permitted to carry away her house, photographically speaking. The seductive wiles and insinuating arts of our Vice-President overcame any scruples which the lady in question might have had to allowing so many strangers to enter her garden gates, and a descent was made. Disappointment, however, was the result, as, in trying to secure a point of vantage for fixing the cameras, it was found an impossibility to get a view without standing up to one's waistcoat in the middle of the river. Fathers of families being in a majority, it was not felt desirable to incur the obvious risks of such a proceeding.

From thence the members proceeded to the private grounds of Mr. Vassall, than which nothing can be prettier in their way. Here in fine weather, and with better light than favoured the party, there is ample store for a good day's work; but time was passing and light was waning, so the word was given to march onwards. Still further down the beautiful dingle, replete with pretty bits, old mills, rustic bridges, weirs, and little attenuated waterfalls, foliage of a most luxuriant nature, and all those little scenes which gladden the eye of the artist, on and on they wandered, hastening to meet the carriages which were to convey the party once more to our hospitable Secretary's tea table.

Then ensued the usual and very acceptable wind-up of these and similar delightful excursions—tea and coffee, and the other solids, and the other fluids, such as teetotallers would never think of mentioning—no, never (the fluids, we mean)! And then—great climax of all, and which so materially added to the universal pleasure—was the fact of the amiable and charming wife of our Secretary herself presiding at the table. Never was there a pleasanter gathering, even if the result in pictures was, perhaps, not quite so good as upon some previous occasions.

Correspondence.

ENLARGEMENT FOR AMATEURS.

To the EDITORS.

GENTLEMEN,—I should much like to compare notes with the writer in last week's Journal of an article entitled *Enlargement for Amateurs.*

I am one of (I dare say) a large number of amateurs who failed to realise the splendid results forecast by the inventor of gelatino-bromide paper. I gave it, as I thought, a patient and fair trial, but did not get any satisfactory results. Of course this was, to a large extent, my own fault.

The whole question has again been brought before my attention in the article written by your correspondent, Mr. H. N. Atkins; and as it is my

serious intention, during the present season, to give it another patient trial, I will at once ask his assistance to help me to solve those technical difficulties which seem to have so effectively disappeared under his skilful and patient manipulations.—I am, yours, &c.,
Cheadle Hulme, September 27, 1884. H. Victor Macdona, M.A.

SENSITOMETERS AND PHOSPHORESCENT TABLETS.

To the Editors.

Gentlemen,—Will you kindly inform me if the sulphide of calcium phosphorescent tablet is a reliable source of illumination for sensitometer purposes? I know it is used by Mr. Warnerke, but I wish to employ it with a form of sensitometer of my own construction, and simply for my own purposes—not as a standard.

Would you also please tell me how the tablets are made—that is to say, how the phosphorescent powder is spread evenly upon glass?—I am, yours, &c., C. Saunders.
September 30, 1884.

[See an article in another column.—Eds.]

THE ROYAL ARMS.

To the Editors.

Gentlemen,—There was an explosion at Bow on September 20th, and Colonel Majendie, Her Majesty's Chief Inspector of Explosives, from the Home Office, sent for me, and requested me to take a photograph of the house damaged by the explosion. I did so, and supplied him with four copies, 12×10. He forbade me selling a copy except through him.

Now, gentlemen, my question is this—Can I in future use the royal arms in my photographic business?—I am, yours, &c., Royal Arms.
September 29, 1884.

EXHIBITION OF THE PHOTOGRAPHIC SOCIETY OF IRELAND.

To the Editors.

Gentlemen,—Permit me, through the medium of your columns, to remind those who purpose sending pictures, &c., for exhibition, and who have not already intimated their intention of so doing, that the last day for receiving will be Friday, the 31st instant.

The form of entry, of which I will be happy to supply copies, should be returned to me *here*, and the packing-cases addressed to care of Royal Hibernian Academy, Abbey-street, Dublin.

I may also mention that there is no charge for space. Carriage of all parcels for exhibition will be defrayed by the Society, consignees paying that on return.—I am, yours, &c., Greenwood Pim,
Monkstown, County Dublin, *Hon. Sec., Exhibition Committee.*
October 1, 1884.

A CORRECTION.

To the Editors.

Gentlemen,—I find that in describing (last week) the process of making negatives for enlargements on argentic bromide paper, I have inadvertently used the word "negative" instead of "*transparency*" in two or three places. Kindly permit me to point out the inaccuracy, which may have puzzled anyone interested in the matter.—I am, yours, &c.,
Liverpool, October 1, 1884. H. Norwood Atkins.

"EDWARDS'S MACHINE FOR COATING PLATES."

To the Editors.

Gentlemen,—Mr. B. J. Edwards has now had the opportunity in two issues of your Journal of refuting the charge brought against him by me, that he had taken out a patent for machinery already in general use, and intended to secure remuneration by granting licenses for the same. He has utterly failed Only one excuse finds utterance from him. The machine had not been used for coating dry plates, but its existence and daily use he does not attempt to deny. It is worse than childish to assert that a man can patent existing machinery if he find a use to which it has not hitherto been put.

My original statements have been fully confirmed by independent evidence, and the conclusion stands thus:—*a.* Mr. Edwards's patent is of doubtful validity *b.* It is scarcely likely that large sums will be paid for its use. *c.* This is not his first offence; *vide* "Edwards's patent grooved box."

May I be permitted to assure Mr. Edwards that no attempts to divert attention from the above sole points at issue will be successful. He will find me perfectly pachydermatous as to any endeavours to injure my business by remarks about imperfections of what I manufacture. All such words will be recognised at once as the result of the total defeat he has so needlessly brought on himself.—I am, yours, &c., Samuel Fry.
September 23, 1884.

Notes and Queries.

J. B. asks—"What is a good formula for developing tannin dry plates for transparencies?"——We reply: The following will answer well:—Pyrogallic acid, four grains; citric acid, three grains; water, two ounces. Add to an ounce of this about two drops of a fifteen-grain solution of nitrate of silver just previous to pouring the developer upon the plate.

Inquirer asks—"Can you inform me if Sprague's ink-photo. process is protected by patent?"——In reply: It is worked as a secret process, and hence no patent exists.

We have received certain inquiries from "Lens" respecting lenses, the rapidity of various classes, and their adaptability for certain purposes. We must decline answering the questions of our correspondent, as it would be very invidious to do so; but we feel quite at liberty to say that there is not a great deal of difference between the whole group of the rapid *genus* of lenses named by him, and it might probably be a long time ere he could discover any difference at all.

Edgardo writes:—"In your issue of September 19th Mr. E. H. Farmer contributes an ably-written article on *Tourists' Cameras, &c.*, and gives his idea of a portable stand. It may interest him and others to know that a stand somewhat similar to the one he describes, with the advantage of freedom of rust, may be obtained from Messrs. Newton and Co., of Liverpool, who, I understand, hold a patent for the same. It packs into a small leather case, and is supported like an opera-glass by a strap from the shoulders."

Felix writes:—"I am making cabinet-size photographs on ferrotype plates. Would you kindly inform me in your *Notes and Queries* if there are any means of obtaining another tint than the greyish one?"——In reply: There are no means known by which a purer white can be obtained than by the employment of a developer containing nitrate of iron. This may be secured by the mixture of nitrate of lead and protosulphate of iron, the precipitated sulphate of lead being filtered out. Nitrate of potash added to the protosulphate of iron will produce a good white, especially if a small proportion of nitric acid be added.

"Can you furnish me with formulæ for photolithographic transfers? I have prepared several but find a difficulty in getting the gelatine to leave the paper. My process and *modus operandi* have been as follow:—

Nelson's gelatine	30 grains.
Bichromate of potassium	25 ,,
Water	1 ounce.

I use strongly-sized paper, which I float on the above solution, dry, and print for the image; then ink with usual transfer ink, float face upward on hot water (say 180° F.), and with a sponge rub lightly to remove unaltered gelatine. I find the friction necessary to do this breaks away the fine lines, while the constant rubbing about of the ink blocks up closely-shaded parts. Any hints which may help me out of my difficulty will be most thankfully received by—Antipodean."——In reply:—It seems probable that the transfer ink employed is unsuitable. If it were made thinner it would possibly answer better. Let our correspondent try the following by way of a change:—Coat the paper with bichromatised albumen, and, after exposure, ink by pressing it in contact with an inked stone. Now develope in cold water by aid of a soft camel's-hair brush. We have taken it for granted that a proper negative, absolutely opaque in the lights, has been employed.

Exchange Column.

No charge is made for inserting these announcements; but in no case do we insert any article merely offered for sale, *that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a* nom de plume *be thought desirable), otherwise the notice will not appear.*

Wanted, a portable half-plate camera and stand, in exchange for a first-class fifty-two-inch bicycle.—Address, W. Kenyon, 39, Mersey-street, Liverpool.

I will exchange a mahogany 5 × 4 camera, two single slides, for good accessories or background (interior).—Address, Malins, Crosswood, Aberystwith.

I will exchange a pony carriage, in good condition, for the electric light, or any other light suitable for photographing by night.—Address, F. Cole, 378, Euston-road, London.

I will exchange two gas bags, 30×24×12 and 22×17×15 (new), safety jet, pressure boards, and tubing. What offers?—Address, J. Brown, 44, Melville-place, Myrtle-street, Liverpool.

I will exchange Letts's *Popular Atlas*, value 42s., for photographic apparatus suitable for dry-plate work.—Address, Atlas, care of Mr. Fulver, stationer, &c., East-street, Chichester.

I will exchange an excellent half-plate French lens, nearly new, cost £5, for backgrounds in good condition and of equal value.—Address, Manager, Midland Studio, Harborne, Staffordshire.

Wanted, a good cabinet lens in exchange for a 10 × 8 burnisher and No. 1 *carte* lens, Dallmeyer's *carte* cameo press, background, &c., or cash.—Address, P. Bermingham, 151, Dale-street, Liverpool.

I will exchange a long-focus cabinet, a whole-plate lens, and a quarter-plate camera, for a short-focus whole-plate portrait lens and whole-plate bellows-body camera; difference adjusted.—Address, John Roper, 16, Hawk-street, Burnley.

I will exchange (all good) Squire's half-plate portrait lens, Grubb's half-plate view lens, Germaine's quick-acting quarter-plate portrait lens, Rouch's 10 × 8 folding camera, and half-plate camera, for anything useful in photography, or gold chain.—Address, Fritz Camera, photographer, 41, High-street, Sydenham.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

Photographs Registered.—

John Edmund Cracknell, 6, Wightman's-terrace, Hornsey.—*Photograph of Autographs.*

John Henry Smelt, 16, Arwenack-street, Falmouth. — *Photograph of Yacht, Mignon's Boat, taken at Falmouth.*

S. Sidey.—Received. Thanks.

Canary Medium. — Apply to Messrs. G. D. Scorah and Co., Leeds-road, Bradford.

M. Morelli.—Apply to MM. Attout-Tailfer and Clayton, 18, Rue des Cordelieres, Paris.

Arctic.—We have heard repeatedly of the bleaching of yellow glass by exposure to light, but cannot say much with respect to it from personal experience.

T. C. K.—The defects do not appear to be due to any faults in camera or slides, but rather to faulty plates. Without more data it would be impossible to hazard any further guess as to the cause.

W. G. M.—The yellow precipitate is not, as you suggest, ferrous oxalate, for whence could the oxalic acid be derived? It consists of a basic ferric sulphate, and from our own experience we fear you cannot mend matters much.

J. I. A.—Avoid acid gum or acid paste for mounting the prints, as it will hopelessly ruin them. Acetic acid is an admirable thing to mix with gum for many purposes, but not for the mounting of silver prints. Make use of freshly-prepared starch.

Distemper.—1. If grey prove too light, probably a light sage green or similar colour would suit you.—2. The portraits have appeared monthly since the commencement of the present year. The numbers are all obtainable, but not the pictures separately.

L. W. J.—1. It is now too late to make application for space in connection with the Photographic Exhibition, which is to be opened to the members tomorrow, and to the public on Monday.—2. Willesden paper will answer quite well for dishes and trays for the purpose mentioned.

Geo. Henston.—The camera is patented, but it does not follow that the mere payment of patent fees will establish patent rights. In this case, however, we should be sorry to counsel you to throw money away in contesting the rights. There *are*, as you say, "patents *and* patents."

W. B. S.—The negatives sent are not by any means perfect. Certain thin portions towards the margins indicate that the developer has not been applied equally, but apart from this the focussing has been very badly done. Again, it does not look well to see the horizon of a view brought up to nearly the top of the plate.

George Ross.—Your pictures have not been fixed properly. An immersion in hyposulphite of soda solution for two minutes is totally inadequate to effect the removal of all the soluble salts of silver. It is quite impossible that you can have paid any attention to the instructions given in the manual you profess to have studied.

J. T. Anderton.—The blisters you complain of are really an incipient form of frilling, and are frequently caused by using the fixing-bath of too great strength. Use one part of saturated hypo. to three parts of water. When the blisters do appear they may be got rid of by flooding the plate, while still wet, with methylated alcohol.

Alpha.—1. The formula explicitly gives all the constituents in *parts*; if, therefore, you take 200 ounces of ether and alcohol the cotton and iodides must also be in ounces.—2. The stain should be sufficient to produce a moderately-tinted film.—3. We presume the collodion will work with the acid bath, but are not aware of its having been tried.

W. H. Wilson.—The prolongation of boiling appears to have comparatively little influence in producing a high degree of sensitiveness if the emulsion be not properly mixed. The mixing of the ingredients should be performed at as high a temperature as possible—at boiling heat if that can be managed; then but a few minutes' subsequent cooking will suffice.

P. H.—The illustration did not appear in this Journal nor, we believe, in any existing English publication. The name you mention is a strange one to us, and the paper must be either one long dead or else has a glorious future before it as an unattempted project. In either case you have been misinformed, as the picture really appeared in a second-class American publication.

S. F. Jones.—It is not wise in you to arrive at an inimical conclusion respecting any process because vile productions are the result of its practice by some individual who, for all we know, is not competent to secure such good features as may intrinsically belong to that process. We all know very well that some of the most charming photographs the world has seen have been made by wet collodion; and well indeed do we and every one else know that negatives which are truly execrable have also resulted from the same process.

Raven.—The yellow deposit is ferrous oxalate, formed in consequence of there being an insufficient quantity of potassic oxalate to hold it in solution. The separate solutions are of proper strength; but if, as we understand from your letter, you employ one part of oxalate of potash to three parts of iron your trouble is easily explained. The proportions should be reversed, namely, three parts of oxalate to one of iron solution; indeed it is better, in a general way, to use four parts of oxalate to one of iron. If you observe these proportions and pour the iron solution into the oxalate, instead of *vice versâ*, you will have no deposit and no necessity for filtration.

Argal.—1. The exact quantity of silver nitrate required would be a fraction over 236 grains, but a little less than this quantity should be employed—say 230 grains.—2. In the dark room.—3. Whichever is most convenient.—4. Like the rest of the operations—in the dark room, of course.—5. If formed separately the chloride and citrate should certainly be washed separately.—6. The plates will keep for a few weeks, but not indefinitely.—7. The plates may be developed with a well-restrained developing solution, but do not behave well with the ordinary developer.—8. Thanks for pointing out the error in punctuation, which had hitherto escaped our notice. The position of the stop is obviously after "suffices."

Received.—Edward Dunmore; J. T. Robinson; "Hypo.;" "S. E. K." In our next.

Photographic Club.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 8th inst., the subject for discussion will be *On Artificial Lighting.*

The Cundall Phototintographs.—Under this designation Mr. James A. Cundall, of New Brighton, near Birkenhead, has devised a system of colouring photographs, examples of which he has submitted for our examination. The style is bold, yet effective, and photographs tinted in this manner will not fail to please many.

A New Photographic Association.—A Photographic Section has been formed within the Literary Club, Blackburn, Lancashire, open to all members of the Club, many of whom revel in the "dark deeds" of photography. During the winter four meetings will be held at the Club for discussion of subjects connected with the art as follow:—October 20, at 8.30 p.m., *Lantern Slides;* November 24, *Plate Making;* January 19, 1885, *Development;* February 23, *Intensification and Reduction, &c, of Negatives.* Two entertainments will also be given in the lecture room to members and their friends—one an exhibition of lantern slides on the 19th of December, and the other an exhibition of prints on the 17th of April next. During the summer it is intended to have a series of monthly excursions with cameras, due notice of which will be given. The Hon. Secretary would be glad to arrange, if possible, to meet other societies in the district on some of these excursions. All communications should be addressed to the Hon. Secretary, Photographic Section of the Literary Club, Blackburn.

Astronomical Photography.—M. Mouchez, the Director of the Observatory of Paris, has communicated to the Academy of Sciences a brief account of some experimental attempts to photograph very small stars, which have been lately made at that establishment. The ecliptical star-charts, commenced by Chacornac, but interrupted in their formation by his decease, were taken up by MM. Paul and Prosper Henry in 1872. These charts include all stars to the thirteenth magnitude. Thirty-six of the entire number of seventy-two required for the whole ecliptical zone were completed by Chacornac. These contain 60,000 stars; while sixteen more, containing 36,000 stars, have been constructed by MM. Henry, who will shortly finish four others, with 15,000 stars. But they now find themselves in face of a difficulty which can hardly be overcome by the ordinary process of charting. The condensation of stars in those regions where the Galaxy traverses the ecliptic is so great as apparently to defy an accurate and complete representation of their stellar contents, on the methods adopted for the greater part of the zone, notwithstanding all the experience and well-known skill of the observers. They have accordingly had recourse to photography, and their first attempts with a provisional apparatus have succeeded so well that there is every reason to expect by this means a solution of the difficulty in question. On plates covering an extent of 3° in right ascension and 2° in declination, obtained with an objective of 0·16 m. diameter and 2·10 m. focal distance, achromatised for the chemical rays—which M. Mouchez exhibited to the Academy—there are shown some 1,500 stars from the sixth to the twelfth magnitude; that is, to the limit of visibility of an objective of that size. The images of the stars have diameters nearly proportional to their brightness, except in the case of the yellow stars, which come out somewhat fainter. These encouraging results have led MM. Henry to commence the construction of a large objective of 0·34 m. diameter, which will be mounted by M. Gautier, and it is anticipated that with this instrument, in the course of an hour, a chart of the stars, to the twelfth magnitude at least, and probably to the thirteenth or fourteenth, of the same dimensions as one of the published charts will be obtained—a work which would otherwise require many months of assiduous labour.—*Nature.*

CONTENTS.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1275. Vol. XXXI.—OCTOBER 10, 1884.

OUR FORTHCOMING ALMANAC.

The time has arrived when it becomes our duty to remind our readers that the ALMANAC for 1885 is in course of preparation, and that we shall be glad to receive contributions from the numerous friends who have assisted us in former years, as well as from any volunteers who may join the ranks.

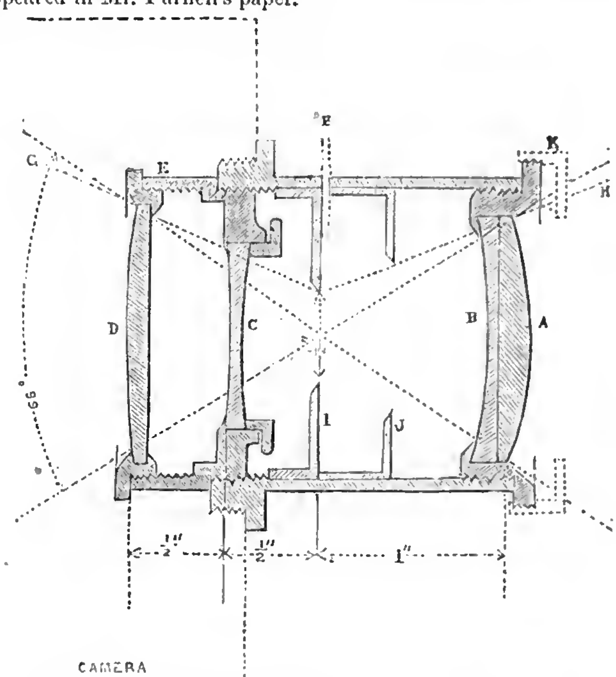
The year has been one of considerable activity from a working point of view, and much has been done and published in connection with the experimental phases of photography. But there must remain a vast amount of unpublished experience which the ALMANAC forms a convenient medium for placing before photographers in all parts of the world. We trust, therefore, that all who may have gained any new knowledge, either in the direction of improved modes of working or of difficulties overcome, will assist us in rendering the forthcoming volume a thoroughly useful one.

In order to enable us to issue the ALMANAC, as in previous years, before Christmas, it is necessary that all matter be in our hands as early as possible. We shall, therefore, esteem it a further favour if contributors will add to the obligations under which they place us by sending in their communications during the present and the early portion of next month.

HOME-MADE LENSES.

The paper which was read by Mr. William Ackland before the South London Photographic Society at its last meeting, and the side issues which arose out of it in the course of the discussion, cannot fail of proving exceedingly useful. Photographers who would not hesitate to set at immediate defiance every recognised canon of chemistry in the hope of improving their emulsions, or just seeing to what their experiments would lead, or what effect would be produced by such experiments, entertain a species of superstitious horror at touching their lenses, the makers of which have issued strong injunctions against their being "tampered" with.

Mr. Ackland's paper was on the lens introduced and advocated by Mr. Thomas Furnell in an article communicated to THE BRITISH JOURNAL OF PHOTOGRAPHY of April 27th, 1883, and the invention (if such a term be allowed) has, it appears, been lying almost *perdu* up to the present time. In order that our observations may be the better understood we here insert the drawing and description which appeared in Mr. Furnell's paper.



A, crown glass, plano-convex, 1·82-inch radius. B, Flint glass, plano-concave, 2·75-inch radius. C, Flint glass, double-concave, 30 and 30 inches radius. D, Crown glass, plano-convex, 7·80-inch radius, or equal to 15 inches focal length. E, Separate portion of mount. F, Slot for loose diaphragms. I, Fixed stop. J, A second fixed stop or diaphragm simply slipped into the tube, and arranged to cut the line G H. K, Hood, with a rectangular opening in front of 1¼ × 1¼ inch, to admit only sufficient light to cover the plate.

In what we have now to say of the Furnell lens it will only be an act of justice to other workers who have gone before to state that in employing this distinctive appellation we do so as a mere matter of convenience, because, as we shall show, combinations bearing remarkable similarity to it have been known previous to the publication of Mr. Furnell's paper.

When a meniscus, or plano-concave, achromatic lens is employed as a landscape objective in the usual way, two things will be observed:—Architectural subjects, in which the lines are straight, have these represented in a slightly-curved manner, the curvature increasing according to the distance from the centre of the picture; and, secondly, that in proportion as the external curvatures of a meniscus lens are deep, so does its power of sharply covering a large field increase—at the expense, however, of a smaller stop being employed and in a position nearer to the lens than if it were a plano-convex.

In the Furnell lens the front achromatic may be said to be the element by which the image is formed, the two back lenses—that is, the concave and the plano-convex, situated at the inner end of the tube—having for their functions the flattening of the field and curing the distortion, without necessarily possessing magnifying power in themselves as a whole, thus leaving the focus of the achromatic front lens nearly undisturbed.

The idea of effecting a cure of the distortion produced through a single combination by the addition of an extra lens, or pair of lenses, without alteration of the focus is a happy one; but it has also occurred to other opticians. So long ago as 1858 the late Mr. James T. Goddard, *apropos* of having observed the aberration of the rays from the flame of a candle a little way out from the axis of the lens, inquires:—"Can we not devise a back lens that, without altering the mean focus, shall yet be able to rectify all this confusion out of the axis?" He then proceeds to describe the means he employed for effecting this rectification:—

"For this purpose I worked a plano-convex plate glass lens on the six-inch tool, and a plano-concave lens of plate glass on the six-inch concave, so that their effect, when the curved pieces of glass were together, was exactly similar to a plain glass; but when the convex side was placed towards the ground glass screen and the concave side of the plano-concave was towards its flat side, and this pair of lenses was held a little behind the achromatic meniscus, the effect was to remedy to a considerable extent the confusion of the oblique image without altering the mean focus, merely leaving, however, a good deal of uncorrected aberration. Further: it was shown that separating the back pair from the front cemented achromatic considerably flattens the field."

In the course of subsequent experiments the forms of both these correcting lenses were altered to a considerable extent. For example, the plano-concave lens was made double concave, and the plano-convex lens was replaced by others—both of a meniscus and also of a bi-convex form. By the law of evolution a non-distorting triple lens was eventually produced out of these experiments. It will be seen that both the added elements of correction were formed of crown or plate glass.

As bearing somewhat intimately upon one of the advantages inherent in the Furnell lens—that of permitting its focus to be altered by the substitution of one element for another—we may here state that this, too, was provided for by Goddard, who, allowing the back lenses to remain undisturbed, had several front lenses of similar diameter, but different foci, adapted to work harmoniously with the back lenses.

Several years ago Mr. Howard Grubb suggested an addition of a similar character to the single achromatic lens. His corrector differed from that of Goddard to this extent—that he retained the achromatic lens in the position usually assigned to it, and placed the correcting lenses in the front of the tube in close proximity to the diaphragm. Mr. Grubb's correctors, also, were formed of plate or crown glass, being respectively plano-convex and plano-concave, the radii of curvature being also alike; hence there was no alteration of the focus of the principal lens. This additional front combination proves very convenient; because it not only corrects the distortion produced by the lens for which it may have been specially constructed, but it also effects the same end with others of different foci. Those who desire to try experiments in this direction may do so without incurring much expense, seeing that spectacle glasses of the requisite form and focus can be procured everywhere.

Attention is directed by Mr. Ackland to the fact that considerable latitude is permissible in the selection of additional lenses, the substitution of one for another effecting no sensible difference in the achromatic correction of the combination. This is a fact to which we have directed attention on several previous occasions. If the front lens of a combination be an achromatic of deep curvature, the back component of the objective may be either achromatised or simple without affecting its power of working sharply to focus. This property is exceedingly useful in all cases in which a variety of back lenses are to be employed in order to provide difference in the focus. We have one combination of this class to which we have adapted three back lenses of different foci, all single menisci of the simple form to which we have already alluded; and, while variety of focus is imparted to the objective in proportion to that of the individual back lens employed, in every instance the visual and chemical foci still coincide. When the lenses are flat this coincidence is not experienced in the same degree. We here refer to the employment of a meniscus lens for the purpose of forming a wide-angle doublet.

It is reassuring to hear from an optician of Mr. Ackland's skill that ordinary spectacle lenses will answer for both the concave and convex lenses in the Furnell objective, provided they are properly centered. This centering may be effected by cementing the lens with pitch to a wooden chuck in a small turning lathe and moving it a little from side to side while the pitch is still soft, until the image of a candle flame reflected from the lens ceases to "wobble" during rotation. Emery powder mixed with water, and applied by means of a piece of soft iron or copper plate, will speedily grind the edges true.

We are much pleased to see this subject brought prominently before the world by one who, like Mr. Ackland, has for so many years occupied a prominent position among the professional opticians of the metropolis, and we trust that it will not be allowed to drop.

ASTRONOMICAL PHOTOGRAPHY.

The merits of photography for astronomical purposes is being rather severely handled by the American astronomers, Professors S. P. Langley and C. A. Young having lately been writing in very desponding terms as to its use and capabilities. The former gentleman (who, as our readers are well aware, has devoted more time and made greater sacrifices of personal comfort than any living astronomer in carrying out observations, having in view the elucidation of the physical structure of the sun), had made his observations in almost inaccessible regions, and at heights where continual existence was almost impossible, and the mere attainment of which, apart from any observational work, was in the case of some of his assistants dangerous to life. His words must, therefore, be received as those of high authority, and will have a tendency to cause some disappointment in the minds of ardent disciples of our science, though a calm review of the situation will tend to show a brighter-coloured picture than he appears to give.

In the *Century* for September this gentleman began a series of articles on the "New Astronomy" of a highly interesting character, which may be read by all photographers who are versed in the higher scientific aspect of the art. In his contribution Professor Langley, while giving a fair meed of praise to the work done by photography, fails to allow it as extended a sphere of usefulness as might be hoped to belong to it. At the same time when we find him speaking, as he does in the October chapters, in such language as the following, there is, perhaps, not much need to fear for the future of photography in connection with exact science. He says, in describing his work in Spain, in 1870, and the preparation for it—"The camera can see far less of the corona (of the sun) than the man, *but it has no nerves* and what it sets down we may rely on." The very facts which he details may be used as an argument in favour of photographic observations; for his experience, founded on the remarkably and unsurpassably favourable atmospheric conditions that are obtained at his station in the Alleghanies, leads him to state that five minutes in twelve hours is about the average period during which correct observations can be made of the sun's surface, and that attempts made at other times to magnify the image would only lead to blurring.

His method of observation is very interesting. A piece of paper ruled into squares is placed like the ground glass of a camera to receive the image of the thirteen-inch equatorial, and the clock-work is then stopped. The time taken for the image of the sun to pass through one of the squares gives the scale of the drawing to be made. The clock is again set in motion, the telescope following the sun and keeping the image stationary upon the paper; then a tracing of the disc and any spots can be made, the finer details being, of course, invisible. The eyepiece is then removed and a polarising eyepiece substituted, thus diminishing the light sufficiently to enable the eye to examine the solar surface for hours together without injury, and so enable the details of the spots to be examined and the outline sketch to be filled in. Then comes the disparagement of photography. At this stage, the Professor says, the photograph will not show these details. It serves to give an outline of the markings, and places them accurately in their relative positions on the disc; but to see the intricate forms with which the black neutral space shown by the photograph is filled we must have recourse to the polarising eyepiece. Yet, notwithstanding the failures of photography, he has to observe that there is a tendency to exaggeration in drawing sun spots.

Professor Young adverts to a similar subject in his address to the American Association for the Advancement of Science. His name also carries great weight. For a moment he rouses expectations as to the good opinion he has of photographic aid; but he quickly ends by being more uncompromising than Professor Langley. He says:—"Photography comes continually more and more to the front, and the idea sometimes suggests itself that by-and-by the human eye will hardly be trusted any longer for observations of precision, but will be superseded by an honest, unprejudiced, and imaginative plate and camera. The time is not yet, however, most certainly. Indeed, it can never come at all as relates to certain observations, since the human eye and mind together integrate, so to speak, the impressions of many separate and selected moments into one general view, while the camera can only give a brutal copy of an unselected state of things with all its atmospheric and other imperfections."

Now, while admitting the weight of any dictum of Professor Young's, we would suggest that there is nothing in his remarks that logically supports his statements. If an artist were to depict a little-frequented street by painting in his one picture all the figures that passed down in a whole day, we apprehend that no one would perceive it as a truthful copy of the scene. Similarly with the sun and its changing surface: it can scarcely be right to place in one view a representation of a series of changes that may have occupied a day. But even were this a fair mode of representation there can scarcely be found in his remarks any indication that a series of photographs could not be taken so as to contain details of all the phenomena the telescope showed.

We may except the remark about atmospheric disturbances. A photograph occupying any appreciable length of time in its production is necessarily subject to imperfect definition, owing to the shifting of the image by the continual change in the atmospheric refraction brought about by heat. The extent to which these quiverings of the air must influence results may be judged of when, as we have learned from Professor Langley, the delicate features of the sun's surface are only distinctly visible during about the hundredth part of the time devoted to its observation, entirely owing to this tremulous effect of the air.

When, however, we have before us the wonderful photographs of the nebulæ in Orion taken by Mr. A. A. Common, and the various star pictures lately alluded to by us, and we see the extent that photography has been made use of by the astronomers in the very place where its fair merits are detracted from in the manner we have described, the photographer may take heart of grace and rest assured that real triumphs await the science in the future, and that its aid will be of the utmost value in scientific research.

We only venture to express a hope that this attempt to pull down photography from its high pedestal will not encourage those pseudo-prettinesses—the namby-pamby engravings of delicate effects founded on photographs which do not contain a tithe of what is represented as being produced by its aid. If we are to have engravings let us have engravings, and if photographs let us have photographs — not those absurdities by the side of which the smoothest and most vapid retouched photographs are pregnant with character and individuality.

THE PHOTOGRAPHIC EXHIBITION.

[First Notice.]

The annual Exhibition of the Photographic Society of Great Britain was inaugurated by the usual *conversazione* on Saturday evening last the 4th inst., and was opened to the general public on Monday morning. The *soirée* was, as usual, well attended, amongst the visitors being the Lord Mayor elect (Mr. Alderman Nottage) and his lady.

The judges this year were Messrs. William Bedford, W. F. Donkin, M.A., F.C.S., F.I.C., William England, J. E. Mayall, F.C.S., F.R.M.S., William Mayland, and Andrew Pringle; and the awards, which were made on Friday, are as follow:—Swiss Views (No. 23), Vittoria Sella; *Instantaneous Sea Studies*, (No. 43), W. P. Marsh; *The Mill Door* (No. 67—composition picture), H. P. Robinson; Platinotype Prints (Nos. 219-20-21), H. B. Berkeley; Interiors (Nos. 234-5), Alf. Tagliaferro; *Mother's Love* (No. 282), J. Hubbard; *Yachts* (No. 309), G. West and Son; *Portraits* (No. 387), Lafayette; Photo-engravings (Nos. 466 and 474), T. and R. Annan; Photomicrographs (No. 483), J. R. Dunlop; *Photographs of Lightning* (No. 485), M. Auty.

The Exhibition is a fairly good one, the average being perhaps higher than usual; but there is a noticeable absence of any specially good work. There are also surprisingly few specimens of so-called instantaneous pictures, the *furore* for that class of exhibit having apparently abated.

Commencing our annual "round" of the catalogue, we find first Mr. J. P. Gibson's frames of landscapes (Nos. 4-7), of which it is difficult to select the best. *On the Tyne at Bywell* and the *Blasted Oak Tree on the Allen* are equally deserving of praise.

Herr Hartmann Koch exhibits several landscapes and architectural subjects of large size, the landscapes being the best. A very curious effect is noticeable in *The Sea Alp* (No. 114): the reflections of the mountains and surrounding objects are well rendered in the lake, but in the immediate foreground it is difficult to decide whether the peculiar markings are supposed to be reflected clouds or merely stones and vegetation at the bottom of the shallow water.

The School of Military Engineering are fully up to their ordinary standard, if they do not pass it. Their Devonshire views—at Lynmouth and in the Lyn Valley—are amongst the best work we have seen of theirs in recent exhibitions, a view on the beach at Lynmouth being especially good.

Mr. Malcolm H. Clerk shows several very clever pieces of composition grouping, which remind us much of similar work by another

No. 13—*The Last Bit of Scandal*. By Malcolm H. Clerk

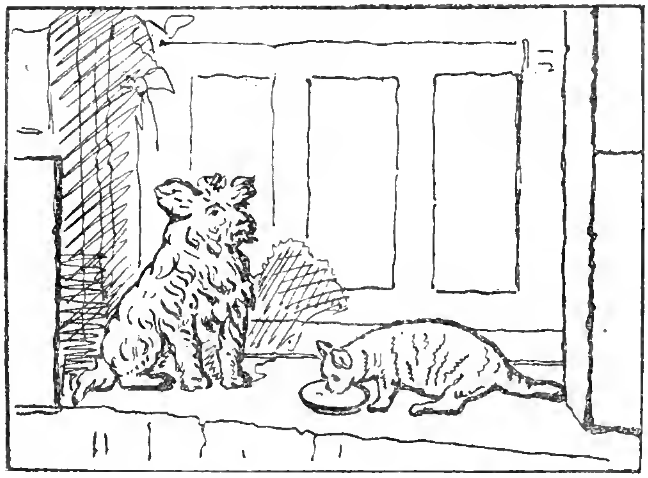
amateur, the late Mr. H. Cooper. One of these—*The Last Bit of Scandal* (No. 13)—we have selected for illustration.

The next exhibitor on the list is Mr. W. Cotesworth, whose *Awkward Lead* and *The Revoke* (No. 15) we hope to illustrate in a later issue. These are two of the cleverest compositions we have ever seen produced by photography; the conception and execution—to say nothing of the humour of these little pictures—are beyond praise. Mr. Cotesworth has also a *Last Bit of Scandal* (No. 441), which is worthy of equal commendation.

Mr. J. Harris Stone shows several pictures of large size—whether enlargements or direct is not stated. Whatever interest these may have for the archæologist they are scarcely up to the needful standard of a photographic exhibition. Most of them are hung so high that it is impossible to examine them minutely; they are, however, easily judged from a distance.

In frame No. 23 we have a fine collection of Swiss views, by Sig. Vittoria Sella, to which the judges have awarded a medal. These are bold and vigorous without hardness or excessive contrast, while, at the same time, there is all that could be desired in the matter of detail and softness.

Dog and Cat (No. 25), an enlargement from a negative, by Miss



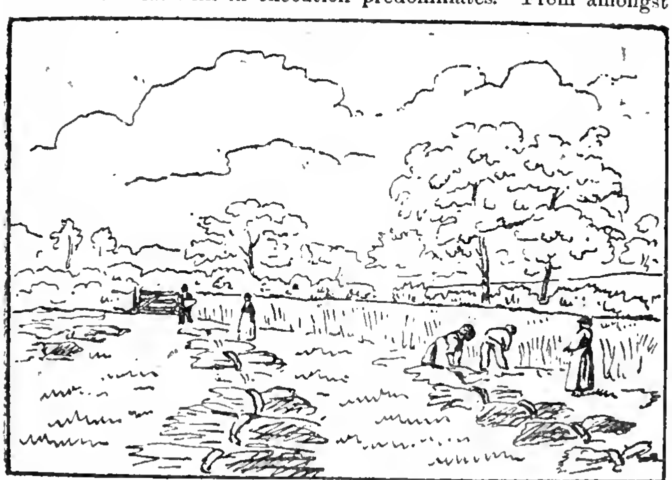
No. 25—*Dog and Cat.* By Miss E. M. ESWORTH

E. M. Cotesworth (a daughter, by the way, of Mr. W. Cotesworth, whose pictures we have just noticed), is a clever animal study, and a fine composition. We have selected it for illustration; but it is impossible in our sketch to convey the expression on the little terrier's face as he watches the disappearance of his food.

Mr. H. S. Mendelssohn is, as usual, well represented—this year n a somewhat new style of picture. Whatever may be the process by which his prints are made—platinotype or bromide paper, we have not examined them closely—the cold black tone in many cases is very pleasing; but in others it must be confessed the result is not so favourable. As regards the pose—all the exhibits being portraits—there is little else but praise to be given, though, in one or two instances, perhaps rather as a matter of taste, a modification might be suggested. We have chosen a portrait of *Mrs. Duppa* (No. 26) as an illustration of an elegant and happy pose.

No. 26—*Mrs. Duppa.* By H. S. Mendelssohn.

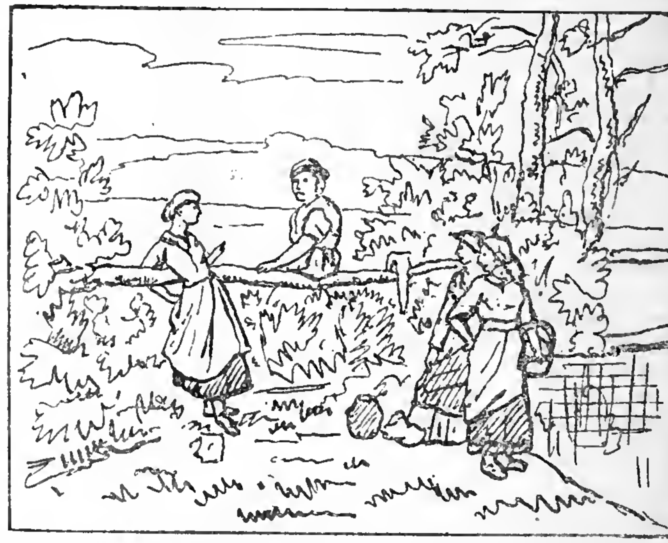
Mr. S. Norman shows several pictures in his well-known style—a style in which it is difficult to say whether artistic taste in selection or technical skill in execution predominates. From amongst



No. 44—*Studies of Corn Fields near Burgess Hill.* By S. Norman.

his *Studies of Corn Fields near Burgess Hill* (No. 44) we have selected one as a sample of composition.

Mr. H. P. Robinson receives again a well-deserved medal. His work this year is, we think, as a whole, better than in former years. *The Mill Door* (No. 67), to which the medal label is attached, is a very fine rendering of a subject which in itself possesses little pictorial interest. As presented to view by Mr. Robinson's camera we have, however, an unmistakably pictorial result. *The Cuckoo* (No. 64), *He Loves Me, He Loves Me Not* (No. 53), and *A Chat with the Miller* (No. 68), are also worthy of careful study; but we prefer, for general excellence, *He Never Told His Love* (No. 66), which is



No. 66—*He Never Told His Love.* By H. P. Robinson

selected for illustration. In this the grouping of the figures is very cleverly managed; but the charm of the picture, which cannot be reproduced in our rough sketch, lies in the expression of the various faces. This, we believe, is Mr. Robinson's seventy-first medal.

We shall resume our notice of the pictures next week, meanwhile we pass on to a preliminary review of the apparatus.

APPARATUS.

The collection of apparatus at the Exhibition is large, much of it somewhat unique, the design, fittings, and finish, as a whole, are unexceptionable, and the entire display is being very critically examined, apparently with discrimination and interest. We commence by giving a synopsis of the collection, to be followed by fuller notices in detail.

A 15 × 12 camera with others of smaller dimensions are contributed by Messrs. Watson and Son, who also exhibit instantaneous shutters of various descriptions.—Tourist and other portable cameras, with slides and an alpenstock stand, are exhibited by Messrs. J. L. Lane and Sons.

Messrs. Sands and Hunter have also a good show of cameras, including three of whole-plate sizes, possessing various peculiarities of mechanical construction; they also exhibit cameras of half-plate size, instantaneous shutters of several descriptions, a camping lamp, and an improved plate book.—One of the patent automatic changing camera-backs of Mr. Thomas Samuels (of which an account was published last year) is exhibited by the inventor, who also contributes packing-boxes for sensitive plates and a half-plate changing-back.—A combined camera, changing-box, and plate-box is exhibited by Mr. Herbert S. Starnes.

The London Stereoscopic Company have sent four cameras—whole, half- and quarter-plate, together with a "*multum in parvo*" half-plate set.—The "*vade mecum*" camera, with two double dark slides, and an instantaneous shutter, owe their presence to the Photographic Artists' Co-operative Supply Association.

The newly-patented "compactum" shutter of Mr. S. W. Rouch finds a place among the other exhibits of Messrs. W. W. Rouch and Co., which consist of their whole-plate patent camera with reversing frame, and the "special correspondent" set, for use on horseback.

Messrs. J. F. Shew and Co. are the largest exhibitors of apparatus in the Exhibition. They contribute about a dozen cameras, each differing in some respect from the other; camera stands of a variety of forms; two kinds of exposing shutter; a folding changing-box; reversing tops for camera stands; the Godstone washing-tray, and an adapter for a camera—a combination readily converting a camera into one of larger size.

Mr. Warnerke affords the visitors an opportunity of examining some Russian productions, consisting of two cameras invented by Professor Ezutchewsky, and made by Klatchko, of Moscow, containing respectively twelve and sixteen plates, which may be brought into the proper position for exposure in rotation in the open daylight.

Messrs. Marion and Co. show their patent new syphon plate washer, a miniature camera, and a camera with Cadett's new pneumatic shutter.—Mr. Cadett himself also exhibits his shutter.—Several specimens of the Phœnix instantaneous shutter of Messrs. Reynolds and Branson are contributed; an adjustable instantaneous shutter by Mr. Thomas Furnell; and two shutters (one a "drop" and the other a "spring") by Mr. T. J. Smith.—A patent "simplex" slide and reversible camera-back are exhibited by Mr. A. G. Hopkins, and a developing-dish by Mr. Andrew Pringle.

In addition to the foregoing there are also pieces of apparatus connected with the lantern, such as Beard's universal self-centering slide-carrier.

As on a previous occasion, we shall describe these in detail, with illustrations where required.

The wave of opinion in favour of yellow light for dark-room illumination appears to be spreading on the continent, as it certainly has to a great extent in America. In the present number of Liesegang's *Photographisches Archiv* the editor states that he has adopted it in his developing-room with great comfort to himself. He says that he finds two thicknesses of golden fabric sufficient, and speaks in high terms of the quantity of light transmitted and the freedom from veil of the negatives developed under this light. For preparing emulsion plates, however, he still considers a ruby light necessary; but it is possible that if he had tried additional thicknesses of the "fabric" he should have found, as some of our English workers state, that the resulting yellow light is at least as safe as a ruby giving the same amount of light by which to work.

From the same number of the *Photographisches Archiv* we cull the following story:—An American gentleman found the prolonged absence of his wife, who was on a visit to her parents, become tedious. He, therefore, had a photograph of his house taken with the wife of a neighbour sitting in the verandah, engaged in conversation with him. The picture being sent to the absent spouse she returned by the next train.

It must, we almost think, have been a photographer who spoiled the Liebig memorial statue at Munich. It was covered over with spots and stripes, and a close examination revealed the fact that silver and manganese had been the agents employed to produce the defacement—probably in the form of nitrate of silver and permanganite of potash. Photographic experiences, however, were made use of in rendering the statue white again. The metals were converted into sulphides by means of sulphide of ammonium, which, as it could not be applied for a sufficiently long time in the liquid form, was mixed with kaolin and placed in contact with the stains for twenty-four hours, after which it was removed and replaced by a fresh supply—also allowed to remain for a day—and then carefully washed. The next step was to remove the sulphide by dissolving in cyanide. This also was done by the aid of kaolin, which was used as a sponge, so to speak, to hold the cyanide. The effect was perfect; all but a few stains were removed, and these few were finally got rid of by a further similar treatment.

There seems to be some disagreement about the appearance of the new comet. Mr. Denning, writing from Bristol, says that it is by no means a conspicuous object; while Lieut-Col. Tupman writes from Harrow, on the same date, that it is a rather bright telescopic comet, capable of being just seen with a binocular. Dr. C. Zelbr, of the Imperial Observatory, Vienna, has been calculating its elements, and finds that it is slowly approaching both the sun and the earth, and consequently increasing in theoretical brightness. About the twenty-fourth of November is the estimated time of perihelion passage, at which period it will be about half as far again from the sun as the earth is. It is now about equidistant from sun and earth, and will slowly approach the earth till towards the end of the month.

The *Athenæum* states that the celebrated Austrian traveller, Mor Déchy, has during the past summer made an extensive journey in the Caucasus, with the combined object of photography and mountain exploration. He had an August of unprecedentedly bad weather, but managed, nevertheless, to obtain upwards of two hundred photographs, which it is hoped may be exhibited at the annual meeting of the Alpine Club next month.

Photography is to the fore also in Major Serpa Pinto's expedition, who is reported to be leaving Mozambique for the Nyassa lake, Tanganyika, and the Upper Congo. His expeditionary force consists of two hundred and fifty carriers and a hundred armed men. A lieutenant of the Portugese army and an English photographer are attached to it. We may expect that this region, about which such extravagant fables were uttered by the old historians, will yield a vast crop of subjects of the most interesting character. Photography destroys some wonderful romancing, though it substitutes its own share of marvels.

With regard to the suggestion to attach the camera screw to the tripod top, so as to ensure its always being at hand when required, Mr. G. Watmough Webster informs us that he can bear testimony to its usefulness, after having had the method in use for nearly two years, the suggestion of the means for doing this having been made by Mr. J. Leigh, of Manchester, who had had it in use for a considerable length of time. Mr. Watmough Webster adopted the method with a Rouch tripod by removing the brass ring against which the screw works and substituting a fresh one tapped so as to fit it. A considerable portion of the thread of the screw from the part nearest the handle was then filed away, so as to allow it to work free when screwing into the camera. When unscrewing it after use, the moment the camera was loosened no further turns were needed, and the screw was left fitting loosely and unable to become disengaged within the central aperture of the tripod head. It will, perhaps, scarcely need remarking that, in case of more cameras than one being in use, either all would have to be adapted with female screws of a similar size and pitch, or the advantages of the method—namely, the assurance of the constant presence of the screw with the tripod—would be lost.

The remarkable sunset glows—such a prominent subject of interest last autumn—are again making their appearance, and from all quarters come accounts of the phenomena and their beautiful tints. The most generally received theory, as our readers are aware, ascribes the strange appearances to the effects of the eruption of Krakatoa last year, the dust ejected from the volcano being supposed still to remain suspended in the air. The same explanation was given by M. Cornu, in a paper read before the French Academy, to account for the corona now visible round the sun, and the variations in its form and colour. His paper gave also a method of increasing its luminosity and photometric observations upon its light.

Apropos of photometers: the *Journal of the Russian Chemical and Physical Society* contains an account of a new instrument for schools, devised by Professor Petronshevky, an adaptation of which might possibly be useful to photographers. This new photometer allows the amount of light received by books, paper, &c., on the desks of the scholars to be accurately and quickly measured. Such an instrument should be of considerable use for many purposes, if its simplicity and accuracy are correctly reported.

Some of the photographs exhibited at the Canadian meeting of the British Association are, perhaps, the most remarkable ever taken. Amongst these, in particular, may be mentioned those by Professors Liveing and Dewar of the spectra of explosions. They were made in an iron tube with quartz ends, and, it may be thought, must have had great elements of personal danger in them.

DIFFICULTIES IN AMATEUR PORTRAITURE.

It is all very well to advise the amateur photographer to "stick to landscape work and to leave portraiture alone." He must possess a great deal of determination if he can adhere to the resolution which he may make in accordance with the advice.

Apart from the natural attraction of portraiture—of working on a human subject which will have an interest in the result—there is the importunity of friends. Why that importunity should exist has always been a mystery to me, seeing how far short the portrait of the most skilful amateur must fall compared with that produced by a professional, who has a studio at his command and is a good retoucher, or employs a retoucher—unless, indeed, the sordid consideration of the saving of money has something to do with the matter.

However, the fact remains that the friends of the amateur will solicit him "to take likenesses of them." There is something a little cool in the request if we take into consideration the expense in both money and time involved in exposing (say) three or four half-plates and printing a dozen cabinet impressions from them. Less than a dozen will never satisfy, whilst the capacity of some individuals for absorbing prints appears to be quite indefinite.

The request is a little cool, I think, in whatever language it is couched; but if, as is often the case, it comes in the form "You may take me, too, if you like," it transcends most things in impudence. To such the amateur, if he be wise, will reply, "Yes, I may." Also "I may *not*," especially as a request put into such words comes always from the mouth of an individual of the "male persuasion," and generally from one who is preternaturally plain looking. Of course the amateur must consider himself honoured by a request in any form to have her portrait taken when it comes from one of the fair sex.

The difficulties which stand in the way of the amateur portraitest, especially if he be situated in London, are by no means small, in spite of all that is said by the vendors of apparatus for the use of amateurs. These vendors naturally find it to their advantage to make out that since the introduction of dry plates the taking of portraits in an ordinary room is a mere joke.

The first and chief difficulty is, of course, that which applies to portraiture of all kinds — the difficulty of posing. Of this I do not consider myself qualified to speak, and, therefore, say nothing.

The next difficulty is that of *lighting*. This is one where a little advice may be useful. To secure roundness without hardness is the great difficulty. It is best to have one window only as a source of light. The wider this is the better. With a very wide window—a bay window, for example—it is possible to get lighting almost as good as in a studio.

The tendency of most beginners will be to place the sitter just by one side of the window—perhaps a little behind it. Then if the camera be placed at the other side of the window a very brilliant lighting may be got, and a portrait *of a kind* may be taken with an exceedingly short exposure — probably but little longer than is necessary in a studio. I have, however, found it quite impossible, with the sitter placed as indicated, to avoid a very heavy shadow on one side of the face, or to avoid having too great a proportion of the face in shade, even supposing the shadow not to be too intense. To get a suitable proportion between light and shadow it is necessary that the angle between the line joining the centre of the source of light and the sitter, and that joining the camera and the sitter, should be comparatively small. In other words, it is necessary that when the sitter is facing the light he may also be *almost* facing the camera. To effect this he must be placed at some little distance from the window, and somewhat behind it. If the camera be now placed at the corner of the window remote from the sitter it will be found that an image is got which is at least two-thirds or three-quarters light — only one-third or one-quarter shadow. A reflector must, of course, be used to soften the shadow. I have found nothing better than a sheet, which may be placed over a screen or clothes-horse, or, still better, may be held in the hands of an assistant—by two if they are to be had. In the latter case the sheet is held so as to extend from the sitter as far as possible in the direction of the camera. If the sitter be looking towards the light the sheet may be kept in motion during the exposure. This will somewhat soften the transition from light to shadow.

The next difficulty lies in the length of exposure which is necessary. Even with the most rapid plates this is at times excessive. In the "table of comparative exposures" which I gave in The British Journal of Photography some time ago, and which the Editors were good enough to reprint in the Almanac, I gave four seconds as the exposure for a portrait in an ordinary room with a lens working at $\frac{f}{6}$ the full aperture of the ordinary portrait lens). Of course this is a very vague approximation, but I think that, with the conditions which I had in my mind at the time I wrote the table, it will be found to hold pretty good. I thought of a sitter placed as I have just described, a fairly large window, a bright north light in the country, and a plate giving about 16° on the sensitometer, that being about the rapidity of the best commercial plates at the time at which I wrote. Excellent plates can now be had at least two or three times as rapid as any that could then be relied upon. Even if these be used, however, the exposures given in the table will be found to be fairly correct *for the conditions usual in a London house*. The light in London is, at the best, not so good as that in the country, and, as a rule, a certain proportion of it is blocked out by houses opposite the windows.

If nothing larger than *cartes* be attempted there is no difficulty in always using as large an aperture as $\frac{f}{4}$, in which case the exposure will be by no means out of the way. When we come to cabinets, however, the difficulty is greater, and we must, as a rule, use a much smaller aperture than $\frac{f}{4}$; indeed, I think $\frac{f}{8}$ is about the largest that will, as a rule, give a tolerable result. We now have our exposure increased to about a-quarter of a minute, which is a very long one if no head-rest be used. My own experience is that four or five seconds is the utmost length of time that the average sitter can remain so still as not to show evidences of movement in a photograph. But it is not only the moving during exposure that is so troublesome; it is the moving of the sitter nearer or further from the camera after focussing and before exposure. The amateur using a camera not specially constructed for portraiture is not likely to be exceedingly expeditious in the processes which intervene between focussing and exposure. Half-a-minute, at least, is likely to elapse. He does not like to tell the sitter to remain absolutely still from the time the focussing is finished till the time of the exposure, because he knows the effect it will have on his expression. If he tell his sitter that he need not remain absolutely still, but that he must not appreciably increase or decrease the distance between himself and the camera, he will only hopelessly confuse him. As a matter of fact it will be found that, in nine cases out of ten, the distance between the head of the sitter and the camera will be found to have altered an inch or two between the times of focussing and exposure. This will not show in the case of a *carte;* but it will in the case of a cabinet or anything larger, if lenses of the proper focal length—that is, double the longer dimension of the plate—be used, and if the aperture be the largest practicable.

For all these reasons I say that for working in an ordinary room—in London, at anyrate—if portraits larger than *cartes* are to be attempted, a head-rest should be used. This should only be caused to *touch* the head, and must not be brought into position till after the posing has been done. My friend, Mr. W. Cobb, gave me an excellent hint in telling me that when the exposure was short it was sufficient to bring the rest to bear on the *shoulder* of the sitter.

Backgrounds are always a trouble to the amateur. If he operate at his own house there is no reason why he should not have one or two prepared backgrounds. If he go to a friend's house to take portraits he must do the best he can. The old idea of the blanket cannot be surpassed for heads which are to be vignetted. It must be placed well out of focus. Nothing looks worse than any indication of the texture. For ordinary portraits a curtain hung in folds makes a good background.

When it is desired to get anything more than a head and shoulders, working indoors, there is the greatest difficulty in getting the camera far enough from the sitter without getting it into such a position that there is too much shadow exposed to it. We must either have too much shadow or must place the sitter at a very considerable distance from the window; in which latter case the exposure will be somewhat protracted — not so much as might be expected, however.

The amateur is not likely to have a studio stand for his camera, and the ordinary tripod may prove a "weariness of the flesh" to him. Its legs gets mixed up in a marvellous way with the furniture, and slip in the most unexpected manner. Moreover, they are usually far too long, unless, indeed, they are of the kind which slide up, and which may be shortened as much as is desired. The height of the lens should not be above that of the eye of the sitter.

Concerning the quality of negative which it is desirable to get in the case of a portrait taken indoors: I may say that I consider that the best pictorial results are to be had from negatives which appear a little under-exposed; such as show, at least, a little quite clear glass. The shadows in a room are always very deep, and the high lights comparatively bright. If we expose so as to work into all the deepest shadows it is ten to one that the face will be spoiled by incipient halation. W. K. BURTON.

SENSITOMETER SCREENS.

IN an article in our last number on *Phosphorescent Tablets for Sensitometer Purposes* we intentionally refrained from any description of the graduated screen, since that subject has been so frequently dealt with in these columns during many years past. We have, however, received several letters requesting instructions; so, in order to avoid the necessity for reference to back volumes, we shall here give a few brief hints.

We have to consider three principal points, namely, the most convenient form of instrument, the most suitable material through which to filter the light, and the relative values of the different steps or tints. As regards the general form of the screen: it consists of a series of graduations formed by superimposing varying numbers of thicknesses of some translucent material. The first question to decide is the best method of arranging these tints in order to secure the maximum of convenience. In the Warnerke screen, as most of our readers are aware, the tints—twenty-five in number—are ranged in rows of five, forming a square of a little over two inches, the numbers running alternately up and down the lines of squares so as to preserve their sequence. This is a convenient and compact arrangement, and, so far as its mere application as a sensitometer is concerned, leaves nothing to be desired. But where, in addition to the reading of the highest visible number, it is desired to compare the density of particular tints produced upon different plates, it does not permit of these being brought into juxtaposition for the purpose of close comparison.

A better form for this purpose, and one which is more easily constructed, consists of a series of narrow strips stretching right across the plate, which may conveniently be of quarter size. Allowing an eighth of an inch at each end of the longer dimension for the rebate of the frame, we can form a series of sixteen bands a quarter of an inch wide—quite a sufficient number for most purposes. If a wider range be required the tints must be made narrower.

Now, with regard to the translucent medium of which the screen is made: many different materials have been used, including tissue-paper (white and coloured), thin sheets of gelatine, ordinary sensitised paper graduated by successive exposures to light, as well as carbon tissue, and even dry-plate films treated in the same manner. In the Warnerke instrument the screen consists of a Woodbury print from a graduated mould; but the process of manufacture is not available to all, nor is it needful to adopt it, except for the purpose of securing uniformity between different screens.

Of the materials mentioned all those are objectionable in which any decided colour is present, as owing to the varying colour-sensitiveness of different plates they are not likely to give reliable results when used for purposes of comparison. What is required is a tint as nearly neutral as possible, the different grades being formed by a gradual suppression or cutting off of the light rather than by a change of colour. Where a colour-screen is employed it may probably prove reliable when employed (say) with a bromide plate prepared in a particular manner, while in connection with a bromo-iodide plate its readings would be altogether different.

These conditions are best fulfilled by the use of colourless tissue-paper, by carbon tissue, or by a dry-plate film, if the latter be developed so as to be free from green fog or pyro. stains. On the whole we prefer the two former.

As regards the relative values of the tints: while it is desirable that some definite ratio should exist between the successive gradations, as in the Warnerke screen, it is not by any means an easy result to attain. The amateur or operator who employs the sensitometer simply for his own purposes will soon find, by actual experiment, the relative values approximately of his different tints; indeed, it is probable that such approximate determinations will be infinitely more trustworthy than those obtained by theoretical calculation. The question as to whether the gradations should be in arithmetical or geometric progression is one that must be decided in accordance with the purpose for which the instrument is required—the former giving a delicate scale of narrow range; the latter a wider range with greater contrasts between tint and tint.

The only objection to the paper scale is that the "grain" of the paper sometimes renders it difficult to read a faint tint; a fine silk paper should therefore be selected, as homogeneous and free from texture as possible. No gum or other adhesive should be employed except at the extreme edges, as that would infallibly produce irregularity. The following is the plan to adopt for (say) a quarter-plate screen. Take as the basis a piece of smooth, preferably patent plate, glass—$4\frac{1}{4} \times 3\frac{1}{4}$; apply a very little paste along the extreme edge of one of the shorter sides, and along this attach a strip of tissue-paper three-eighths of an inch wide. Allowing an eighth of an inch for the rebate this will give the first quarter-inch tint. Again: paste the edge and attach a second strip five-eighths of an inch wide, and so on, each time increasing the breadth of the strip by a-quarter of an inch. When the last tint is reached—that is to say, when the fifteenth piece of paper measuring $3\frac{1}{4} \times 3\frac{7}{8}$ has been attached—the last piece is cut a little larger than the full size of the glass, sufficient allowance being made for it to overlap an eighth of an inch. This is folded over and pasted to the front of the glass, and serves to keep all the rest in position. It may be necessary or desirable to progress by double thicknesses or to depart from the strict order of arithmetical progression; but by this method it is obviously impracticable to adopt geometric progression—at least for such a long range of tints.

If carbon tissue be employed it should, after sensitising, be squeegeed on to collodionised glass, and, when dry, stripped. In order to graduate it, the tissue, with a piece of opaque paper or thin card in contact with the collodion surface, is so arranged between two pieces of glass clamped together with American clips that the opaque paper may be drawn out gradually a-quarter of an inch at a time, in order to give successive exposures of varying lengths. Suitable means will readily suggest themselves to the ingenious operator, by which the arrangements may be carried out so as to obtain regularity and neatness. The tissue is mounted for development upon a quarter-plate, and treated in every way like an ordinary carbon print.

With regard to the graduation there will be a very wide latitude. Exposures may be made of gradually-increasing length, or a unit being fixed similar exposures may be repeated the requisite number of times. If the light be variable it will be advisable to adopt as the unit a very faint tint on albumenised paper in the Woodbury or similar photometer.

A gelatino-bromide plate may be treated in precisely the same manner; but in this case the relative values of the tints will depend more on the power of the individual plate to render the different gradations, than to the careful regulation of the times of exposure. In fact, except for very rough work the dry plate is not to be recommended. The carbon image, on the other hand, depends entirely upon the length of exposure given to each tint, and the relation of tint to tint cannot be varied in development. The whole range of tints may likewise be intensified, if necessary, by any of the well-known methods, without in the least destroying their due relations.

In conclusion: we may repeat that such an instrument as we have described, consisting of the home-made screen and phosphorescent tablet, can be of little use except to the operator himself, and must not in any way be regarded as a standard, even though similar conditions of construction be followed as nearly as possible. Still, for individual use, it will be found a convenient guide.

ON FURNELL'S LENS.

[A communication to the South London Photographic Society.]

IN addressing you this evening I intend my remarks to apply more especially to the amateur, whose equipment usually includes but one lens to reproduce all he may attempt in his photographic rambles; but I trust they will interest even the practical photographer who is armed with a whole battery of lenses.

It is well known that in order to produce pleasing results and artistic excellence in landscape photography one lens is insufficient, and even three of different focal length would be no excess. That is, a lens of short focus for buildings in close and confined situations and another of medium focus for general views are requisite, whilst a third of much longer focal length is needed to reproduce distant objects, &c.; and any lens capable of variation in its focus so as to serve for these varied purposes would be a boon to both the amateur and professional photographer.

In THE BRITISH JOURNAL OF PHOTOGRAPHY for April 27, 1883, Mr. Thomas Furnell described a photographic lens specially suitable for landscape and architectural photography, the focal length of which may be varied at will within certain limits, and which has certainly not received that attention from photographers its merits deserve.

The Furnell lens consists of a front combination of two lenses of somewhat novel construction. The outside one is of crown glass—

convex on its exterior and plano on the interior; and the inner lens is of flint—plano on its inside and concave on its back surface—the plano sides of the flint and crown being cemented together by Canada balsam. Behind the front combination, and separated from it by a distance about equal to its diameter, is a double-concave lens of flint glass. The most posterior lens is placed at a slight distance from the concave lens; it is of crown glass and plano-convex, and three back lenses of varied foci are supplied to complete the set. By using one or other of the back lenses, or no back lens at all, we can obtain with the half-plate lens either of the following focal lengths—seven, eight, nine, or fifteen inches. This lens gives a flat field, straight marginal lines, freedom from flare, covers well with stop No. 16 P. S. S. (Photographic Society's standard), and can be made at a moderate cost.

One peculiarity of this lens is that, if the front cemented combination be well and carefully made, the posterior lenses may be of far less accurate workmanship, ordinary spectacle lenses *if properly centered* acting quite as well as those made with all the optician's care and skill. Moreover, the concave flint lens may be replaced by a concave spectacle lens of *crown* glass; and, further, the curves of the three back plano-convex lenses may be altered to either double-convex or meniscus without injury to its working powers or disturbance of the chemical focus. In order to test its merits I have made one of these lenses with every possible care and attention in strict accordance with the author's description. To be enabled to give an unbiassed opinion I placed it in the hands of Mr. A. Cowan, and some of the results of his trials are now before us, proving Mr. Furnell's lens to be both useful and efficient; but if you ask me if I am *entirely* satisfied with this lens my answer would be a negative one, for its many good qualities are marred by two defects. These are want of rapidity and a total absence of uniformity in the stops; and to remedy these defects I have strong hopes of shortly bringing out a lens on somewhat the same lines, under the title of the "Compound Doublet." This compound doublet will consist of one brass mount only, into which any one or two of the lenses forming the set may be screwed for use.

By varying the lenses employed I hope readily to obtain for the half-plate size either a focal length of six inches, of eight and a-half inches, or of twelve inches. These focal lengths have been selected because they are especially suitable for general use, embracing horizontal angles respectively of 65° with the six-inch, 45° with the eight-and-a-half-inch, and 31° with the twelve-inch focus; and, further, with six stops it can be worked so as to give all the advantages of the Photographic Society's standard stops.

These six stops I propose to engrave as follow:—A on the largest, then B C D E and to F on the smallest. The first four, A B C D, will be 8, 16, 32, 64, when used with the twelve-inch set of lenses. The middle four, B C D and E, will be 8, 16, 32, and 64 with the eight-and-a-half-inch set of lenses, and the last four, C D E F, will be 8, 16, 32, and 64, when used with the six-inch set of lenses.

Such is a rough outline of what I hope to accomplish, and all that I have hitherto done in this matter points to success at no very distant period of time. If success be gained it will be largely due to Mr. Furnell, as his writings have certainly pointed out the path by which that success can be reached. W. ACKLAND.

THE SODA DEVELOPER MODIFIED.

As the soda developer for gelatine plates is just now receiving a large share of attention, I make no apology for asking you to favour me with space in your Journal to record the results of some experiments that have occupied my spare moments during the last two years. I think they explain satisfactorily some of the anomalies which, judging from what one reads in the pages of the journals, seem still to perplex not only amateurs, but professionals, in the pursuit of our art-science.

At the beginning of dry-plate work it seemed to me—as, doubtless, it did to others—most desirable to get rid of ammonia, if possible, in the operation of development, on account of its extreme volatility, and the possible consequences to health of constantly inhaling an atmosphere charged with its vapours. This last consideration particularly has led me from time to time to try other formulæ which did not contain the objectionable free ammonia. Still *none* of the substitutes for that alkali proved equally good; for, with them, either the development proceeded too slowly or the colour of the developed image was unsatisfactory. So there was no help for it; ammonia had to be retained, or pyro. must be exchanged for the oxalate developer, and I have a strong preference for the former.

When Mr. H. B. Berkeley published his sulphite-of-soda formula I tried it, and formed a very high opinion of its merits; but a short experience of the use of sulphite of soda and citric acid convinced me that it greatly retarded development. Observing Mr. MacLellan's recommendation for preserving pyro. with sulphurous acid alone, and perceiving that its volatility would prove objectionable to its use, I substituted this acid for the citric mentioned in Mr. Berkeley's formula with the best results. I published the alteration in THE BRITISH JOURNAL OF PHOTOGRAPHY, and have since observed that others have recognised the advantage of the change.

About this time I tried the effect of soda along with the pyro., preserved by different agents, and was surprised to find that it yielded better results with the sulphite of soda, as above prepared, than it did with other preservatives. With several acids—notably the boracic, as the keeper of the pyro.—hardly any development was effected, so powerfully did salts (those formed with the soda) counteract its energy. There was one—I believe only one—objection to the new formula, and that was the colour of the image, which I could not then modify to my satisfaction; so ammonia was restored to its old place, and thenceforth for some time attention had to be given to the prevention or cure of green fog, which was the chief fault, in my opinion, of sulphite of soda.

More recently I noticed that soda was again attracting attention, so I resumed my experiments with it, and this time they proved completely successful. I had discovered a new way of bringing pyro. under the keeping power of sulphurous acid, which I was sanguine enough to think would altogether displace the old method in my practice. It was as follows:—Pyro., one part dissolved in ten parts of sulphurous acid (strength nine per cent.), barely neutralised with ammonia. Thus prepared with sulphite of ammonia the mixture keeps well, is more colourless than a solution made with sulphite of soda, and, moreover, works cleaner, the plates being more free from green fog.

This new preparation was tried with soda (*plus* sulphurous acid) in place of the ammonia bromide, and the result was all that could be desired as regards energy and colour of the image; but there was a trace of green fog, and this circumstance struck me forcibly, because it seemed to confirm a suspicion which had been excited in my mind by a singular coincidence—previously noticed—that green fog had disappeared almost entirely, even on plates very prone to it, when the pyro. kept by sulphite of *ammonia* was used in conjunction with the ordinary ammonia bromide solution. But now, on the contrary, green fog made its appearance (even under soda development, which was supposed to be exempt from that evil) when ammonia took the place of soda in the ingredients of the pyro.; so it was fair to conclude that a combination of the two alkalies in the developer was the cause of green fog, or, in other words, the tendency of ammonia to produce green fog is much increased by the presence of soda. A repetition of the above experiment, using pyro. solution containing *soda* instead of ammonia, proved the justness of the conclusion; for now the film turned out absolutely free from all trace of the evil, and the colour of the image was perfect.

I have not yet worked by the new method long enough to be able to speak with certainty of its merits; but, thus far, it seems very likely to bring about a revolution in my practice, and ammonia may at length be altogether superseded. The following is the formula I am now using:—

No. 1.

Pyro.	1 part.
Sulphurous acid	1 „
Water (distilled)	8 parts.

No. 2.

Saturated solution of carbonate of soda	6 parts.
Sulphurous acid	1 part.
Bichromate of potash (five per cent. sol.)	1, 2, or 3 parts.
Water	18 „

To develope a half-plate: take one drachm of No. 1 and mix with two and a-half ounces of No. 2. Use in the ordinary way. The addition of bromide does not seem to be needed, except in the case of over-exposure of the plate. Development proceeds more slowly than with ammonia, but otherwise soda has several advantages. Its only failing is a slight tendency to produce frilling on some plates very prone to the fault; but this may easily be prevented by passing the plate through a bath composed of *protosulphate of iron*—say two ounces to the pint of water—with a quarter of an ounce of tartaric acid to make it keep. The sole function of the sulphurous acid in the above formula is to modify the colour of the developed image; therefore no more of it should be used than is necessary to produce the colour desired, because the *sulphite of soda* formed in the developing solution powerfully retards its action, as may easily be proved by omitting the acid in No. 2, when it will be found that development goes on with great energy, rivalling pyro. and ammonia.

Finding that the sickly-coloured image which is produced when sulphurous acid is omitted from the above formula can easily be made to take a pleasing and suitable tone, by passing it through the iron bath before named between the operations of developing and fixing, I have been induced to alter my practice in favour of this latter method, because it saves time, and the result is quite as good.

The plate should be well washed both before and after immersion in the iron bath, in which it should remain from two to five minutes, according to the tone required. The longer it stays the blacker the image becomes.

Bichromate of potash takes the part of an accelerator, but how it does so I am unable to say. About two years ago I added a little to my pyro. developer to see if it would prevent green fog, when, behold, it accelerated energy! It must have the effect of hardening the gelatine also, because there is less tendency to frilling when it is present. W. Hanson.

SILVER PRINTS.

In reading Mr. W. K. Burton's communication on *Silver Prints* in your issue of the 26th ult., there appear certain points confirmatory of the theory that hyposulphite of soda is not *the* cause of fading. It is, however, somewhat unfortunate that the sensitised paper used was a secret preparation, as all the experiments are based on unknown quantities. That ready-sensitised paper contains less soluble silver salts and a considerable quantity of some acid not contained in paper prepared at home is patent to most persons who use it. However, that the image is substantially the same as when ordinary sensitised paper is used there is little doubt; at the same time the additional unknown substances used to effect its preservation may possibly affect such experiments as those made by Mr. Burton.

In his experiments Nos. 1, 2, and 3 the prints have all faded almost to obliteration, *no* hypo. being used. In experiment No. 10 hypo. was used for a very short time—ten seconds—and the print remains good. The deductions to be drawn are, firstly, that silver prints fade, whether subjected to the action of hypo. or not, *if not washed.* This is precisely the effect that might have been anticipated; but if, when well washed after partial fixing, they remain under circumstances unchanged for a considerable time—I may add if thoroughly fixed—they will remain unchanged for an indefinite period. Whether subjected to the action of light or enclosed in a portfolio makes no difference. That the effect of fading is produced by causes other than hypo. I have frequently endeavoured to point out, both in communications to this Journal and also in papers read before the photographic societies, with my reasons for so thinking. May not the same substance that causes the deterioration of gelatine plates when used to pack them, and, as you have shown, is *not hyposulphite*, be the cause of the difficulty? I merely throw this out as a suggestion. The more rapid and pronounced effect may be owing to the extra sensitiveness of the gelatine plates.

Mr. Burton's idea that the time usually given to fixing is unnecessarily long is rather dangerous, for he may rest assured if any salt soluble in the hypo. solution be undissolved and left in the paper the print is certain to decay; it will turn yellow, brown, and unsightly in a short space of time. The more it is exposed to light the sooner will the change take place. The same effect will occur if, after the hypo. has effected its purpose of dissolving the silver salts, it, with them in solution, is not thoroughly washed out of the paper, the hyposulphites being extremely prone to decompose.

If the substances we desire to eliminate were, as Mr. Burton seems to think, confined to the very thin layer of albumen it might be sufficient to give a very brief immersion in the hypo. bath. But it is not so, for they more or less entirely permeate the substance of the paper from front to back. This is practically demonstrated in obtaining a plain paper print by floating the back of the paper instead of the albumenised surface on the silver bath. Even if the process of silvering be performed as rapidly as possible on the albumen side of the paper and dried it will be found that a touch of hypo. solution on the back of the paper will rapidly produce a dark stain of sulphide of silver. The fixing process must, therefore, be continued until the whole substance of the paper is deprived of the salts therein contained; and then the hyposulphite solution with its dissolved silver salts must be thoroughly and effectually removed by washing, for not till then can we pronounce the silver print permanent.

Mr. Burton asks—How can it be made evident that the proofs are fixed? If he will try the experiment of holding a print up to the flame of a gas burner from time to time during the process of fixing, he will have no difficulty in perceiving a disappearance of mottling and the gradual clearing of the paper as the fixing process progresses. It is customary to allow the prints to remain in the hypo. a short time after the clearance is apparently completed. About a quarter of an hour is the usual time occupied for the whole process; but with very thickly albumenised paper a little longer time is advisable, as it is always as well to be on the safe side.

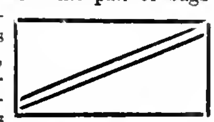
We may fairly conclude that, if a finished print become yellow or brown all over or spotty, either the fixing has been imperfectly performed or the proofs have been badly washed afterwards; and that if a print fade without changing yellow or brown it is owing to the very slight, delicate character of the impression in the first place, or to its having been in contact with some substance prejudicial to its permanency *outside* the usual processes necessary to form a silver print. From numerous examples that have from time to time been brought under my notice I believe that a thin negative which will print in a very short time in the shade will never produce a thoroughly permanent silver print, and that a very *lightly* printed proof from any negative whatsoever will remain but a short time without showing signs of fading. To produce permanent work there must be a certain amount of strength in the impression to begin with—sufficient to carry it satisfactorily through the different processes it has to undergo from the printing-press to the mount. Edward Dunmore.

BOTTLES *VERSUS* GAS BAGS.*

Apparatus for Storing Gases: its Cost and Dangers.

Gas Bags.—Bags made in the early days of the lime light were bladder-shaped or globular, placed between square pressure-boards held in place by four corner rods, as in Dr. Woodward's apparatus, described and figured in his work on *Polarised Light;* or square, made after the manner of an accordion or bellows-camera body, so as to expand into a square receptacle on being filled with gas, and fall "flat as a pancake" when empty. These were usually placed in a square box, which served as a guard when travelling and for pressure-boards when the lid was weighted. Then came into use the better form of wedge-shaped bag, which afforded an element of pressure supplemental to that of the weights employed, namely, leverage. These were placed, when required for work, between "a pair of pressure-boards" hinged at one end, the cross pieces of wood employed for strengthening the boards being utilised as rests for the weights.

Of late years, to economise space and weights, Mr. B. J. Malden placed both bags between one pair of pressure-boards, wedge-end to wedge-end, with the thin edges of the wedge-shaped bags raised by a suitable arrangement of the boards to secure a safe balance of the weights. Another operator, ignoring the extra leverage pressure obtainable from the wedge-shaped arrangement, placed his pair of bags "head to tail," so as to form a square pile, thus:—



In this case, a skeleton box held both bags in place when filled for travelling. The lid, working on guides, served as the upper pressure-board and sustained the weights. By an ingenious arrangement of hinges the four sides folded down and packed the bags when empty into a small space for the homeward journey.

Gas bags are made of various strengths according to price. For "oxy-spirit" or "blow-through" jets "thin bags," made of cream-coloured material, are employed. When both oxygen and hydrogen or house gas are employed with "mixed gas jets," "thick bags" must be employed to sustain the greater amount of pressure required to secure the greatest amount of light attainable by the "bag system." To do all that is obtainable by forethought to provide against accident, I used always to have my thick oxygen bags made in light-coloured material with the stopcock bright, and one stopcock on the jet bright *en suite*, to aid the eye of the operator as to all oxygen connections. My hydrogen or house gas bag was made of thick, black material, with black stopcock to bag, and that on the jet black *en suite*, so that all the hydrogen connections were also at once recognisable. To prevent the lighted jet being extinguished by accidental pressure, I employed red-rubber tubing, from which the coil of spiral wire used in its manufacture had *not* been removed, with the exception of a couple of inches at the ends of each length, left for "springing-on" to the stopcocks. All my stopcocks were made with single lever taps, which stood parallel with the delivery-tubes of the cocks when the gas passage was closed and at right angles when full on. The stopcock of gas

* Continued from page 618.

bags was of larger size than usual, being a full three-eighths of an inch in the bore. Lashings were affixed to each cock to prevent the lever handle being accidentally opened when not in use, so as to avoid waste of gas or admission of extraneous air.

The dangers which beset gas bags are—1. Using them for the storage of oxygen when newly made, with an atmosphere of methylated spirit or hydro-carbon rubber solvent unejected. This is avoided by distending all new bags with air by the aid of a cheap double-bellows, closing the cock, leaving for some hours, emptying by rolling the bag up tight, with the cock full open, driving the air out inch by inch as the bag lies flat on the floor, and closing the cock till connected with the generating apparatus. Those who wish to preserve their bags would do well to empty them after each exhibition, distend with air by means of double bellows, and keep them distended for some hours. Oxygen has a deteriorating influence on bag material if left in for any length of time. I may here state that I never came across an instance of delivery-tubes being choked by the *débris* from the decaying lining of a gas bag, for the reason that I never employed old bags; but, from what I have seen at *post mortem* examinations of defunct bags, I can believe blockage from such a cause very probable, although I should not have thought it possible that such *débris* could form a train from jet to bag for an explosive "run-back."

2. From the accidental admixture of oxygen and hydrogen in the same bag, or of hydrogen and atmospheric air *when not under sufficient pressure.*

3. Accidental admixtures of the gases, &c., may come about through blundering operators, by sheer "cussedness," as our American friends very graphically designate that bull-headed stupidity not difficult to discover among the "lime-light men" at our places of public entertainments, and gentlemen very learned in classics, theology, and other non-scientific subjects, who, because it is their calling to teach others, cannot bring themselves to believe it possible they are themselves open to be taught the proper manipulation of a scientific instrument, when in the commonplace form of "a magic lantern." With this class it is rarely possible to get any explanation how a blow-up has come about, as they have only vague recollections, if any at all, as to *what* they did do, antecedent to "an accident."

In the recent accident at Drury-lane Theatre, had the bags *been under proper pressure instead of free* when a light was brought near, the probability is no explosion would have occurred. Another cause of admixture is when an oxygen and hydrogen bag of equal size are connected by tubing with a mixed-gas jet, when the most powerful light (next to the condensed gas method) is desired and both pressure-boards are loaded with one hundredweight each; and if in the dark half-a-hundredweight *slides down* out of proper place from the upper end, or *falls off.* In a little time the gas *from the full-weighted bag,* not being able to find sufficient vent at the nozzle of the jet, works round through the delivery tubes to the insufficiently-weighted bag, and an explosive mixture is there found with a train of mixed gas in the tubes extending to the light at the nozzle. At the moment of greatest inflammability being attained the explosion occurs.

Again: with the same arrangement, with weights equal and in *proper position,* one of those individuals who are so fond of "loafing" around a busy operator, and what is vulgarly but graphically termed "noseing" the apparatus, finds the upper edge of one of the bags conveniently placed for resting his elbows on, or he may rest his foot thereon, or he may even sit upon that bag (I am only putting on record what *has* occurred!). Of course he imparts an extra (and unthought-of) pressure on *that* bag, and drives the gas therein over to the companion bag. Then he withdraws his weight, and a "*suck-back*" occurs at that moment at the nozzle, the train is ignited and "up (or down) goes *that* donkey," with it the apparatus, and probably the innocent operator!

Here it may be a fitting place to point out that an exhibitor cannot be too careful as to building up a barrier round his apparatus which will exclude dangerous intruders, and literally keep people "at arms' length." Who would have calculated on such a *contretemp* as this:—A well-known lantern exhibitor whilst lecturing noticed a diminution of the light on the screen. His assistant could not correct this shortcoming, so the signal "turn up lights" was given. On overhauling the gas bags the pin of a large brooch was discovered thrust through one of them. A lady sitting on a form used as part of the barrier had undone her shawl, and, seeing the cushiony protuberance, deliberately, but "without malice aforethought," turned the scientific appliance into a pincushion. Another cause of admixture is through using a large bag (as for hydrogen, where two volumes to one of oxygen are burnt) with a small bag, in which case the weights being placed at the upper end of a longer pressure-board the increased leverage forces the gas from the large bag round through the connections into the small one.

Palpably it is safer to employ two bags for hydrogen, though one bag *of proper shape* would suffice.

The results arising from unequal pressure by weight and leverage can be demonstrated without danger by filling the gas bags with atmospheric air. Such experiments appeal to the eye in a manner not so likely to be forgotten as mere verbal or printed warnings. Absolute explosions can be made with small bladders filled with a mixture of house-gas and atmospheric air, the weights, &c., being confined within bounds of striking distance by stout cord when used in model apparatus.

4. The fourth source of danger *is the key to all the ordinary causes of accident when dealing with lime-light apparatus,* namely, insufficent pressure on the gas receptacle—be it gas bag, gas-holder, or gasometer—before a light is put to the nozzle of a *mixed-gas jet,* or while the jet is burning. A half-hundred weight *on each receptacle* is sufficient to avoid accident.

From the very first lecture and demonstration I ever gave on lantern manipulation I did my best to impress this simple axiom on the minds of my students, in a paraphrase of the old admiral's (some say it originated with Oliver Cromwell) address to his crew before going into action—just such advice as that rough-but-ready type of the old sea-dog of the British navy, Commodore Sir Charles Napier, would have given to "his following," namely—"Put your trust in Providence, but keep your pressure up!" You have here the secret of safe manipulation and "*all there*" in a nutshell.

I once had a customer who was so clever as a linguist and theologian that I was afraid to let him have a set of dissolving view apparatus till I had "put him through his facings" in the manipulation of his purchase. His ire was great when I suggested the advisability—nay, the necessity—for such a practical course. When I state that he was great on a new reading of "Revelations" wherein Napoleon III. was the undoubted "anti-Christ," and that I had to get up a set of lantern pictures of the most mysterious character, with maps of the world as it was and as it was to be, and portraits of illustrious persons—with horns innumerable on their brows (having reference *to political matters—solely!),* bulls, bears, and rams, apocryphal from a strictly natural history point of view, &c., &c., &c.—why most of my readers will justify me in the decision I came to, and as the result will show. He came (from the country), and he saw (how I manipulated), and he conquered (all the little details, I flattered myself). He paid his account and took himself and his apparatus "right away" home. The next night I was awakened out of my first sleep by a violent ringing of our house-bell. A telegram informed me he had blown his purchase "all to smithereens!" and cursing me in Biblical phraseology for supplying him with such dynamitical apparatus. Feeling this unjust I slept "the sleep of the just," and next morning requested particulars. The response amounted to this:—Instead of purchasing, begging, borrowing, or *other alternatives,* a set of four half-hundred weights, he loaded his pressure-boards with all the fenders and fireirons he could collect from about the house. The carrying out of instructions as to equal pressure on each bag was, consequently, *vague.* He "lighted up;" there was a soft, spluttering noise, and a poor—very poor—picture on the screen. Then he (did *just what I had warned him not to do)* put one hand on each bag, pressed his hardest, and exclaimed—"Ah! *that* is just such a light as Mr. Highley got; that is it—that is beautiful!" Then he took his hands off, freely perspiring with his efforts; then—there was a bang! He was on his back! the windows were blown into the street, two large folding-doors wrecked on their hinges, the pressure-board mere matchwood, and the bags ripped and smoking like fusee paper. Here comes the curious part of this truthful story. There were twelve persons surrounding that apparatus, and not one was seriously hurt—*a characteristic* of oxyhydrogen explosions. The force expends itself in an angular direction upwards, after the manner of gunpowder—as dynamite does downwards, and nitro-glycerine in a horizontal direction.

Where one bag for oxygen is only required—as with the oxy-spirit jet, or oxy-house gas blow-through jet—the chances of accident are reduced to a minimum. The space at my disposal will not allow me to go into details as to bell gasometers, Pepys' gas-holders, and other metallic contrivances seldom used but in lecture-rooms, institutions, or well-appointed theatres, such as the Alhambra, Surrey, &c. The same rules apply to such store vessels as I have specified in regard to bags; but *the system* of working presents fewer chances for one receptacle to be more heavily weighted than the other. Theatres are conservative strongholds, so there is little wonder that metallic store vessels are the exception and not the rule. This is not so in America. If gas bags are kept filled with gas for some days, they will be seen to shrink in bulk, and the contained gas will have become deteriorated. This is not so with metallic reservoirs.

Now, as to cost:—

	£	s.	d.
A bag of medium quality, 36 × 24, and 24 inches in the wedge, with stopcock	2	12	6
Pair of best pressure-boards	1	0	0
Six feet of red rubber wired tubing	0	5	6
	£3	18	0

	£	s.	d.

SAMUEL HIGHLEY, F.C.S., &c.

OPINIONS OF THE LONDON DAILY PRESS ON THE PHOTOGRAPHIC EXHIBITION.

THE PHOTOGRAPHIC SOCIETY.—The annual exhibition of the Photographic Society of Great Britain, which will be opened to the public today in the Gallery of the Royal Society of Painters in Water-Colours, in Pall Mall East, will be remembered rather by reason of the generally high level of the results obtained than for any startling novelty in the treatment of subjects or methods of work. There are, indeed, very few pictures among the thousand or more exhibited which would not have been ranked with or next to the leading productions of five or six years ago. The causes of this advance along the whole line will be found directly, to some extent, in the revolution which has taken place in the chemical processes of photography, and secondarily—and in consequence of this change—in the conditions under which the camera can now be employed, in the enrolment among the exhibitors of a largely-increased number of amateurs of cultured taste, enjoying means and leisure for the successful practice of the art. A traveller may pack in his portmanteau the whole of the apparatus he requires to photograph scenes or places he visits, and on his return home may hand the sensitive plates to a professional photographer, to bring out or develope the images latent in the dry gelatine films, and to print direct from or to enlarge the pictures produced. How long the plates may be kept after exposure in the camera cannot yet be said, but, as an instance in the Exhibition shows, they may safely be kept at least as long as any traveller is likely to be obliged to postpone the after processes. Dr. G. Berwick shows *Dumblane Cathedral* (481)—a clean, sharply-defined print from a negative exposed in July, 1880, and developed in July, 1884. Moreover, if the traveller choose his point of view well, paying due regard to the forms in which the objects before him appear to be grouped in his camera and to the position of the sun at the time—in short, to the composition and lighting of the work—he may, like Professor Donkin in his Alpine studies, return with small pictures that on enlargement are as pleasing in effect as they prove full of the most minute and instructive physical detail. While touching on the reproduction of Alpine scenery we may conveniently direct the attention of the visitor to the set of views in Switzerland—*The Lyskamm, Mont Blanc, Märjelen See*, and *Monte Rosa* (23)—by Signor Vittorio Sella, to which a medal is awarded. These large and singularly fine pictures are printed direct from the negatives taken in the Alps.

In comparison with the changes which have been made in other branches of the photographic art, the most important advance noticeable this year is in portraiture. The greater uniformity of quality obtained by improved methods of manufacturing sensitive gelatine plates has, no doubt, something to do with this. A photographer's attention, too, is not now distracted by fears lest his prepared plate should be spoilt if he stops to improve the pose of a subject at the last moment; but with the power obtained by the use of rapidly-impressed plates of taking portraits which are more or less satisfactory as pictures of people in their own homes, there has grown up a demand for more naturalness and ease in style. Several examples may be found in the gallery of this change, which substitutes for the plain or painted background and the classic pillar and balustrade, or the hack table and chair, the luxury of Oriental hangings and æsthetic furniture and surroundings, with a tendency, however, it must be observed, to so fill the picture with pretty detail that the portrait of the sitter is apt to be lost in the crowd of objects. The series of portraits of ladies (243-252), for which the judges have awarded a medal to Mr. H. S. Mendelssohn, may be cited, those of *Lady Brooke and Child* and of *Miss Grant* showing both the gain in freedom of treatment and the dangers of over-elaboration of accessories. Turning to the introduction of figures into landscapes and interiors it is matter for congratulation that the photographers who were tempted by the facilities new discoveries placed in their hands to essay the presentment of emotional incidents already show a chastened ambition. Brought in as the groups of children and rustics are in Mr. H. P. Robinson's *The Cuckoo* (64) and *He Never Told His Love* (66), in Mr. J. Gale's *Off to Market* (69) and *The Smuggler's Cave* (70), and as the little girl feeding ducks is in Mr. John G. Horsey's view of a charmingly-embowered homestead *The Pets* (183), pictorial effect is heightened by the presence of the figures; and even in the cottage interior, *Mother's Love* (282), a composition by Mr. J. Hubbard which has gained a medal, the photographer is well within the bounds set him by his dependence upon the dramatic attitude of his model. When, however, he goes beyond this and attempts the portrayal of strong feeling—as in an admirably composed picture of a country churchyard where a girl has thrown herself upon a grave in a passion of grief, hiding her face in her sister's lap—the very realness of the scene suggests unreality and simulation, because the author of the picture has not the painter's privilege of presenting such an incident as imagined, and the mind revolts from the supposition that the camera could be turned in cold blood on a scene of such distress.

Of instantaneous photography there are many specimens, the most remarkable for artistic worth being the medal pictures of *Yachts Racing in the Solent* (309), taken by Messrs. G. West and Son from a sailing boat, so that camera and subjects were both moving when the exposure of the plate was made. Another medal is awarded to Mr. W. P. Marsh for *Studies of Breaking Waves*; and there is a well-defined and consequently apparently motionless express train, of which the picture (206) by Mr. C. Grassin was taken with an exposure of the three-hundredth part of a second. Studies of woodland, mountain, sea, and clouds are as numerous and as freshly-delightful to the lover of good photographs as ever, admirable among many being *Views at Hampstead* (381), by Mr. Edward Dunmore; *Rydal Water* (366), and other views, by Mr. W. Wainwright, jun.; *At Home and Abroad* (352) and some Yosemite and other scenes, by Mr. Andrew Pringle; *Bonchurch Old Church* (202), by Mr. J. Duncan Pierce; several in a set by Captain Abney; *Views in Surrey* (537), by Mr. C. A. Ferneley; *North Wales* (465), by Mr. A. E. Durham; *The Valley of Desolation*, South Africa (552), by Mr. R. Harris, a stormy seascape; *Rescued* (260), by Mr. H. J. Godbold; and *Peeps into Cloudland*, obtained by Mr. B. Wyles. Arresting attention by their delicacy of tone the platinotype prints repay one for the close examination they invite. A medal has been deservedly awarded for a set exhibited by Mr. H. B. Berkeley (209, 219, and 221). The chilliness of a misty wintry river scene (167), by Mr. G. Renwick, is suggestively rendered by the cold bluish grays of this process, which, with quite another purpose, is no less happily suited to the copy by Mr. F. Hollyer of Mr. Burne Jones's painting, *The Six Days of Creation* (145). Architectural work is well represented by Mr. F. Machell Smith's wondrously-massive and solid-looking *North Portal of the Cathedral at Chartres*, by the marble-like brilliancy of the Rev. J. S. Knight's *Temples and Monuments at Athens*, by Mr. G. Hadley's *Interiors of Lincoln Cathedral*, and Mr. Alfred Tagliaferro's medal picture of the *Tombs of the Knights of Malta in St. John's Church* (234). Mr. Henry Stevens again contributes some of his matchless studies of flowers and foliage. Of the scientific and educational uses of photography there are examples in the microscopically-small pictures on glass of Saturn's rings shown by Mr. A. Ainslie Common, F.R.A.S., and again in the magnified photographs of sections of plant stems, parts of insects, &c., by Mr. J. Renton Dunlop, and two photographs of lightning by Mr. M. Auty (485). Small but masterly copies of oil-paintings are shown by Mr. Edwin Cocking. Photo-engraving is illustrated by Messrs. T. and R. Annan, and the portraits of the *Late Duke of Buccleuch* and *Sir Daniel McNee*, and the three-quarter figure of a girl are full of promise for the future of this branch of art.—*The Times.*

THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The exhibition of photographs by this Society, which will be opened today at the Galleries of the Royal Water Society in Pall-mall, is chiefly remarkable for the advance in artistic excellence observable in the landscape work, which, as on the last occasion, forms the prominent feature. Photography is fast advancing its claims to be regarded as an art as well as a scientific and mechanical process, and, in place of the clear, hard backgrounds and disproportionate dark foreground patches that used to characterise landscape scenery under the lens, it is now possible to represent mist-clad hills, delicate gradations of distance, and soft shadows. This is especially instanced in Mr. W. England's beautiful views in Switzerland, Mr. Vittorio Sella's *Snow Scenes from the Alps*, which have gained a medal, Mr. J. P. Gibson's *Autumn Evening on the Tyne*, and other views, *The Picturesque Spots of North Devon* taken by the School of Military Engineering, Mr. G. Renwick's *Winter Scenes*, and Mr. J. G. Horsey's *Bits of Surrey*. Among the medallists Messrs. G. West and Son carry off the palm with photographs of *Yachts Racing in the Solent*, taken from a sailing boat, which are perfect little pictures for form and effect. Messrs. T. and R. Annan, of Glasgow, exhibit results of the new photo-engraving process, which is similar to copper-plate engraving, only that it is untouched by hand and is produced entirely by light and shade. Mr. H. P. Robinson is again successful with rustic groups of cottagers, and Mr. B. Wyles has some very fine effects in cloudland that should be interesting to artists. Mr. W. P. Marsh exhibits some striking instantaneous studies of *Sea Spray*, which have obtained a medal. In portraiture there are but few notable exhibits. The London Stereoscopic Company have good portraits of *Mr. Alma-Tadema, R.A.*, and *Mr. G. Grossmith*; and Mr. Mayall shows a praiseworthy portrait of *Mr. James Glaisher*, the President of the Society. Mr. Lafayette takes a medal for exceptionally fine portraits; so do Messrs. H. S. Mendelssohn, H. B. Berkeley, A. Tagliaferro (for church interiors), M. Auty (for photographs of lightning), J. Hubbard, and the Autotype Company. Groups of amusing figure subjects are by Mr. Malcolm H. Clerk and Mr. W. Cotesworth. It is noticeable that the use of the gelatine plates has so far superseded the old method that examples of the latter are quite the exception.—*Daily News.*

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The President (Mr. James Glaisher, F.R.S.) and Council inaugurated the annual exhibition of the Photographic Society of Great Britain on Saturday evening by a *soirée* at the Gallery of the Royal Society of Painters in Water-Colours, Pall-mall East. The Exhibition, which will open today and remain on view till the 13th of November, can hardly be said to be disappointing, although there is little to be noted in the way of advance either in the artistic qualities of the exhibits or the scientific application of photography as compared with recent years. Some progress has, however, been made in the process of photogravure, and the specimens shown by Messrs. T. and R. Annan, of Glasgow, are remarkable for delicacy and mellowness of gradations. Klic's invention seems destined to become invaluable for the production of works suitable for high-class book illustrations, and Messrs. Annan are undoubtedly working it with great success. These monochromes are printed from copper plates, which are engraved by chemical processes, the tints resembling in their flatness water-washes of Indian ink or sepia. It is difficult to distinguish between some of the specimens of photo-engraving and carefully-finished drawings in black and white, the resemblance being so close. Messrs. Annan have this year, as last, been awarded a medal for the scientific application of photography. Many of the best photographs are exhibited by non-professional gentlemen, who study the subject purely *con amore*, and are able to devote to it almost any amount of time and capital. In this category may be cited the frame of instantaneous views taken from a yacht in Scotland by Mr. T. W. Boord, one of the members for Greenwich; also the effective studies of flowers in vases, by Mr. Henry Stevens, of King-street, Covent-garden. Captain Abney, R.E., F.R.S., again, is an accomplished master of the art, and the diversified subjects which he exhibits, produced from gelatino-iodo-bromide plates of his own preparation, are equal to anything that has yet been done by means of the camera. Several other non-professional photographers contribute excellent work. The combination pictures of Mr. H. P. Robinson are interesting examples of the artistic manipulation of photography. He has been awarded a medal for *The Mill Door*, a work of real merit. In some other of his pictures the figures are not quite so natural, betraying by their pose their knowledge of the photographer's presence. At the same time it must be admitted that Mr. Robinson's productions are more free from this obvious defect than are those of most of his *confrères* who attempt combinations of figures and landscapes taken on separate plates. The instantaneous studies of sea-waves dashing on the shore, and mountains of feathery spray, exhibited by Mr. W. P. Marsh, have gained a medal. It would be useful if in these, and similar examples, it were stated whether there had been any retouching. It is difficult to distinguish in all cases whether the pencil of the artist has been employed or not, and any intimation with respect to this matter would be welcomed. In portraiture the practice of retouching is largely adopted, and does not debar the exhibitor from the Society's awards. It should be made a *sine quâ non* in all such cases that a print from the untouched negative should accompany the hand-elaborated example. The spectator would then be able to discriminate between pure photography and skilled or unskilled—and it is more often unskilled than skilled—handicraft. The Photographic Society do not seem to distinguish by their awards the one from the other; and, although the novice can easily detect retouching more or less laboured here and there, it would be a point gained if he could, by comparing the negative print with the hand-finished performance, be enabled to judge of the quantity and the quality of the artist's work. Possibly some of the sitters might object to being displayed publicly without having their angularities and blemishes toned down and their wrinkles obliterated; but in the interest of photography these scruples ought to be disregarded. There are exhibits in portraiture by Mr. J. Lafayette, Mr. J. E. Mayall, Mr. H. S. Mendelssohn, Mr. W. Byrne, by the London Stereoscopic Company, enlargements by the Woodbury Company of negatives by Messrs. W. and D. Downey, and a frame of comically-treated cats and dogs by Mr. H. Pointer, all worthy of commendation. Mr. Cecil V. Shadbolt, the aëronaut, contributes photographs taken from the car of the "Monarch" balloon, on the 13th of August last, in an ascent from the Crystal Palace; and, as everybody cannot go up in a balloon, these views—one of them of streets resembling a carpet of geometrical pattern—cannot fail to interest, altogether irrespective of any scientific merit or otherwise which they may possess. On the tables will be found an assortment of cameras, shutters, plate sets, lanterns, and other photographic *paraphernalia*, by different makers, and of the most recent pattern and approved type.—*Morning Advertiser.*

,, 15	Photographic Club	Anderton's Hotel, Fleet-street.
,, 16	London and Provincial	Masons' Hall, Basinghall-street.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

On Thursday, the 2nd inst., at eight o'clock, a special meeting of this Society was held (in accordance with a resolution passed at the June meeting) at the House of the Society of Arts, John-street, Adelphi, W.C., "to consider the future of the Society." Mr. W. Ackland occupied the chair.

It was announced that a framed testimonial and a cheque for fifty pounds had been sent by the Society to the widow of their late President, the Rev. F. F. Statham, and a letter of acknowledgment from Mrs. Statham was read.

Mr. W. Brooks having taken the chair vacated by Mr. Ackland, the latter gentleman read a paper on *Furnell's Lens.* [See page 647.]

The Chairman thanked Mr. Ackland for his paper. He considered that the lens described would supply a want long felt, particularly as he understood it was a cheap lens; not that we had any reason to complain of the performance of the lenses issued by our best opticians, but the price was too high for many, especially amateurs. He hoped the results that Mr. A. Cowan got would prove that the Furnell lens possessed all the good qualities Mr. Ackland attributed to it.

Mr. A. Cowan passed round a number of prints from negatives taken with the Furnell lens. The lens had been used with back combinations of very various form and focal lengths. One set of prints showed that there was no appreciable disturbance of the chemical focus with any of these combinations, and another that there was no appreciable distortion. He did not think that the lens could compete with a set of good double combination lenses; but for amateurs and others who could not afford such a set he thought it would be invaluable. He had himself had the courage of his opinions, and had recently gone out to take architectural subjects provided with the Furnell lens only.

Mr. J. Traill Taylor said he was grateful to Mr. Ackland for proving what he (Mr. Taylor) had been trying for years to hammer into the heads of the photographic public, namely, that when the front combination of a doublet lens was a deep meniscus the back combination could be varied greatly in form, material, and focal length without appreciably disturbing the relation of the chemical and visual foci, and without giving appreciable distortion. He (Mr. Taylor) then sketched on the black board a contrivance somewhat similar to that introduced by Mr. Furnell, for which a patent had been taken out by Mr. Howard Grubb some time ago. He (Mr. Taylor) had tried it, and had found it excellent. He also mentioned the lens of Morrison, of New York (already described in these columns), in which there is combined with a deep meniscus front combination an *uncorrected* back lens, the focal length of which latter might be varied.

Mr. Cowan asked whether, when two combinations of different focal lengths were used, there was any rule as to what particular relative lengths gave the best result as regarded flatness of field.

Mr. Ackland knew of no rule.

Mr. Mackay asked whether the lenses were necessarily corrected exactly as Mr. Furnell showed, or whether any other method of correction might not be employed.

Mr. Ackland said that possibly other means of correction might be used, but that there was the advantage of cheapness and convenience in the form shown.

Mr. Haddon thought it was more difficult to make flat surfaces for lenses than to make curved surfaces, and therefore considered that the correction of the front combination might be more easily effected by having curved contact surfaces.

Mr. Taylor observed that it was true that opticians considered it easier to produce a curved than a flat surface, and they invariably preferred it for their contact surfaces, on account of the increased power it gave them to obtain actinic correction.

Mr. Ackland said that, when he talked of flat, he did not mean mathematically flat. Curves of long radius might be used.

Mr. W. K. Burton asked if a lens of any considerable size had been made after the Furnell pattern. It was only when large sizes were attempted that the test of the design of a lens was severe.

Mr. Ackland replied that no large lens of the kind had been constructed.

Mr. W. Cobb said that he had an instantaneous shutter constructed to work between the combinations of a lens. He had had various lenses of his own adapted to this, and as a consequence could interchange one combination of any of these lenses with a combination of another. He had tried all the possible changes of combinations, and had got the best result with a front combination of a Voigtländer and a back combination of a rapid rectilinear.

Mr. Taylor remarked that there might be an advantage in the arrangement which Mr. Cobb mentioned, as a doublet which had a flatter front than back combination gave good results. Such would be the case in the arrangement mentioned by Mr. Cobb.

Mr. T. Bolas said the whole thing seemed to him to amount to this—that it was possible to combine various lenses much more freely than was commonly supposed. It was, however, curious to see how the opticians set their faces against such procedure. You went to one of the best opticians and asked him if you could use a single combination of his doublet as a landscape lens. He would doubtfully shake his head; but should you suggest the use of one combination of one of his lenses with another combination of another optician's lens, he would simply stand aghast.

Mr. F. A. Bridge knew the feeling of opticians in the matter pretty well. He had heard that by bringing the combinations of a doublet closer to each a wider angle could be taken in than when they were arranged as sent out; but he had not dared to go to the manufacturer of a doublet to get the necessary adapting tube made.

The Chairman then proposed a vote of thanks to Mr. Ackland. This was carried by acclamation.

There was after that some discussion as to whether or not the November meeting should be a technical one. It was eventually decided that it should not.

It was announced that at the November meeting Mr. J. Traill Taylor would show on the screen a set of sixty lantern slides to illustrate a lecture on *Florida: Its Orange Groves and General Features*, which he would then deliver.

After this there was a discussion on "the future of the Society," the upshot of which was that it was determined to send a circular to members requesting them to express an opinion as to whether the Society should continue to meet or not. A committee was nominated to draw up the circular. The meeting was then adjourned.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on Thursday, the 2nd instant, the chair was occupied by Mr. A. L. Henderson.

The Chairman exhibited an appliance which he had brought from America, called an "automatic retoucher." It consisted of a pencil moved rapidly backwards and forwards in the holder by clockwork. The effect of this movement was that a series of dots or mechanical "stipple" was produced as the pencil was drawn across the surface of the negative. The lead of the pencil was stated to be metallic, instead of the usual plumbago. He also described a mechanical contrivance called an "air-brush," by means of which a fine stream of pigment was projected upon the surface to be worked upon. This was intended for finishing enlargements, and in artistic hands fine effects were stated to be very rapidly produced. In illustration of this a sketch of a human eye and part of a face were shown, which had been produced in the Chairman's presence in an exceedingly short space of time.

A photograph was shown which many years before had been sized with gelatine and then coated with dammar varnish. On one portion where the varnish had not gone over the picture the latter was considerably faded, whilst the remainder was bright. The composition of the varnish used was one ounce of dammar to two quarts of benzole.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The ninth ordinary meeting of this Society was held in 5, St. Andrew-square, on the evening of Wednesday, the 1st instant,—Mr. W. Neilson, President, in the chair.

The minutes of the last meeting having been approved,

Mr. Norman Macbeth proposed that a small committee be appointed to draw up details for a monthly competition among the members, in order to make the study of the picturesque more an object of the Society. He said:—Having brought this motion before the Society at the last meeting, I have much pleasure in now laying before the members some notion of the object and its possible operation. Indeed it would be a good arrangement for the Society if each department were kept distinct and under special committees, so that full justice be done to them respectively. For instance: I would divide the objects of the Society into three departments, namely, the chemical, the artistic, and the mechanical. I would have small committees to each, not exceeding three, and that they have no other department to occupy their mind but the one which they were specially adapted for and appointed to. This suggestion may yet form the subject of the Society's consideration. In the meantime I would press upon you the claims of the artistic department, particularly in reference to composition and effects of the pictorial. With a view to the study of this I would propose that at each monthly meeting of the Society members bring forward some of their selected work done during the summer; that these be submitted not so much for mere criticism but for friendly conference; that members be called upon to give their opinion as to the respective merits of each, and specially pointing out what they conceive would be an improvement. At the close of the conference a vote by papers, numbered according to the number attached to the respective work which the members consider best, to be taken. The one having the greatest number of votes to be set aside for the custody of the committee, and at the close of the session another vote to be expressed by the Society as to the best of all that were formerly approved of, and probably some award be given. This, Mr. Chairman, is what presents itself at present to me as to the carrying out of my notion. Of course we shall be happy to hear any suggestion which members have to make on the matter, and then (if approved of) proceed to appoint a committee for drawing up details.

The motion was seconded by Dr. Hunter and carried, and Messrs. Norman Macbeth, Alexander Matheson, and John Simpson were appointed as a preliminary committee to consider the matter.

The President proposed that the balloting for new members be by means of tickets with the words "admit" and "reject" printed upon them, the ticket to be dropped into the ballot-box by members on entering the room. This was agreed to.

The following gentlemen were proposed as new members, to be balloted for at next meeting:—Mr. F. W. Palmer, Mr. Edward Binning, Mr. Alfred G. Tagliaferro, and Mr. Charles Waterson.

Mr. J. M. Turnbull next communicated some notes on *Sulphite of Soda in the Developer*. Having traced the history of this salt as an adjunct to the developer, he proceeded to show the reason for the contradictory evidence as to its usefulness. He pointed out the unstable character of sulphurous acid, and also of the liability of the sulphite of soda to change to sulphate. The sulphite of soda as purchased was usually strongly alkaline, and to remedy this many people added citric acid; but that produced citrate of soda, which was a powerful restrainer, hence *sulphurous* acid should replace citric acid. By this means a reducer was formed instead of a restrainer. Sulphurous acid was, however, a feeble acid, and it required about fifty per cent. of that acid to be added to the ordinary sample of sulphite of soda to secure the desired acid reaction. It was to be remembered that the same sample of sulphurous acid was constantly getting weaker, the gas which formed the acid constantly escaping every time the bottle was opened, and therefore it was necessary to ascertain by test paper that sufficient acid had been added. When these simple directions were followed the sulphite developer was entitled to all the praise and none of the blame that had been bestowed upon it—the development being rapid, and the negatives beautifully clean and of fine colour.

In reply to a question concerning the hydrokinone developer,

Mr. Hugh Brebner said he had discarded as impracticable the formula issued therewith, namely, two grains of hydrokinone, one ounce of water, and five minims of liquor ammonia, as even with a full exposure he could only succeed in bringing out the very faintest of images, and that, too, after an absurdly protracted development. By increasing the proportion of hydrokinone from half per cent. to somewhat less than two per cent. he found that very great density, perfect detail, and exceptional quality could be easily produced with considerably under-exposed plates (home made). Captain Abney, the introducer of this developing agent, claimed that with a four per cent. to six per cent. strength only half the exposure necessary with alkaline pyrogallol was required. Dr. Eder, again, stated that "a two per cent. aqueous solution of hydrokinone, to which a few drops of ammonia have been added, is thin, but admits of silver intensification." He (Mr. Brebner), while regretting the limited extent of his experience, nevertheless expressed his opinion that hydrokinone promoted abnormally-short exposures, great density, and exceptionally-fine quality. The only drawback which he found this developer to possess was an apparently characteristic ruddy-brown colour, which, although beautiful in itself, was scarcely conducive to rapid printing. He (Mr. Brebner), however, deprecated the acceptance of his evidence as conclusive upon any point whatsoever.

Mr. A. B. Stewart next developed several negatives by the potash developer of Mr. Beach. He said:—For some time back considerable discussion has been going on as to the merits of a developer which would seem to be, for general use, better suited to the requirements of the photographer than any other yet published. I now give a summary of that correspondence. Of the innumerable developers which have from time to time been promulgated, the principal survivors seem to be pyro. and ammonia, pyro. and washing soda, and ferrous oxalate. Hydrokinone I do not include, as its price, if nothing else, would probably prevent its general adoption. But to each of the developers which I have mentioned there exists some objection. The pyro. and ammonia developer gives off noxious fumes, and in cases of prolonged development causes stains and fog in the negative. Of the washing soda I have had no experience, but I see from the photographic journals that complaints are largely made that the negatives produced by it are apt to be yellow. The objection to the ferrous oxalate is that it is non-elastic; there is no latitude for exposure, and, in my experience, prolonged development produces iridescence, especially round the edges of the plate. The potash developer of Mr. Beach, however, seems to be free from these objections. The published formula is—

Pyro. Solution.

	Warm distilled water	2 ounces.
	Sulphite of soda (chem. pure)	2 ,,
Dissolve. When cold add—		
	Sulphurous acid	2 ounces.
	Pyrogallic acid	½ ounce.

Potash Solution.

A	Water	4 ounces.
A	Carbonate of potash (chem. pure)	3 ,,
B	Water	3 ,,
B	Sulphite of soda (chem. pure)	2 ,,

Combine A and B in one solution.

For a 5 × 4 plate with instantaneous exposure, take one and a-half ounce of water, two drachms of pyro. solution, and one and a-half drachm of potash solution. The advantages claimed for this developer are—that with it plates require less exposure, that it does not give off any deleterious fumes, that it does not fog or stain the negatives, it needs no restrainer, but is simply modified by dilution to meet over-exposure where necessary. Complaints have been made by some workers that this developer causes the plates to frill. I can only say that I have not found it to do so, and I do not use alum until after fixing, when I put the plates in a chrome alum bath for a few minutes. You will observe that chemical purity is strongly insisted on in the formula given; but I may tell you that in making my solutions I used the ordinary commercial qualities of the different salts, and while this may be the reason of the dark colour of my pyro. solution I do not find that the developer works any the worse. I had intended to bring plates with varied exposures, but yesterday afternoon when I began to prepare for tonight the sun had disappeared, though the air was clear, while the wind was so high that my camera would not stand without being held, and an accident to my shutter rendering it useless, I had to make the exposures as rapidly as possible with one hand, while I held the camera with the other. My lens was an old French stereoscopic doublet, with a focus of four inches; and the aperture of the stop I used was a-quarter of an inch in diameter for the first plate and three-sixteenths for the rest. The plates are Britannia plates.

A discussion on the question—*Has the Introduction of the Modern Gelatine Dry Plate been Advantageous?* was to have been opened by Mr. J. Howie, who, it was understood, would have replied in the negative; but, as he failed to make an appearance,

Mr. W. Crooke said that from all points of view he considered the modern gelatine plate had been of immense advantage. For landscapes and studio work they enabled subjects such as moving objects and passing expressions to be captured that could not be seized by collodion; but for reproductions of engravings and similar objects requiring strong contrasts, he believed collodion still maintained its supremacy.

Members were reminded to send in specimens of work for the annual display which takes place at next meeting. These should be in the hands of the Curator not later than the day before the meeting (Tuesday, 4th November), so as to allow of their being hung properly.

A vote of thanks to the Chairman terminated the proceedings.

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

The first monthly meeting for the session 1884-85 was held on Thursday, the 2nd inst., in Lamb's Hotel, Dundee,—Mr. J. C. Cox, President, in the chair.

After the routine business had been disposed of,

The President delivered his annual address as follows:—I have no intention, as I am credited with in the circular, of giving an address; but you will expect from me a word of congratulation on this the opening night of our fifth session. Before I do so allow me to refer—and it is with regret—to the loss our science has sustained by the death of several prominent workers, namely, the Rev. F. F. Statham, who was twenty-five years President of the South London Photographic Society; Mr. H. Baden Pritchard, editor of the *Photographic News*; and Mr. C. Jabez Hughes—whose names were honourably associated with the literature of photography. Of these our immediate connection lies with Mr. Pritchard, who, as you will remember, so kindly acted as one of the judges at our highly-successful photographic exhibition three years ago, and whose decisions gave the utmost satisfaction. He was a staunch supporter of everything tending to the advancement of photography, and we cannot but lament his early death. Nor can I but notice the decease of Mr. Colin Sinclair, of Edinburgh, who also kindly gave his services as judge at our exhibition. The report of this Society, which you have before you, and which I understand is to be taken as read, must, if we look back two or three years, convince us that it is thriving beyond expectation both in regard to membership, attendance, quality of work produced, free offering of papers on interesting subjects, and last, but by no means least, the credit at our bankers. Not the least of our success, I may say, is due to our young Secretary, Mr. D. Ireland, Jun., who is an enthusiast himself, backed up by his friends, the Committee of Management and the members in general. He certainly has worked well for the Society, and he means, I have no doubt, to still further increase his usefulness. I have to ask you to accord him a vote of thanks, and the same to our worthy Treasurer, Mr. J. Robertson, and to our Auditors, Mr. Baxter and Mr. Rodger. The School of Photography, established in Regent-street, by the Polytechnic Christian Institute, is quite a sign of the times. The following extract I take from an *Art Magazine*:—"Here the amateur may obtain that practical knowledge which far outbalances all theoretical reading, and after one course of lessons—which are gratuitous—may execute work in which he may well take pleasure, besides thoroughly mastering the principles of the art. Indeed, more may be learned in one lesson at the School, by reason of the excellent practical method followed, than by the study of all the wilderness of manuals. The application of photography is now so extended and varied, and its practice so simplified, that it appeals to all classes and professions, as well as to those who are attracted to photography for its own sake. With ladies, too, it is fast becoming a veritable hobby. It involves no risk of accidents—of burnt and blackened hands, and injured dress." This, gentlemen, is what has been established in London, and we as a Society might follow the Regent-street school, though in a much less degree, by offering practical lessons, even at a small fee, in at least the rudiments, as a trial. I think we should find out from among us if anyone would undertake this. One or two passing remarks, and I am done. Why is it that we have been unable to induce ladies to join this Society? We have to blame ourselves—not them. You may tell me we have tried them; but they reply—"It is no good joining your Society, for we do not understand. I rejoin—"Form the class of rudimentary demonstration I have hinted at, and then there will be some inducement for them to join us." They do not, like numerous gentleman amateurs, want the theory of working; they wish to know merely how to go about things correctly, without asking the "reason why." I do think this is worth our consideration. I should also like at this meeting to broach the idea of holding another exhibition, and I think that at next meeting we should have a discussion on the advisability of arranging another one.

Mr. G. D. Macdougald then read an interesting and able paper on *Chemistry and Photography*, on which some discussion ensued, and for which a hearty vote of thanks was awarded. [This paper will appear in our next number.]

It was remitted to the Council to make arrangements for a series of lecturettes, to be given at the monthly meetings, on different branches of photography.

An inquiry was found in the question-box as to whether better results were obtained by washing prints thoroughly before toning, and it was agreed that although the toning was quicker in the case of an imperfectly-washed print, still most of the tone was lost in fixing. A washing of about half-an-hour in the case of ready-sensitised paper was recommended.

A vote of thanks to the Chairman brought the meeting to a close.

COVENTRY AND MIDLAND PHOTOGRAPHIC SOCIETY.

A meeting of this Society was held on Thursday, the 2nd inst., Mr. Councillor Andrews in the chair.

The minutes of the previous meeting having been read and confirmed,

The Chairman showed a very portable camera stand made out of three bamboo fishing-rods, which was greatly admired by the members present on account of its lightness and simplicity of construction.

Mr. T. Baynton, who had promised a communication on *Practical Dry-Plate Development for Beginners* for this evening, having been called upon by the Chairman, said:—"Mr. Chairman and gentlemen,—I am not here this evening to advertise the 'Coventry' plate, of which, as you know, I am the manufacturer; neither am I here to give information or instruction to you, Mr. President, and many other gentlemen I see around this table. I am here, however, at the request of the Secretary for the purpose of demonstrating to beginners a simple and satisfactory method of development, by which the veriest beginner can produce good negatives; and I may here say that there is nothing novel either in the formula or manipulation."

A negative and print from the same was here passed round, the President and members present observing that it was equal in pluck, detail, and brilliancy to a fine wet-plate negative.

The formulæ used by Mr. Baynton are as follow:—

No. 1.

Citric acid	20 grains.
Water	20 ounces.

No. 2.

Am. fort. ·800	1 ounce.
Pot. brom.	100 grains.
Water	3 ounces.

Into two ounces of No. 1 put four grains of pyro.; add one drachm of No. 2, and immediately flow over the plate.

The meeting then adjourned to a large and well-appointed dark room to witness the demonstration.

Mr. Baynton remarked that he had several plates exposed on the same subject as negative and print shown—*A Dilapidated Cottage, Out-houses, and Neglected Garden.* The exposures were made in sunshine—time, half-a-second. He (Mr. Baynton) here said—"Now, gentlemen, which shall I make first—a thick or thin negative, or one of printing density?" [The meeting decided to have one of proper printing density first.] The solutions were measured and at once thrown over the plate, the dish being kept in motion. In a few seconds the high lights were seen, and gradually the whole image was brought out. The developer was allowed to act until the shadows were considerably coloured, the operation lasting two and a-half minutes. After fixing and slight washing, the negative was placed in a saturated solution of alum, to which some protosulphate of iron had been added and again slightly washed. It was now handed round for inspection, the members declaring the result to be perfect. Another plate was developed. The solutions were of the same strength, but the development was stopped earlier, or before the shadows lost any of their brightness. He (Mr. Baynton) remarked that many amateurs would consider development in this case complete; but he would show them that the result would be plenty of detail, but a want of density. [The result was as stated.] Another plate was now placed in a dish, the solutions being half as strong again. This time the development was carried on until the shadows were completely obliterated, the result being an extremely thick, dense, but clean negative.

The meeting then adjourned to the light, and

Mr. J. M. Danks, in proposing a vote of thanks to Mr. Baynton, remarked that although that gentleman said the introduction of iron into the alum was nothing new, it was certainly a "wrinkle" for him; and, from what he saw of the tone produced thereby, he thought it was just the thing for transparencies.

It was decided to devote the next two or three meetings to the question of development, as required by plates wrongly exposed. Mr. Baynton promised to develope some transparencies at the next meeting.

Correspondence.

THE ETHOXO-OXYGEN LIMELIGHT.

To the Editors.

Gentlemen,—Mr. Broughton's statement in regard to the possible "catching fire" of my patent ether saturator is calculated to produce a false impression.

Your readers should understand that it is not only free from danger (the flame can be instantly smothered with a handkerchief), but it cannot possibly occur except under circumstances which would cause a really dangerous explosion with saturators which have no porous filling. Even the best safety tubes have such objectionable features that only those who are afraid will use them; so it is very desirable to have a saturator which even a careless operator can use without them, and feel sure his life is not in peril. My saturator has this merit, together with that of giving a *perfectly steady* light, with no obstruction to the flow of oxygen.

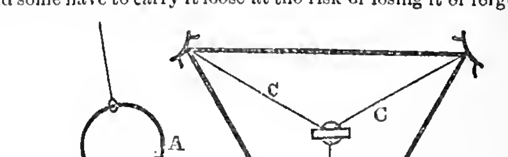
Mr. Broughton appears to insinuate that I "praise" my own invention; but I certainly have not misrepresented it, and my claims will be allowed by everyone who knows all the facts.—I am, yours, &c.,

Philadelphia, September 23, 1884. Fred. E. Ives.

THE CAMERA SCREW.

To the Editors.

Gentlemen,—Several of your correspondents seem to find a good deal of difficulty in rapidly placing the screw which attaches the camera to the stand, and some have to carry it loose at the risk of losing it or forgetting it.



B, Collar on screw. The split ring, A, must just pass over this; when the three small rings are put on, it cannot come off again. C, String.

I have fastened mine to the triangle, as shown in the diagram, and never find any difficulty or delay in setting up for a "shot." It is always in its place.—I am, yours, &c., A. Corbet.

Adderley Rectory, Market Drayton, October 4, 1884.

THE TRICYCLE AND THE CAMERA.

To the Editors.

Gentlemen,—An article appeared in your last issue on *Where to go With the Camera* and photographic trips on tricycles, which is interesting, but the author does not say the size of plate or apparatus used or the kind of tricycle he rode. I think it would be always better, especially to riders, if that were mentioned; for I carry a whole plate set on my rotary "Coventry," and find twenty to thirty miles quite enough for one day's work, although I have gone fifty miles and over occasionally. The weight, with two double slides and a dozen extra plates—which I change in a bag, and which I also use for a focussing-cloth—is about thirty pounds, with stand.

I have always made my own plates with much success, and several batches I have made from Mr. A. F. Genlain's formula—which appeared in THE BRITISH JOURNAL OF PHOTOGRAPHY of July 13, 1883, page 403—without a single mishap. I am now using plates twelve months' old, and find them equal to others freshly made. I develope with Martin's formula, which, in my opinion, cannot be beaten.—I am, yours, &c., W. CLARK.

31, *Coventry-street, Brighton, October* 6, 1884.

EDWARDS'S MACHINE FOR COATING PLATES.

To the EDITORS.

GENTLEMEN,—I am pleased to see by your last issue that your correspondent, Mr. S. Fry, has concluded to abandon the blustering tone of his previous communications. His last mild effusion, although containing assertions about as accurate as his former statements, needs no special reply from—Yours, &c., B. J. EDWARDS.

Hackney, London, October 6, 1884.

[This letter must close the correspondence.—EDS.]

THE CAMERA OF THE FUTURE.

To the EDITORS.

GENTLEMEN,—As regards the alleged haste of camera-makers to meet the wants of the public: how is it that, although the necessity for a falling front has been known and felt for years, also the necessity for about double the length of motion for the rising front than that usually allowed, these benefits have never been obtained, although they involve but a trivial amount of carpenter's work?

I sympathised a few years ago with Mr. Donkin in his narrative of how he had to hack his new camera about to get a falling front.—I am, yours, &c.,

October 8, 1884. W. H. HARRISON.

[We think that Mr. Harrison overlooks the fact that *many* of the cameras of the present day provide the means of lowering as well as raising the lens; and some of them possess this property in a very marked degree.—EDS.]

DEVELOPING FORMULÆ.

To the EDITORS.

GENTLEMEN,—In reference to the leader on *Anomalies in Developing Formulæ*, in your last number, perhaps the following may be of interest.

I have been doing little but experiment in the spare time I have had for the last six months, trying to get a developer that would give me the density I wished for. I tried numerous combinations with iron, and ultimately gave that up. I then went back to a combination with pyro., but gave that up, and now I have been using various makers' plates, with *one* developer, *without* ammonia ·880, *without* bromides, *without* pyrogallic or iron, and think I have got what I want.

I hardly like to be too confident at present as to my success, but an over-exposed plate does not give a *thin* result, but the dense result of the old wet plate, and no fog either with under- or over-exposure.

If it be likely to be of interest—which I shall see by the insertion or otherwise of this—I will next week give the developer; one component of which, by the way, is not quite new.—I am, yours, &c.,

Greenhithe, October 8, 1884. W. T. F. M. INGALL.

[We shall be very glad indeed to publish our correspondent's new developer.—EDS.]

Notes and Queries.

IN reply to a query by "J. S.," we have to state that, if our information be correct, several leading dry-plate manufacturers in the United States of America are of European birth. Cramer is a German, Carbutt an Englishman, Inglis a Scotchman, and so on with others.

"PLEASE give, in your next Journal, the meaning of 'orthopanactinic.'—H. B. SHARP."——In reply: Without going into the etymology of the term, it is intended, in its application to a lens, to signify that such lens produces pictures that are rectilinear, or free from distortion.

"IN using Chadwick's oxygen generator for the lime light I have at times been troubled with the jet gradually stopping up during an exhibition. Has any other reader been troubled in the same way? Can anyone suggest a remedy? I have tried lime in the water of the gas holder, but that does not cure it.—OXYGEN."

W. COTESWORTH writes:—"Mr. Hammerton, in his book, says that one disadvantage of silver point work is that it cannot be reproduced by photography. I have tried a head on pure white paper (I enclose result). I find that with this most delicate of all pencil work great care is required, and I cannot reproduce it with a pure white ground, as in the original, with gelatine plates. Query: do you consider it possible to obtain the density and pure white ground with gelatine? Would it not be quite possible, and, indeed, not difficult, with collodion?"——In reply: We imagine that this class of work should be done by collodion rather than by gelatine. The greatest possible intensity must be obtained—such an intensity as, for instance, can be produced by the agency of bromide of copper applied as a bleaching agent, followed by an application (after washing) of solution of silver nitrate; or of bleaching by means of diluted hydrochloric acid with bichromate of potash, followed by an application of solution of Schlippe's salt. Either of these would ensure a white ground being obtained.

OPERATOR writes requesting us to furnish him with a formula for compounding a developing powder for wet collodion negatives.——In reply: A developing powder consists of protosulphate of iron mixed with other ingredients, all of which are crushed and mixed in a mortar. It is altogether impossible to give the composition of any of those powders which, at one time or another, have been placed on the market; but we have heard of one that was stated to consist of a mixture of eighty grains of acetate of soda, one hundred grains of loaf sugar, and three hundred grains of protosulphate of iron—all finely powdered and intimately mixed—this proportion being intended to be dissolved in a pint of water.

"SCOTLAND" says:—"I have bought a stock of negatives belonging to a photographer who has been sold up by order of the Sheriff. Amongst these negatives are some copyright ones. The copyright is mine now, I suppose, to publish from these negatives, now my property."——In reply: Our correspondent is wrong. The negatives are his, because he purchased them in an open and legal manner; but unless he has had the copyrights of these negatives properly transferred to him he cannot make any use of them whatever. If he issue so much as a single print the proprietor of the copyright, whoever he may be, can come "down" on him without ceremony and lay an action for damages. See and get the copyright in these pictures assigned at once, and then the negatives may be utilised without fear.

Exchange Column.

No charge is made for inserting these announcements; but in no case do we insert any article merely OFFERED FOR SALE, *that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a* NOM DE PLUME *be thought desirable), otherwise the notice will not appear.*

Wanted, a dark slide for my half-plate camera, in exchange for either chemical or electrical apparatus or books.—Address, CHEMICUS, 50, Coltart-road, Liverpool.

I will exchange THE BRITISH JOURNAL OF PHOTOGRAPHY for *Photo. News*, posted on Monday; also set of gramme 50 to $\frac{1}{100}$ gramme.—Address, H. GOVER, 101, Waterloo-street, Hanley.

I will exchange, for anything useful in photography, a rolling-press, almost new, with 12 × 8 polished bed, and a background, one side plain and the other exterior.—Address, J. EDWARDS, 79, Ashford-road, Eastbourne.

What offers for THE BRITISH JOURNAL OF PHOTOGRAPHY from January 1st, 1877, to present date? Wanted, whole-plate view lens; difference adjusted.—Address, G. H. E. SUTTON, 64, Oak-terrace, Sycamore-road Nottingham.

I will exchange Cook's tourist camera, by Elliott, changes twelve plates $7\frac{1}{4} \times 4\frac{1}{2}$, with lenses complete; also portrait lens, for whole-plate or 10 × 8, four-inch diameter, twelve-inch back focus. What offers?—Address, G., 2, Eardley Villas, Eardley-road, Streatham, S.W.

I will exchange a magnificent excelsior folding tricycle (folds to twenty-seven inches), nearly new, cost, with accessories, £23, for a 12 × 10 bellows-body camera and a 4D Dallmeyer's lens. Send specimen of work. —Address, J. T. FIELD, 8, Montpelier-row, Blackheath, S.E.

I will exchange a 10 × 8 brass-bound Kinnear camera, swing-back, &c., with changing-box for same, by Rouch, and fitted with a Ross's 10 × 8 medium-angle doublet. Wanted, a whole-plate portrait lens by Ross or Dallmeyer.—Address, MANAGER, Meadow's Studio, Arkwright-street, Nottingham.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

NOTICE.—*Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a* NOM DE PLUME *as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.*

PHOTOGRAPHS REGISTERED.—

Thomas Roberts, Bradshawgate, Leigh, Lancashire.—*Photograph of Henry O'Connor, S.J.*

John Hodge, 31, Union-street, Stonehouse, Devon.—*Photograph of the Interior of Plymouth Guildhall.*

George Washington Wilson, Queen's-cross, Aberdeen.—*Group Photograph of Mr. and Mrs. Gladstone, Lord and Lady Aberdeen, and others; also Group of Mr. and Mrs. Gladstone, Lord and Lady Aberdeen, Miss Gladstone, Lord Haddo, and Lady Marjorie Gordon.*

MEADOW.—Your query was answered in our issue of August 22nd, at page 544.

T. WALLACE.—Write to Dr. Liesegang, of Dusseldorf. We believe he supplies the paper.

R. A. DUNN.—The plates show a marked example of the so-called "Coignet spots," and in an exaggerated degree; indeed, it is about the worst specimen we have seen for some time. Discard the gelatine and try another sample.

T. A.—You should have acidified the bath after sunning and filtering. The fog is fully accounted for by your omission.

GINGER.—1. We have had no experience with the paper. You had better write to the manufacturer.—2. The Royal Academy opens the beginning of May next.

J. T. CLARK.—Dissolve the gold in a mixture of one part of nitric to three of hydrochloric acid. Do not use more of the solvent than is actually necessary for the solution of the metal.

A YOUNG BEGINNER.—You should experience no difficulty in the operation. If air-bubbles get imprisoned press them out with a squeegee or with the finger. With care, however, none need be formed.

G. FOXALL.—The appearance is probably due to the efflorescence of alum used in the preparation of the emulsion. No doubt if you had examined the plates carefully before exposure it would then have been perceptible.

A.—The spots are caused by the silver paper being pressed in contact with the negative while it contained hyposulphite of soda. The only method of avoiding them in future is to wash the negatives more perfectly than you have done hitherto.

J. J. EMANUEL.—The stains on the prints are clearly due to careless manipulation, chiefly caused by being handled with fingers contaminated with hyposulphite of soda while they were being washed to free them from the silver, or whilst they were in the toning solution.

THE PHOTOGRAPHIC EXHIBITION.—We regret that some of the exhibitors in Pall-mall should think fit to write requesting "a notice" of their exhibits. We regret it because it is a certain means of securing their entire omission from mention of any sort, favourable or otherwise.

J. R. WILSON.—Do not remove the prints from the mounts, but carefully wash off the dirt with clean water and a soft cloth. Arrange the pictures so that they are illuminated with a strong *side* light, and copy in the ordinary way, giving a full exposure and making the negative tolerably dense.

CELT.—1. The knowledge can only be acquired by experience.—2. If the pictures are *really* taken instantaneously there will, of course, be no necessity.—3. About the same, or a little longer. Why not try the experiment by developing two plates side by side? It would increase your experience.

PRINT.—Touch out the spots with oil colour, thinned with rectified spirit of turpentine. Use the colours sold in tubes by the artists' colourmen. These, when thinned with the turpentine and applied sparingly with a sable pencil, will dry in a very short time, and will not be removed when the print is enamelled.

T. D. P.—The charge is certainly not excessive, if the instruction be good. You may, with perseverance, teach yourself photography. Whether you receive instruction or teach yourself you must bear in mind that considerable experience will be necessary before you can successfully practice photography commercially.

J. W.—From what we recollect of the scene the picture must be taken pretty early in the day, otherwise the glen will not be artistically illuminated. Without this the photograph will possess but little merit compared with those of the same subject which are to be found in the shop windows. The subject is a difficult one to deal with.

DYNAMO.—1. Such a machine will yield a light suitable for portraiture.—2. One of Siemen's lamps will be about the best for the purpose. A less expensive contrivance may be made to answer, but you will then have to regulate the carbons by hand.—3. It is simply a concave reflector, somewhat like a large umbrella, lined with white paper or even whitewashed on the inside. This contrivance you can make for yourself.

S. E. K.—1. Any of the so-called slow combustion stoves will be suitable. The one mentioned by you is very convenient; but no stoves of this character are adapted for cooking purposes.—2. With a good paper, sensitised on a plain solution of nitrate of silver slightly acid, there should be no difficulty in keeping it from one day to another.—3. Write the name of the subject on the negative neatly with black varnish. It will then appear in white letters on the prints.

X. Y. Z.—1. The colour appears to be all right—at least for this season of the year. Darker may be required in the height of summer.—2. Stop off nearly all the top and front light, and rely more upon the side light.—3. The coarseness is due to injudicious lighting. You have built a studio in which you are clearly unable to manage the light successfully. Such a studio is certainly capable of yielding good results in skilful hands; but it is of a form that is the most difficult to manage, so as to get the best and most uniform effects under all conditions.

RECEIVED.—J. D. England; Henry Holman. In our next.

HOLDER FOR THE *CARTE* PORTRAIT.—To the numerous devices for supporting a *carte* or cabinet in a leaning direction on a table or shelf Messrs. Richards and Wilkinson, of Birmingham, have added another, which, being well made, will compete seriously with those flimsy foreign productions to be seen so commonly in toy shops and bazaars.

ALBUMENATE OF SILVER.—Herr O. Löw has, says the *Archiv*, thoroughly investigated albumenate of silver. In the dark, in an ammoniacal solution of nitrate of silver, albumenate of silver does not change, and it is not until heat is applied that a reddish-brown substance is precipitated, which redissolves in ammonia, and from which it may be re-precipitated by dilute sulphuric acid. It is also soluble in excess of the acid as well as in all dilute alkalies, but it is insoluble in alcohol and in water. If the reddish-brown substance be digested in baryta water or in muriatic acid the greater part of the silver will be thrown down in the metallic state. The nitrogenous substance remaining in the solution possesses the reactions of peptone. Quantitative analyses of albumenate of silver showed a variable quantity of silver, depending upon the duration of the digestion and on the amount of nitrate of silver present; usually, however, it was about thirty-two per cent.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 15th inst., the subject for discussion will be *On the Collodio-Albumen Process as Applied to the Production of Transparencies for the Lantern and for Enlargement.*—To-morrow, Saturday, the 11th inst., there will be an outdoor meeting on Wimbledon Common, leaving Waterloo Station by the first train after 2 p.m. for Putney Station, to meet at the Windmill on Wimbledon Common.—Visitors to the Exhibition of the Photographic Society are invited to the Wednesday evening meetings at Anderton's Hotel, Fleet-street.

NEW EXPEDITION TO THE CONGO.—The *Mittheilungen* says that Lieut. Schulze, the commander of the German expedition to the Congo, spent the last few weeks of his stay in Berlin learning something of practical photography at the Technical High School, and took with him a first-class outfit of photographic apparatus. The exposed plates are to be sent to the laboratory of the Technical High School, Berlin, to be developed. The other members of the expedition, which sailed from Hamburg on the 1st August, on the steamer "Professor Woermann," comprised a topographer, a physician, an anthropologist, a botanist, a zoologist, and a mineralogist, in the persons of Lieuts. Kuno and Tappenbeck, Drs. Wolff and Büttner.

ON STRIPPING-OFF GELATINE NEGATIVE FILMS.—In the *Bulletin de la Société Francaise* M. Bory recommends dipping the plate bearing the negative to be stripped off into a very weak solution (say 1 to 50 to 500) of fluoric acid, washing well first in spring water, and then in distilled water. To prevent expansion of the film he recommends hardening it in alum for several hours. He finds that in stripping negatives in this way retouch in lead pencil is not injured by the washing. In order to get the gelatine film free it should be gradually removed from the glass while in the alum bath after it begins to come off and to dry. He also recommends a dilute solution of fluoric acid for cleaning glass bottles and other vessels. The best cures for injuries caused by fluoric acid are, he says, aqueous solutions of ammonia or borax. Fluoric acid is generally considered rather a troublesome and dangerous substance for unskilled persons to meddle with, though that objection may not be valid for such very dilute solutions as that mentioned by M. Bory.

A TONING BATH FOR COLLODIO-CHLORIDE PRINTS.—The *Archiv* says a solution of acetate of soda in water, to which a little dilute solution of chloride of gold is added just before toning, is an excellent toning bath for collodio-chloride of silver prints. It is not advisable to prepare at first a bath containing one gramme of chloride of gold to one or two litres of water, as in a few days its toning power would suffer, and one would be constrained to add fresh gold solution. It is more economical not to add more gold to the bath than is required to colour the number of prints to be toned. It is, therefore, recommended to prepare two solutions—one containing thirty grammes of twice-dissolved acetate of soda in one litre of water, the other containing one gramme of brown chloride of gold in three-quarters of a litre of water. The first of these solutions is intended for constant use, and is to have a certain quantity of the gold solution added to it before each time of using. The excess of gold, which in time falls to the bottom of the bottle, is allowed to remain there until a quantity sufficient to make it worth while to redissolve has collected. In this way there is extremely little gold actually lost. The gold solution itself does not precipitate any gold, and, like the soda solution, keeps an unlimited time. About an hour before beginning to tone, a quantity of gold solution should be added to the latter. This quantity will be larger or smaller according to the superficies of the prints to be toned and the bluer or redder tone desired. A little practice will soon enable one to judge of the quantity required. Should the prints tone too slowly in consequence of too little gold having been added they may be removed and a little more added, though when there are many prints to be toned it is best not to put in more gold than sufficient to tone them in about five minutes. The toning may be checked at any moment as with silver prints, and the print should not be washed, but transferred at once into a fixing bath of one litre of water to fifty grammes of hyposulphite of soda.

CONTENTS.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1276. Vol. XXXI.—OCTOBER 17, 1884.

THE SODA DEVELOPER AND SULPHITE OF AMMONIA.

Mr. William Hanson's article in our last number is a valuable contribution to the discussion which has been going on for some time on the above subjects both linked and singly; and the views of so old and experienced a practitioner deserve the closest attention. Mr. Hanson's conclusions are arrived at as the result of practical experience, and with their ultimate accuracy we perfectly agree; but we would offer one or two suggestions in connection with our contributor's theoretical deductions.

The first point mentioned by Mr. Hanson is that most of the substitutes for ammonia developed too slowly, or gave an image of an unpleasing colour. With regard to the former statement, we think from our own experience that it will scarcely be found to be borne out by fact, if the same degree of alkalinity be observed in the different solutions. It is quite possible that in using carbonate of soda — or other carbonated alkali — even in comparatively strong solution, there may be a less feeble developing action than with an apparently weaker solution of caustic ammonia. As regards the latter fault there is, perhaps, more reason to complain; but, as there are many who successfully employ soda in spite of the complaints made by others of yellow stains, it is probable that the truth lies in the fact that we do not yet know how to use it properly.

The superiority of sulphurous acid over others, such as citric or boracic, we can also readily endorse, since the salts of the two latter are known to be powerful restrainers of development; while sulphurous acid and its salts are reducing agents, and as such—especially the salts—actually aid development instead of retarding it. In proof of this we have shown that pyro. and sulphite of soda alone, without ammonia, soda, or other alkali, are capable of very satisfactory development. Free sulphurous acid would, no doubt, have a similar effect but for the superior restraining power it possesses by virtue of its acidity, weak though that may be. But it must be observed that the superiority noticed by Mr. Hanson, when using carbonate of soda in conjunction with sulphite of soda and sulphurous acid, may be due to the absence of restraining sulphates, citrates, *et hoc genus omne*, rather than to any specially beneficial action of sulphurous acid.

Then, again, in reference to green fog, which is supposed to be prevalent with certain plates when ammonia is used and to disappear when carbonate of soda is substituted: if, as there seems now little reason to doubt, green fog be a silver stain any substance employed in the developer which is capable of dissolving silver bromide will tend to the production of this defect. Looking at the question from this point of view, both ammonia and sulphite of soda are solvents of bromide of silver, and hence both capable, under favourable circumstances, of causing green fog. Sulphurous acid is not—or, at least, to so slight an extent as to be practically inappreciable—a solvent of the silver haloid, and it is therefore practically free from that tendency; and sulphite of ammonia, which exercises a far less solvent action than the corresponding sodium salt, therefore offers a chance of greater immunity from the evil.

The combination of ammonia with pyro. and sulphurous acid is, therefore a better one than ammonia with pyro. and sulphite of soda, or carbonate of soda with pyro. and sulphurous acid, which last combination, of course, results in the formation of sulphite of soda, and consequently reintroduces the tendency to produce green fog. The fact that Mr. Hanson obtained green fog with a carbonate of soda developer containing sulphite of soda is no more surprising than that an ammonia developer should produce the same result. In either case the necessary silver solvent is present, and it only requires that the exposure should be short enough, or the development sufficiently protracted, in consequence of other retarding influences, to bring out the green fog in all its strength.

The theory propounded by Mr. Hanson that the combination of ammonia and soda in the same developer is the cause of green fog requires some further proof. The result obtained in the case quoted by him can be more simply explained by reference to what has been said above. He uses carbonate of soda (*plus* sulphurous acid) in conjunction with pyro. and sulphite of ammonia. The result of such an admixture is to form sulphite of soda, and probably to liberate a quantity of ammonia. It may, perhaps, truly be said that the effect is produced by the mixture of the alkalies, but the conjunction of the *quasi* innocuous carbonate of soda with the equally harmless sulphurous acid would quite suffice to explain the trouble.

The recommendation to use as little sulphurous acid as possible is a good one, but we must dispute the correctness of Mr. Hanson's reason for this advice. He says * * * "*the sulphite of soda* formed in the developing solution powerfully retards its action, as may easily be proved by omitting the acid, when it will be found that development goes on with great energy, rivalling pyro. and ammonia." We have already shown that sulphite of soda does not "slow" development, provided it be not oxidised into sulphate. Sulphurous acid may, however, have a slowing action, but not in the way suggested. Carbonate of soda is a more powerful agent in development than the sulphite; hence, if a portion of the former be converted into the latter then the developer is weakened. Add to this that the carbonic acid liberated in the operation will—some of it at least—remain in solution. Carbonic acid being a restrainer, we have now a weakened and restrained developer, which will answer to Mr. Hanson's result without calling in any retarding action of sulphite of soda.

The substitution of sulphite of ammonia is a step in the right direction; but so long as either ammonia or soda, or both, may be used, so long will it be impossible to completely guard against green fog. So far as the retarding of the developing action is concerned, that can be overcome by employing pure sulphite of soda or freshly-made sulphurous acid. The chemical knowledge and experience involved in the manufacture of sulphurous acid or of sulphite of soda is so small that we would almost advise our readers to make these substances fresh whenever required.

MOUNTING LANTERN SLIDES.

Among several subjects brought forward for discussion at the last meeting of the London and Provincial Photographic Association that of the most suitable means of mounting lantern transparencies elicited the greatest amount of interest.

There are some slides which, while beautiful in themselves, are yet mounted in such a slovenly manner as to seriously detract from their saleableness and appearance while in hand. In other cases the paper bindings get frayed and torn away from the glass before the slides have been many weeks in use. To those who are not professionally engaged in the manufacture of lantern slides the subsequent mounting is the *bête noir*—the fly in their pot of ointment. It is no uncommon thing to hear a photographer say—"I will make as many transparencies as you like, but absolve me from having to mount them."

And yet the mounting is a sufficiently simple matter when analysed. You take hold of the photographic transparency, place a suitable mat upon it, cover it with a clean glass, and run a strip of binding paper round the edges. That is all. It is this strip of binding paper that causes trouble. No matter what skill and time are involved in its application, in many instances a day will not have elapsed ere it splits away from the glass, and the disgusted neophyte concludes with some bitterness that there is something about the glass which is repellent of paste.

There are two important points to be observed in the mounting of a transparency. One is to obtain a suitable paper for the purpose, the other being to avoid pure gum arabic as a paste. A solid-bodied paper with a glazed outside surface looks well; but one of this class, suitable for the purpose in question, is not to be procured in the open market. It is requisite that the binding paper be soft enough, and of a texture sufficiently open to absorb the mountant and to become quite flaccid when moistened with water or with the paste that is to be applied. This state of flaccidity is of vital importance, as otherwise the paper will not remain in contact with the glass plates when sharply bent round their edges.

One manufacturer stated at the meeting referred to that, such was the difficulty he had experienced in obtaining binding paper of a character entirely suitable, he had to get it prepared specially for his purpose at a cost greatly in excess of that at which apparently similar paper could be procured. The paper known as "needle paper" was advocated by another maker as being well adapted for mounting. It is of a good colour (very dark blue) and becomes quickly flaccid when wet, being hard and strong when dry. Paper of that class, we may observe, is extensively employed for this particular purpose.

A thin black paper of the consistency of thick tissue paper has been employed with a considerable amount of success. Being thin and porous it adheres to the glass most tenaciously. Hardness is imparted, after it has become quite dry, by passing over it a camel's-hair brush charged with ordinary negative varnish. One gentleman, who prepares many slides for his own use, expresses an opinion that this forms a somewhat better mounting paper than any other he has yet employed.

The next important consideration is that of the mountant. We have said that pure gum must be avoided. Paper which has been coated, no matter how thickly, with mucilage composed of gum and water alone will inevitably crack away from the glass before long. This, however, may be rectified by mixing with it a little sugar or glycerine; but it is this addition of sugar that constitutes all the difference between success and failure. A handy way of preparing binding paper by its agency is to have the paper cut in sheets of the width of thirteen inches—assuming the slide to be of the usual dimension of three and a-quarter inches square—and then coat one side thickly with the saccharated mucilage. When dry it is cut into strips of the width of three-quarters of an inch—more or less to suit the taste; but whether the width be short of this, or in excess of it, uniformity should always be adhered to for the sake of appearances. A supply of these strips should be kept in readiness.

The mounting of a transparency by the agency of such strips is really a very simple matter. A strip of the coated paper is rendered flaccid by being drawn over a postage stamp damper, a sufficient duration of time being allowed to elapse in order to ensure the desired end being effected. This may with some papers be one minute, although a period of two minutes will probably be required in most cases. The transparency and its cover, with the mat intervening, having been grasped by the fingers and thumb of one hand, the strip of paper is laid down, gummed side up, on a suitable pad lying on the table. This pad may consist of a few sheets of blotting-paper or of any similar body. Bringing one corner of the glasses, which are held edge up, down upon the extreme end of the strip, they are pressed down as nearly in the centre of the strip as possible, and rotated so as to wrap the paper entirely round their edges, the final end of the strip (if such an expression be allowed) joining the commencement end. By the finger and thumb of the disengaged hand the paper is now bent over upon the sides and pressed into close contact with the glass, a little care being taken so as to get the corner portions to neatly overlap.

Common flour or starch paste is sometimes employed with most excellent effect. When this is the mountant, the strips of paper should be softened by being sponged with water previous to the paste being brushed over it; for it is doubtful if the paste itself would render it sufficiently flaccid to fold over as nicely as could be desired, unless in the case of very thin binding paper. This class of paste adheres well under the various viscissitudes to which a lantern slide is subjected.

A hint was thrown out by Mr. W. Teasdale, of Leeds, who was a visitor at the meeting to which reference has been made, that certain Birmingham manufacturers would not be averse to making preservers of thin brass for the special purpose of mounting lantern slides, provided they imagined that there would be a demand for them. This, if done, would prove an inestimable boon to those of the photographic fraternity who indulge in lantern work. The facility of mounting, the neatness of the finished picture, and the ease with which a picture could be dissected in order to effect any change either in itself or in its mat, are all features which will approve themselves to the photographer. We hope, therefore, that before long we may be in a position to announce the advent of these long-needed, much-to-be-desired lantern slide preservers. Then the production of these transparencies will be indeed a pleasure.

PRACTICAL HINTS ON MOUNTING AND PLATE-MARKING.

It will be remembered that a few weeks since we gave some practical hints on the artistic mounting of photographs. The method then described was that of mounting the pictures on "linen and stretcher," which is suitable, chiefly, for those of the larger dimensions. We, however, promised to revert to the subject and give some practical details of mounting on plate and India paper, and likewise producing the plate-mark such as is seen on engravings, which also greatly enhances the appearance of photographs mounted with a margin. We shall now redeem our promise.

One of the chief difficulties met with by the novice in mounting pictures on plate paper, whether with the printed imitation tint or with the India paper itself, is that of avoiding the cockling of the mount. This arises from the moisture in the mountant expanding the picture, which contracts again on drying. Different plans for avoiding the difficulty have been adopted, one of which is that of damping the mount evenly all over, so that it becomes thoroughly expanded before the picture is placed upon it. Then, as they dry, the mount and print shrink together. The plan, however, more generally pursued is to employ a mountant that contains but a very small proportion of water. If the mountant contained no water at all there would be no expansion of the paper, and, consequently, no cockling of the mount. India-rubber solution fulfils this requirement, and makes an excellent mountant for photographs on plate paper; but, unfortunately, in time the rubber "perishes," loses its adhesiveness, and eventually the pictures leave the mount.

Starch paste, made much thicker than is usual and applied sparingly to the print, answers very well indeed. Professional mounters, we are informed, usually employ a thin solution of glue, and apply it very sparingly with a sponge instead of a brush. The best mountant we have ourselves tried for preventing cockling is a thin solution of gelatine, in which a large proportion of methylated alcohol is made to take the place of water. This solution, when thinly applied, practically causes no expansion either of the print or the mount.

At a recent meeting of the Photographic Club, when the subject of the artistic mounting of photographs was the topic under discussion, Mr. G. Smith explained the system of mounting that was adopted, and probably is now, in the establishment of MM. Goupil et Cie., of Paris, in which the mounting, rolling, plate-marking, and titling of the pictures was done in a single operation. As this method is simple, expeditious, and completely avoids all risk of cockling, we shall give it in detail.

The plan was this:—A quantity of India paper was coated with starch paste, on one side only, and allowed to dry. The prints were starched on the back and also allowed to dry. They were afterwards trimmed. In the evening of the day before the pictures had to be mounted the requisite number of pieces of starched paper were cut to size. These were then moistened, much after the manner in which paper is damped for printing purposes. A few sheets were placed on a flat surface, a few sheets more were dipped in water and laid upon them, then a few sheets of dry on them, and again some wet, and so on in alternate layers. When the whole batch had been thus treated it was allowed to remain under pressure till the following morning, by which time the moisture in the wet sheets had permeated the dry ones. The paper was then ready for use. The object of this treatment was to render the paper evenly moist without having it actually wet.

The mounting was accomplished as follows:—A metal plate, with the title engraved upon it and inked in, was placed upon the bed of a rolling-press. On this was put—in proper position, known by small register marks—the photograph, face downwards, then on it a sheet of India paper, starched side uppermost, and over this was laid the mount. The whole was then passed through the press, and the operation was completed. It will be seen that in this method of mounting both the print and the plate paper are kept dry, and it is only the intervening India paper that is moistened—the starch on the prints adhering to the unstarched side of the India paper, and the starched side of that to the mount, so that cockling is most effectually avoided. The plan, as described, is for working on a large scale; but the same system may be utilised for single prints, the only precaution necessary to be taken being that the starched India paper is *evenly* damped before using. This may easily be accomplished by placing it for a time between moistened sheets of blotting-paper. This method of procedure is far preferable to that usually pursued of first sticking the India paper on to the mount, and on that mounting the print.

It may be well to mention, for the information of those who may wish to do their own mounting, that India paper—or, rather, what is known as such, for we are told that very little genuine India paper is now employed in printing—may be procured from most wholesale stationers who make foreign papers a speciality. It can be had in a dozen or more different shades or tints, and the size of the sheet is somewhere about (for we have not an entire sheet before us as we write) forty-two or forty-three by thirty inches. The sheets should be starched whole, as the paper will keep any length of time. If a stock of the paper be prepared it will be ready for use whenever a piece may be required.

We shall now say a few words about plate-marking, which so much improves the effect of pictures when mounted with a margin. This is usually done by rolling the print, after mounting, upon a highly-polished steel plate with bevelled edges, and an elastic material, such as two or three thicknesses of blanket or felt, between the back of the mount and the roller. But the photographer who works on a limited scale only, and yet wishes to do his own mounting, may not care to go to the expense of a number of steel or copper plates for the different sizes of pictures, as they are somewhat costly, and, moreover, require considerable care to preserve their highly-burnished surface from oxidation when not in constant use.

However, expensive plates are not absolutely necessary, if we are content to make the rolling of the print and the plate-marking separate operations. Let the print be mounted and rolled in the ordinary way. What is then required is a zinc plate of suitable size for the marking. Sheet zinc ready surfaced may be procured from any dealer in lithographic materials. That known as "12 or 14 B. W. gauge" is the most suitable for our present purpose. The edges of the zinc must be slightly bevelled with a file and finally polished—first with snake stone and water, and then with a piece of charcoal and oil.

The method of using it is this:—A piece of paper, the size of the mount, is placed on the bed of the press. On this is adjusted the zinc plate, face upwards, in the exact position the mark is required. The mounted print is then laid, face downwards, and arranged so that its edges exactly coincide with those of the sheet of paper. By this simple means accurate registration is secured. Over the back of the mount is then laid a couple of thicknesses or so of felt, such as is used in pressure-frames, or of blanket. The whole is then passed through the press. With an elastic material at the back of the mount, very little pressure is required to produce an impression of the plate compared with what is required to roll or surface the print itself.

MORE ABOUT FRILLING AND BLISTERS.

We have continued the series of experiments upon this subject, the results of which we have on former occasions brought before our readers; and we are already able to throw fresh light upon the causes of these troubles and upon the application of remedial measures. It goes without saying that a plate subject to blisters or frills is less common now than used to be the case; but that it is to be met with in commercial plates of good standing is sufficiently proved by the appearances presented by a batch of plates that have recently been brought before us, and which, indeed, were the cause of our experiments being resumed, the plates in question having been made by one of the oldest houses devoted to that branch of manufacture.

The complaint about their action was that the negatives produced upon them were rendered utterly useless by the appearance of a multitude of small blisters, which no treatment that the gentleman who sought our advice had been able to apply was of the slightest use in mitigating. He put them down as caused by the weather; but when we learnt that the first plates of the same batch were entirely free from the defect it was perfectly obvious that the matter was one of mode of treatment rather than deterioration or imperfection in the manufacture. As no light could be thrown on the subject by the owner we requested him to leave us a few to experiment upon, and after a time we were able to find a complete cure of a thoroughly satisfactory nature.

The evil only making its appearance in connection with the operations of fixing and washing, our attention was naturally given entirely to that phase. In a former article we showed how, in the majority of cases, a complete cure for frilling tendencies was to be found in the draining of the plate thoroughly from hypo. before placing it to wash, and with these plates we found our method uniformly successful. There are, however, two drawbacks to this plan—first, the time wasted, so to speak, in waiting for the draining to be thoroughly carried out; and, secondly, if the plate remain for too long a time subject to the influence of the hypo., the tendency, more marked in some plates than others, for the image to become weakened and apparently dissolved. By giving the negative full intensity, and not protracting the draining period for too long a time, little or no fear need be entertained on this score; still, if the same effect without this drawback could be obtained by other means, they would, as a matter of course, be adopted, all other things being equal.

Guided by precisely the same principles that actuated us in instituting the experiments leading to our giving to the photographic community the above-mentioned cure for frills, we were able to arrive at a mode of treatment which, with the plates in question, enabled us to produce or prevent at will the appearance of the blisters. We have pointed out how it has been proved that when a crystalline substance passes by osmotic action through what may be termed the pores of a membranous or other similar substance, it is, as a rule, replaced by a definite quantity of water; and that salts vary considerably in the relative amounts of water that they require to replace them—such a salt, for example, as chloride of aluminium being replaced by nearly three hundred times the quantity of water that would pass to replace chloride of sodium under the same conditions. It is, as we have said, clear enough that the most likely cause of blisters at this stage is the replacement of the hypo. by a so much larger quantity of water, and the consequent tension placed upon the film which is sufficient to cause it to separate from the glass, the result being blister or frill, according to the place in the film where the action takes place.

Draining the film well removes a large portion of hypo., and leaves a smaller quantity in the film to be replaced by water, and thus blisters do not form. The question that arises is—Cannot the hypo. be removed by any other means before placing the plate under the tap? We saw no clear way of removing the hypo. from the film, but the same effect could be produced by not putting it there; in other words, by using a weaker solution, and, as a consequence, leaving a smaller quantity to be exchanged for its osmotic proportion of water. This was a very simple thing to try, and it answered completely. With the plates left in our hands we were able to produce any number of blisters by using an extremely strong fixing solution, or to have a negative perfectly free from them by diluting the same solution with an equal bulk of water.

Upon communicating the results of our examination to the owner of the plates he was able to remember that, previous to his blister difficulties, he had made a fresh fixing bath, and that as the water had stood for several days over an excess of the crystals, and had been stirred at intervals, the solution must also have been almost saturated, and thus in a condition most favourable for the full play of the osmotic action we describe.

Another consideration is introduced which suggests also a course of inquiry that might have favourable results. We have shown how water replaces certain salts in large quantities; but it is also known that this power of replacement is capable of being considerably modified by the presence of other substances, sometimes even in very small proportions. Thus, carbonate of potassium has its powerful osmotic action of two hundred and twenty times that of chloride of sodium reduced to almost nothing by the presence of an equal portion of the latter salt.

Again: sulphate of potassium, which has a moderate action, has it reduced to a minus quantity (that is to say, more salt than water passes through) by the presence of the merest trace of a strong acid, while an alkaline carbonate raises it most considerably, from twenty-one to over two hundred degrees. The inference we would indicate to be drawn from these facts is that the conditions of the fixing bath may greatly influence the osmotic action, and, in consequence, the frilling tendencies of plates submitted to its action. It is not to be recommended that we should add a strong acid to the hypo. bath, though there may be less evil than might occur with paper prints. Still, it is worthy of trial whether and to what extent the frilling and blistering might be governed by the addition of small quantities of hydrochloric or oxalic acid. It would be a nice question to discriminate whether the frilling tendency of acid *qua* acid, or its possible reduction of osmotic force, would be the greater power. That old hypo. baths must gradually become acid is obvious from the well-known reaction between the oxygen of the atmosphere and the dissolved salt, and whether in practice sufficient ammonia to neutralise it is introduced from partially-washed plates is open for experimental proof.

There is here, however, matter for a large number of experiments, which we shall, on our part, follow up at some future time. Meanwhile, there is no subject that could be more easily taken up by the general reader, and in his hands we leave the matter for the present.

THE PHOTOGRAPHIC EXHIBITION.

[Second Notice.]

In consequence of the backward state of the catalogue, and some little irregularity in the making of the awards, the following names were omitted from the list of medallists last week:—Portraits, H. S. Mendelssohn. Enlargements, Autotype Company. Instantaneous pictures, C. Grassin. Winter scenes, G. Renwick. *Genre* picture, *Out of Sorts*, Adam Diston. Small studies, G. Hadley; and *genre* picture, *Knuckle-down Fight*, Mrs. S. G. Payne. With the exception of Mr. Mendelssohn's, these form a second edition of the judges' awards.

Resuming our notice of the pictures, we find a number of frames of various descriptions of work by Mr. B. Wyles. First in numerical order is a frame of *Studies of Reed Plants* (No. 11), all of which are simply but artistically arranged, the most pleasing being *Marguerites.* Several frames of large sky studies, *Cloudland*, are excellent renderings of sky and cloud, but lack pictorial interest and completeness. Two figure subjects entitled, for no very obvious reason, *Rustic Figures—Sticks* (No. 169), and *Rustic Figures—Flowers* (No. 186), show careful posing. The remainder of the exhibits consist of views in Wales and elsewhere.

Mr. John Jackson's frame of *Views* (No. 18) contains some admirable work—as bright and fresh as the staunchest supporter of the wet plate could wish. *Druidical Remains at Stanton Drew* and *Wickham Bridge on the Frome* are especially noticeable. *Walton Castle, Clevedon* (No. 447), by the same artist, is a splendid study of fir trees, with the castle in the distance; and *A Somersetshire Lane—Evening* (No. 540) is a tasteful selection of west-country rustic scenery.

Mr. W. E. Debenham exhibits two charming studies in red chalk, of which we prefer No. 30—two little children gracefully posed, whose expressions have been caught with wonderful felicity. No. 283, a single figure subject, is so utterly skied that it is impossible to examine it.

Messrs. Robinson and Thompson exhibit a number o frames of views. An enlargement of *Venetian Boats* (No. 31) makes a most pleasing and artistic picture, but much of its beauty is due to the brush. Nos. 137, 138—two views of *Mersey Sailing Club, The Start*—are good average specimens of that class of work. The first is slightly marred by a want of detail in the white sails of the yachts—a fault from which the other is free. A frame of views, *Photographed during a Voyage from Liverpool to Venice* (No. 161), completes this exhibit. Noticeable amongst these are a street scene, Catania, and Vesuvius with his head hidden in cloud.

Mr. T. W. Boord, M.P., shows a frame of *Instantaneous Views, taken from a Yacht in Scotland* (No. 33), which are good studies of light and cloud.

Messrs. Adams and Scanlan exhibit a number of frames of theatrical portraits, the best of which is *Miss Dysart as Princess Ida* (No. 310). A frame of cabinet studies from "La Mascotte," "Serpolette," and other plays (No. 353), contains some excellent photography.

Mr. Valentine Blanchard's *Andrew Levy, Esq.* (No. 36), is a fine picture as well as a good portrait. His *Siesta* (No. 129) is grace-

No. 129—*A Siesta.* By Valentine Blanchard.

fully posed; but if the reclining lady were really enjoying her midday "nap" she would scarcely hold so steadily to the sunshade. As a sample of posing we have selected this for illustration. *A Message from the Sea* (No. 292) represents two fishermen who have just landed the name-board of some unfortunate wreck—"only this and nothing more." The exaggerated perspective of the board and the obtrusive block in the foreground rather detract from the merits of an otherwise clever picture.

Mr. Joseph Gale is again well represented, though his subjects are this year scarcely up to his usual high standard. *On the Skirts of the Downs* (No. 52) is a clever picture of a flock of sheep with the distant downs for background. *Off to Market—You'll Take Care of Baby* (No. 69) is the best composition of Mr. Gale's, and the picture tells its own story. A rustic cottage, a pebbly brook, and wooden bridge form the groundwork of the subject. The figures are two—mother and daughter—the former of whom calls out as she crosses the bridge the words of the title. No. 70, according to the inscription on the mount, is *The Smugglers' Cave*, but the catalogue describes it as *A Bundle of Shavings*. The mixture of names, however, serves to explain the picture. The background is filled by huge rocks, an opening in which leads to the smugglers' cave. At the entrance two rough-looking men—smugglers without doubt—are cooking at a fire composed, we presume, of a "bundle of shavings." *At Rye—Oh! Fie!!* (No. 71) does not suggest any connection between subject and title. At anyrate, in our ignorance of what the young woman has in her basket we are unable to find any. The composition is a good one, but poorly rendered in our drawing.

No. 71—*At Rye—Oh! Fie!* By J. Gale.

Three frames of portraits of high quality bear the name of Lafayette, of Dublin, and a medal has been awarded to two of these (Nos. 387-8) containing three-quarter length figures of "grand panel" size. No. 179 contains portraits of smaller size, all being of excellent quality from a technical point of view, while artistically there is little to find fault with. The selection made from No. 179, as an example of posing, is scarcely done justice to in our illustration.

No. 179—*A Portrait.* By J. Lafayette.

Mr. W. W. Winter is represented by four figure studies of large size. The most pleasing of these, *Just Off* (No. 173), which we have selected for illustration, represents a young lady, fully armed, "just off" to tennis. *Undecided* (No. 174) is a new rendering of the old, old story, the fair subject being evidently undecided whether to say "yes" or "no" to the all-important question contained in the letter she holds in her hand. *Sad Moments* (No. 190) and *Pleasant Thoughts* (No. 191) are in the same style; but the latter is a particularly happy *coup*, the expression and attitude being alike natural and appropriate to the idea conveyed by the title.

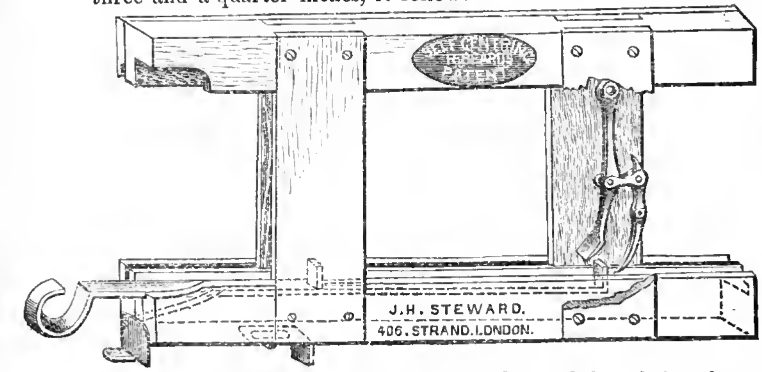
No. 173—*Just Off.* By W. W. Winter.

Messrs. Morgan and Kidd exhibit a large number of specimens of their work upon argentic-gelatino-bromide paper and opals, all of which are of considerable excellence. One of these, *A Portrait* (No. 98), we have chosen, because of the ease and elegance of its pose, for illustration.

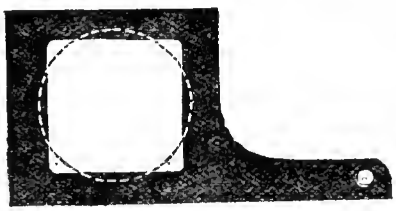
No. 98—*A Portrait.* By Morgan and Kidd.

APPARATUS.

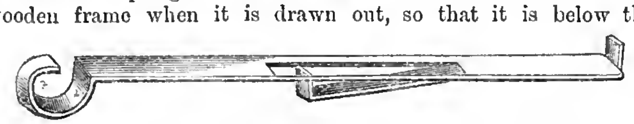
Distributed upon the tables are several specimens of a novel sort of lantern slide adapter, the utility of which strikes the observer at the first glance. This ingenious adapter allows of any commercial slide being automatically centered in the stage of a lantern. A difficulty previously experienced with registering slide-carriers has been the liability of damage to the slide by its falling out, and the necessity of the operator remembering the kind of slide that preceded it in the frame. A reference to the accompanying diagram will show that on the photograph being placed on the metal runner (when drawn out) in any position between the two projecting pieces, and the runner pushed home, the end comes in contact with the point of the lever and acts upon the photograph, so that it is brought to rest exactly in the centre of the opening. As the length of some slides, such as the original Woodbury slide, is four and a-quarter inches, the French *four* inches, and the English standard three and a-quarter inches, it follows that considerable trouble is



saved by this arrangement, as it allows of any of them being shown in rotation or consecutively without being put in separate carriers.

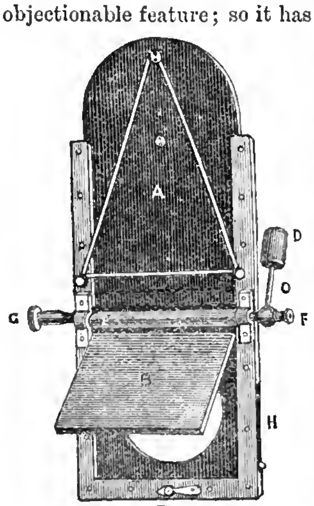


There is a supplemental groove in the frame for allowing metal masks to be inserted — circular or cushion-shaped — so as to preserve identity in the case of slides with various-shaped mats. The projecting piece on the runner is made to spring down into the hollow at the end of the wooden frame when it is drawn out, so that it is below the



level of the runner when inserting the slide. We give this adapter a cordial welcome on account of its undoubted utility. It is invented by an experienced lanternist, Mr. R. Beard, and the specimens in the exhibition are contributed by Mr. J. H. Steward, optician, Strand.

It is not long since we had occasion to chronicle an improvement in the clever instantaneous Phœnix shutter which emanates from the firm of Messrs. Reynolds and Branson, Leeds. In the "original edition" of this shutter there was a spring, similar to the mainspring of a watch, employed to aid the throwing up of the flap of the shutter, on the tension of which depended the rapidity with which this was effected. Owing to the liability of the spring to become unhooked or disarranged by the sudden, if not jerky, nature of the action to which it was subjected, this was felt to be an objectionable feature; so it has been removed in favour of a system



The shutter consists essentially of two movable parts, the drop portion A and the flap B, the movement of either of which can be accelerated independently — the former with a rubber band, and the latter by means of a weighted arm. The flap in moving upwards gives a gradation of exposure from foreground to sky; this action is extremely valuable in landscape photography and for cloud effects. When an exposure of about one-quarter of a second is desired, the band is removed and the flap is raised by means of the weighted arm C; the weight D being alterable as to size, and movable as to acting distance from spindle E. The arm C rotates on spindle, and may be fixed in any position by milled screw F. Very slow exposures may be made by fixing A by means of the pin attached to shutter, and by regulating the exposure by B; the movement in this case is imparted by means of milled head G. When this action of the shutter is used, the catch I must be released and the weighted arm clamped. The slowest automatic action of the shutter is obtained (without rubber-band) when the arm and weight are arranged at an angle of about 20°. If a rather quicker motion is wanted, arrange weight and arm at an angle of about 40°, and move the weight to its extreme acting distance, as shown at D.

in which a small weight forms the means of determining the duration of the exposure. This is shown in the annexed diagram, of which the above detailed description will prove acceptable to many. It will thus be seen that the degree of control which may be had over the shutter is practically illimitable. They appear to receive a large share of the attention of visitors to the Exhibition.

The London Stereoscopic Company exhibit four cameras—respectively whole-plate, half-plate, and quarter-plate. These are characterised by good workmanship and design. Another camera by these makers—the "*multum in parvo*"—is of different construction. It has several ingenious features which tend to increased facility of adjustment. Especially is this the case with the swinging of the back, both in a horizontal and vertical direction. The horizontal swing is effected by the simplest of all methods, namely, having the back of the camera attached to the base-board by means of a single screw in the centre, round which the back rotates. The vertical swing is obtained by having the hind portion of the base-board separated from the main portion, and connected with it by hinges and clamping-pieces at the sides. Notwithstanding the fact that in its construction there are some new departures to facilitate the folding and render it generally compact, we do not imagine that it will fulfil all the requirements of those who have of late been giving their suggestions as to the points which should find a place in the tourist's camera of the future.

THERE ought really to be some plan devised to enable exhibitors of apparatus to send their goods to Pall Mall with a reasonable hope of getting them back again whole. As it is, the amount of damage done during the period the exhibition is open is very great, especially to small articles, such as instantaneous shutters. It is scarcely desirable that the "hands off" principle should be adopted, nor is it possible to have attendants always present to exhibit each article, though this year an attempt has been made to improve matters by instructing one of the attendants in the working of all complicated apparatus. But we do think a notice might be posted, for the benefit of the blundering individuals we frequently see wrenching away at slides that will not open, to the effect that apparatus they do not understand is to be let alone until the attendant can explain it to them. Under the present system many manufacturers of apparatus refuse to exhibit at all, consequently the collection, as a whole, consists of a mass of fossil apparatus that most of us have seen years ago.

WE have before us an admirable print from a negative of Dunblane Cathedral, sent to us by Dr. Berwick, of Sunderland—sharp, clear, and brilliant as one could wish to see. The detractors of gelatine plates—those who insist that they must deteriorate by keeping—will be surprised to hear that this plate was exposed on July 21st, 1880, and developed July 21st, 1884. Four years between exposure and development is a fair test. How long the plate had been kept *before exposure* is not stated, but it matters not.

A COURSE of twelve lectures is being delivered under the auspices of the Committee of the Liverpool Free Public Library and Gallery of Art by the Rev. S. J. Perry, S.J., F.R.S., F.R.A.S., director of Stoneyhurst Observatory, the subject being *The Nature and Motions of the Bodies that Compose the Solar System.* A novel feature in this course is that each lecture after the first will be preceded by a discussion of the subjects dealt with at the previous lecture. A syllabus will be printed for each lecture, and this will be accompanied by a series of questions which may be answered in writing by those who desire to qualify for a certificate of proficiency. The first lecture was delivered on Thursday, the 9th instant, the series to be continued on succeeding Thursdays. The lectures are being largely illustrated by photographs and sketches.

WE see recommended a new use for the familiar "hypo." In a twenty-per-cent. solution, with the addition of a little carbolic acid and glycerine, it is said to be of great value as a dressing for contusions and bruises, the method of use being to saturate a cloth with the solution and keep constantly applied.

ACCORDING to M. Heddebault, when a mixed parcel of woollen and linen rags is exposed to superheated steam under a pressure of five atmospheres, the wool melts and sinks to the bottom of the vessel in which it is placed, leaving the cotton, linen, and other vegetable fibres intact and suitable for manufacture into paper. The pulp, through this purification from the presence of wool, is more valuable, yet does not cost more, seeing that the wool marc, from containing so much nitrogen, has a commercial value for fertilising purposes. Every method of improving the purity and evenness of quality of paper is of interest to the photographer, the quality of whose work in many departments is dependent in a great measure upon the paper he employs.

The foreign journals have been discussing methods for the detection of tartaric acid in citric acid—a by no means infrequent accompaniment. We have known cases where the one acid has actually been substituted for the other, though, at the present time, it would not pay to use the first-named acid as an adulterant, the prices being almost alike. According to one authority, Herr H. Akenstadt, tartaric acid may be detected by adding five drops of a five-per-cent. solution of the suspected sample to about half-an-ounce of lime water, which must be strong or the reaction will not be discerned. If tartaric acid be present a milkiness will ensue, and become more marked as the solutions gradually mix, shaking the mixture being carefully avoided.

Herr Push prefers to mix a small quantity of the citric acid in a dry test tube with ten times its weight of sulphuric acid, and then to allow the substances to react for an hour. He then places the tube in a water-bath heated almost to boiling, when the materials will melt to a lemon-yellow coloured liquid, which will remain unchanged for an hour if the sample be pure, but will become brownish coloured in half-an-hour, and reddish brown in an hour, if tartaric acid, even in so small a proportion as one-half per cent., be present.

The ammoniacal solution of shellac is said to be useful for the formation of dyes, and on the description given for making them a capital mode of colouring fabrics for dark-room windows might be founded. It is stated that a solution of aniline yellow in water, for instance, added to the ammoniacal solution—a description of a mode of making which has often appeared in our columns—gives a dye which is waterproof, and applicable to wood or paper. It is obvious to those who have any acquaintance with aniline dyes that the presence of ammonia will be utterly inimical to the integrity of some of the colours. Magenta red, for example, when boiled for some time in the lac solution, is first converted into red and then into violet. Still, there are colours that could be usefully employed, and the presence of the lac would so protect the surface of the fabric as to enable it to be sponged in order to remove the almost inevitable splashes from the dark-room manipulations.

The purification of egg albumen often assumes considerable technical importance, and various intricate methods for performing it have from time to time been proposed by chemists; but in a late number of the *Medical News* a method of a much simpler character, devised by Dr. Reichart, is described. He simply treats the solution of albumen free from membrane with carbonic acid gas, or even with the contents of a bottle of seltzer water. A precipitate of globuline, &c., is produced, and, when filtered off, leaves a solution of pure albumen.

We gave our readers, some few months ago, an account of the far-fetched standard of light adopted at the Paris Conference. The subject bristles with difficulties, and it is far from easy to believe that a quantity of melting platinum just ready to solidify can ever have much success as a standard on account of the vast difficulty surrounding its production. Some such feeling has actuated the members of the Philadelphia Electrical Congress, for, though they condemn the Paris unit as impracticable, they are so far from proposing a substitute that they were compelled to shelve the question for a time—or, in other words, "the subject awaits a report by-and-by."

The result of the new Patent Laws has been the production of a complete crush of work, leading to delay of a most inconvenient character. A competitive examination was held on the 9th ult. for the appointment of twelve more examiners, and the names of the successful candidates have already been published. Notwithstanding, however, this extra aid, the opinion prevails that at least double the number is required to enable the work of the department to be carried on without unnecessary delay.

THE LATE H. T. ANTHONY.

It is with the deepest regret that we have to announce the unexpected demise of Mr. Henry T. Anthony, of New York, whose portrait we so recently presented to our readers. Little thought we, when our portrait and brief biography appeared, that the hale and hearty subject would so soon be called away. But so it is; and photography generally — especially American photography — has now to mourn the loss of one of her oldest and most indefatigable votaries. The sad news arrived by cable, and no particulars are yet to hand. We extend our warmest sympathies to the bereaved relatives, as well as to the members of the firm of which the deceased had been so long a prominent member.

THE CAMERA OF THE FUTURE.

If twenty-five years' experience of amateur work in landscape photography with both wet collodion and dry-plate methods be any recommendation, I shall be glad to add my mite to the general information on the above-mentioned subject. I have used only one camera—a 12 × 10 size, of the form known as "Captain Fowke's," now quite obsolete; but I have never regretted my purchase. It is as good and as serviceable now as ever, though I have modified it by removing the "cone" in front; and it is with the idea that part of its constructive principle may be embodied advantageously in the future tourist's camera that I venture to offer my suggestions on the subject.

What we want in cameras for landscape work (but which would be equally valuable in the studio) is lightness as far as is compatible with sufficient strength for wear and tear, and the utmost possible celerity and ease in putting up and taking down, without loss of time or looseness of parts, which may be liable to be laid aside or lost in the field. The first is obtainable by doing away, as far as possible, with metallic fittings; the last is the study of the present period.

The main principles of Captain Fowke's camera are simplicity of construction, rigidity when set up, strength of material without excessive weight, and compactness for portability; but it has the defects of requiring considerable time and manipulation in setting up and taking down again, and many loose parts in the form of thumbscrews, brass rod, and loose base-board, which are troublesome to pack up and protect.

It would occupy too much space to describe the construction of this camera for the information of those of your readers who are unacquainted with it; but I will embody its most useful points in the description of a proposed form of camera I have been thinking out, but have not yet put into actual practical form.

What are our chief wants in a camera? In these days of variety of lenses we require a camera to open out to considerable focal length whilst closing up very compactly. I take as a standard for description a 10 × 8 instrument. In order to utilise the lens power to the utmost advantage the sliding body should pull out backwards from close contact (of three inches inside space) to eight or nine inches for portable symmetrical lens, and to (say) eleven inches full stretch for figure subjects. But it would be a great convenience *for certain work* if the focussing length *could be doubled* (say to twenty-two inches) for the sake of using the back lens only (as a meniscus) of any of the "doublet" or "symmetrical" lenses, or long focus portrait lenses for large heads; and this can only be got by adopting an extension of body towards the front as well as at the back (to be used only in special cases as mentioned).

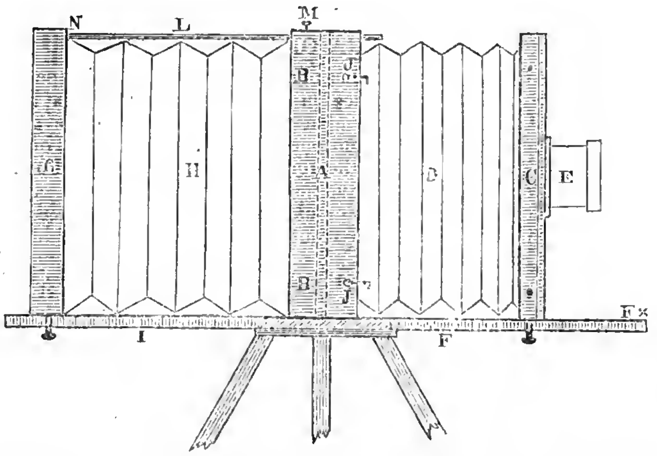
This front extension will, of course, add a little to the bulk and weight of the camera; but it can either be adopted for convenience or discarded as unnecessary, according to the wishes of the purchaser. It is a convenience of which I should much approve if it had been attached to my camera. The arrangement is an old one, and I only mention it as *not* being *a necessary portion* of the construction if *greater lightness* for carriage be the *chief* consideration. The accompanying diagrams will explain the plan I propose.

One of the principal points I wish to urge at starting is that *there is no practical necessity for any form of rack-and-pinion or screw-focussing arrangement.* These contrivances are expensive additions to the mechanical construction of cameras. They add materially to the weight, they interfere with the freedom of motion of the back frame, particularly in "side swing," and the utmost delicacy of focus can be obtained quite as easily—I think more easily—without them. I have never used them, nor felt their want. The "Fowke" camera back part is simply a free sliding movement along the surface of the tail-board, kept in place by two thumbscrews moving along two slots in the tail-board, and clamped there by a turn of the screw on each side when the focus is obtained. It is easy, certain, and firm when arranged, and gives an unusual amount of "side swing." I consider it might, with advantage, be adopted in all cameras in lieu of the stiffer-working rack-and-pinion or screw-focussing plans now so common.

The square form of camera is best, as giving more scope for rise and fall of the lens in front—a very important point in all cameras; and a reversible back frame makes it convenient for changing from horizontal to perpendicular in exposure of plates.

Fig. I.—A is a square frame of wood strengthened internally by another narrow frame glued on at right angles to it, shown by the

FIG. 1.



dotted lines B B—the width of A to be *just sufficient* to contain a *double* bellows-body when closed up, both parts being attached to the inner frame B. One part, D, is to extend forwards (only when specially required); the other, H, backwards for general focussing. C is the front of the camera (attached to the other end of the bellows) on which the slide for raising and lowering the lens is fixed with its lens flange and lens, E. *When the front part is used* C is pushed forward and fastened to its base-board, F, at any desired distance, but it can be extended to the full length of F. When not required it remains (in its position as packed up) close to A, to which it is clamped by brass side hooks (or best by bolts). G is the back part of the camera to carry the focussing-screen and dark slides. It pulls out to the full extent of its own tail-board when desired; or it can be closed up to A, thus giving a focussing stretch of about three to eleven inches. As shown in *fig.* 1, the camera double bodies are *almost* fully extended as for use with long-focus portrait or meniscus lenses; but for ordinary landscape work C would be closed up and clamped to A, using only the back extension, in which case the centre of attachment to the tripod head would have to be placed further back at the point of central balance. Two such attaching points are desirable.

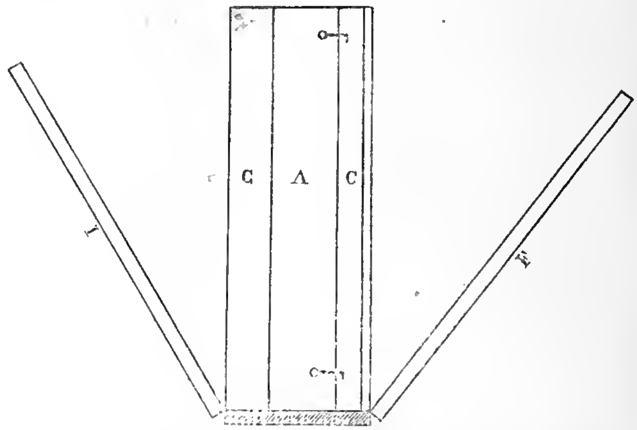
The two base-boards F and I are hinged to the bottom of A, and are strengthened in their horizontal position by the usual method. The back frame, G, can be fitted with the well-known appliance of hinged focussing-screen and reversing-frame for dark slides; *but no perpendicular or horizontal "swing adjustments" are necessary*, as the *free movement* of that part in the slots of the tail-board *allows more latitude than can be obtained by the usual complicated construction.* The fastening screws of C and G can be made either with thumbscrews underneath (as in Fowke's camera), which should be made *to slacken* out *but not to come right out*, or by milled-headed screws on the *top* of G, with a rod passing down each side of the frame and tightening against flat buttons underneath the tail-board. I prefer the bottom screws; they are more handy for use in getting the focus, and equally serviceable without costly construction.

Now turn to *fig.* 2, showing the camera partly packed up. A, G, and C all slide closely up together, F folds up in front, and I folds up at back, protecting the more fragile parts by their solidity. When folded up they are fastened by either brass clamps or leather straps across the top of A. A leather strap handle along the top of A will give hand-grasp for carriage.

The front base-board, F, when let down, would be somewhat in the way, and cut off some of the foreground *when the front, C, was not extended.* It should, therefore, be fitted with hinges, which, by a sliding movement sideways, can be "unshipped" and the board taken quite off and laid aside. It can be left at home for field work, and only attached when wanted for long-focus work; but the back tail-board must be a fixture, *strongly hinged and made as rigid as possible.*

There is one other point of construction to be mentioned. The *upper edges* of frames C and G would not be steady enough without some support beyond the rigidity obtained from the screws fastening them to their base-board. To obtain this a light brass rod, L, should screw into the front upper edge of G at N, in the centre, passing loosely through a hole in the top of A, and be clamped at any

FIG. 2.



required distance by a milled-headed screw shown at M. This rod is a very important element in the "Fowke" camera. It ensures great steadiness in the back frame when clamped, *and enables the back to be treated as a perpendicular swing-back*, either forward or backward, by means of the clamping screw; and I find it exceedingly useful in obtaining sharpness of foreground.

Sundry little minor contrivances can be adopted to complete the convenience of the instrument, but would take up too much space to describe; and, as I want to state chiefly the main features of the arrangement, I purposely leave them out.

Now notice the ease and simplicity of setting up or taking down. Open the tripod, fasten the camera on by the centre screw, unfasten the top clamps (or straps) and let down the base-boards. Now slacken the thumbscrews and draw out the back, then slip in the brass rod and screw it into the front of G. Attach the lens (by Mr. A. Pringle's method, for greatest convenience and celerity), and it is ready for work.

There are no loose parts, except the brass rod, which will go inside the front base-board. I think for *lightness and compactness* it will compare favourably with any form of camera, and the weight and inconvenience of rack and pinion or focussing-screw are avoided. The construction is so *simple* and *free from complications* that I consider *it ought to be inexpensive.* Double dark slides should be used, to be carried in a separate case from the camera; and the camera, when folded up, should slip into a light waterproof cover fitted with straps *to be carried as a knapsack.*

Amongst minor conveniences it would be a good thing if all cameras were fitted with *two spirit levels* in the main body, A—*one at the side*, horizontally fixed, to give the perpendicularity from back to front; and one *on the top* for horizontal correctness. It would save time and *give certainty* of the perpendicular position of the camera where buildings or interiors are to be taken.

If any camera maker cares to try his hand at a cheap *model* of this ideal camera, I shall be pleased to assist with ideas as to details. GEORGE BANKART.

THE FURNELL LENS.

I WAS much interested in what appeared in the last issue of this Journal respecting my lens; but I think the concluding remarks of the editorial article may cause many persons to alter, or add to, their lenses without exactly knowing the why or wherefore, and get into a muddle, thus gaining me anything but a blessing. But if they, leaving mathematics out of the question, should adopt some simple rule that anyone can understand, they will be the more likely to succeed.

Most doublet lenses have an adapter to lengthen the distance between the lens and stop when one of them is required to be used singly, and this lengthening piece is, doubtless, suitable to the depth of the front meniscus lens. This is important, if altered to my system, as the outer surface of the front combination requires to be distant from the stop one-tenth or one-twelfth of its focal length—the deepest meniscus requiring the shortest distance; but, of course, this is tolerably well known by this time.

If a back portion containing the two back lenses be added to the mount the concave lens must have the *curves* the length of three times the focal length of the front combination, and placed with its back surface a distance from the stop equal to one-twentieth of the focal length of the front lens. The function of the concave lens is to flatten the field, which can be made either round, flat, or concave according to the position in which this lens may be placed.

The focal length of the plano-convex lens should be one and a-half time the focal length of the front lens, but this can be varied. The function of this lens is to straighten the marginal lines and shorten up the focus. This lens may be a bi-convex, with its flattest side opposite the concave lens. The cell of the back lens can be placed equidistant from the stop with the front cell; but there is a latitude here, which is not, however, worth entering upon at present.

This addition to their lenses will make a nice little job for some of the amateur mechanics during the coming winter.

THOMAS FURNELL.

ACID IN EMULSIONS: A WARNING.

It has often been remarked that writers and experimentalists observe a not very honourable silence on the subject of their failures. Many seem to know nothing about the matter, yet there is not one photographer out of twenty who, at some time or other, has not been at his wits' end.

So it was with me one day when the reality and pleasure of plate-making seemed to be no more. As long as I followed the Editors' sound advice on emulsion and plate-making all went well—in fact, "as merry as a marriage bell;" and also when I followed the instructions of Captain Abney. But other days came, and with them other thoughts; in a word, I bade my former masters good-bye and began to think I could improve my emulsions, and consequently my plates, by using more acid, as others were doing with apparent success.

Now there can be no doubt that I was merely following the teaching of the past year or two, which decidedly favours the free use of acid. Some have even said that acid in an emulsion will keep out a whole train of evils; others that it will prevent fog; while many most emphatically stated that they could not get satisfactory results with acid. For my own part, I have little hesitation in saying that the too free use of acid is a step in the wrong direction, and one fraught with danger to a certain class of experimentalists.

The careless way which many writers mention the subject leads one to suppose that they do not appreciate the effect of acid in gelatine emulsion. With the exception of our Editors, no one has, as far as I can learn, directly written on this subject, which, if mentioned at all, is always very briefly handled. Yet I do not see why it should not be as exhaustively treated as the other side of the question, especially when we consider that a few drops—sometimes one—will spoil a large batch of emulsion, and render the image in the finished plate undevelopable.

There is another thing with regard to acid which many writers do not consider, or else they would not dose their pyro. with acid, as many of them do. By adding acid to pyro. it is easy to produce not only a slow plate, but reversal of the image.

But to return to the subject of acid in emulsions. According to Capt. Abney we have the following change:—"Acid organic compound bromine yields organic bromide and hydroxyl. The bromine, when coming in contact with gelatine, liberates hydroxyl or peroxide of hydrogen. This, as is well known, is a very strong oxidiser, and it will oxidise the neighbouring molecules of gelatine, or else the silver sub-bromide, and so produce an undevelopable image."

To prove that the introduction of an acid into a gelatine emulsion will cause the above important change I made the following experiment, and prepared four emulsions with four different quantities of acid. I used the boiling method, and in each case added the bromide to the silver along with the acid.

The first emulsion was prepared with 200 grains of silver; to this I added the bromide with one drop of hydrochloric acid. If the chemicals be acid an emulsion is decidedly better without this addition. The resulting emulsion was excellent, and always is when I use the minimum of acid. The plates work rapidly, develope easily, and fix quickly—qualities which cannot be obtained with an acid emulsion.

The second was prepared with two drops of acid, and the plates were precisely three seconds slower. I do not use a sensitometer, because I believe the true test for a plate is in the camera.

The next one was prepared with five drops of acid. With this quantity came a great change: plates coated with this emulsion were very slow, giving weak images, subject to reversal.

The fourth was now prepared with chemicals from the same stock; but in this case I added ten drops of acid. On mixing this emulsion I observed that the precipitate was very fine and the colour a beautiful red by transmitted light. At the end of fifteen minutes' boiling the colour had changed to a very decided blue—the most rapid change I ever got from the red to the blue variety. The emulsion was carefully washed as usual, and plates exposed in a good light with a large stop. On development, which was greatly prolonged, there was not the slightest trace of an image of any kind—thus proving that the free use of acid will destroy the developable image.

The question may be asked—What are we to do with the spoilt emulsion? With me it is a simple matter. My method is as follows:—I set the emulsion aside for one month (or more), by which time the alkaline reaction will have set in; but often this is accompanied by another evil, namely, decomposition of the gelatine. If so, pour the liquid emulsion into a larger jar, fill up with hot water, allow three days to settle, pour off the supernatant liquid, and again fill up with hot distilled water. In twenty-four hours it will again have settled to the bottom, when most of the water can be poured off and fresh gelatine added to the silver bromide.

An acid emulsion treated in this way will be found to yield plates as good as the best in the market. Let those who have doubtful emulsion by them "go and do likewise," and they will not regret the simple experiment.

HENRY HOLMAN.

ON CHEMISTRY AND PHOTOGRAPHY.

[A communication to the Dundee and East of Scotland Photographic Association.]

The science of chemistry is that which takes cognisance of the combinations of matter. One would imagine that this science must form a most important item in the education of a photographer, as he uses chemical substances to a considerable extent. As a rule, however, it does not. Photographers apparently, speaking of them as a body, have no inclination to understand the minutiæ of chemistry. This disinclination may be the result of a widespread opinion that a knowledge of chemistry is not necessary to the production of a good picture. A week or two ago, in one of the photographic journals, a writer gave it as his opinion that, in order to excel, photographers should not trouble over the minutiæ of formula or about any technical part of photographic work. To strengthen his position, he remarked that the true artist never condescended to paltry matters of that kind, but rather accepted materials put to his hand and questioned nothing. This gentleman instanced the old painters taking their painting material as they found it, their main object being to put colouring material on their canvas in a particular way.

Now, while we might all agree with this writer when he says that the main object to be kept in view by the painter or the photographer is the putting on of colours or the printing of lights and shadows in a particular way, it would manifestly be absurd to say he is not to trouble himself about the underlying technics. I doubt not, if we could get close up to the back window where Raphael or Rubens was working, we might find these gentlemen very busy with other implements than the brush and canvas. There is no reason to doubt—nay I have good reason to believe—that these good old painters made, mixed, and ground their own colours, and paid a very great deal of attention to the medium through which they were to give to the world their thoughts and ideas. We may well imagine their fear of colours fading or darkening.

The absurdity of the position is increased when applied to photography. If photographers in past years had taken processes and material as they found them, and remained content therewith, where would our art-science be in this year of grace? A more than ordinarily enterprising man might possibly be trying to take instantaneous photographs on daguerreotype plates; but this, perhaps, is not what our friend means. Photographers should be graded. First, there would be the great photographer himself—the idealistic and etherial. He would be surrounded and possess large and small satellites such as the camera-maker and the plate-maker, while such operations as printing, toning, fixing, and mounting would be done by obscure persons. He, the great, would sit in the centre of all, not dirtying his hands in the slightest, but devoting his whole energies to the production of ideas. In fact, this gentleman wished the term "photographer" to apply only to the man who searches out good combinations, makes good grouping, or has a knowledge of what does and what does not form a good pictorial landscape—just such an individual as would get his man John to inform him what lens to screw into the camera to suit a particular view; who would get John to estimate the light and the number of seconds necessary for exposure; who would further cause John to make plates, develope plates, to print, tone, fix, and mount; and, finally, to put into a frame the finished result for the exhibition wall as photographed by his august master. It would be very wrong to say that John in this case was better than his master, unless we knew if an equal power was possessed by John of finding or making good subjects, in which case he would be distinctly better than his master.

And this leads me to the subject of the evening—*Chemistry and Photography*. Should a man who essays photography know something of chemistry? Is a knowledge of the science a help or an encumbrance to him? An answer which will satisfy every case must be carefully framed, and to that end I would divide photographers into two great classes—the photographer whose sole object is to make and multiply pictures, who does not care very much about the means by which the pictures are made; and the photographer whose object is not only the making of pictures, but, in addition, the making of new and superior methods of operation.

To the photographer who simply makes pictures chemistry is not of much benefit; for chemistry, although it has to do with combinations, will not enable an operator to combine a number of individuals into a good group or to combine a tree and a mountain to form a good landscape. To the other photographer chemistry is of importance, as it enables him in some measure to intelligently examine already-known phenomena, and prevents him making absurd blunders or advocating absurd theories, as is too frequently the case amongst his other brethren. As an instance of the little yet aggravating mistakes sometimes made: the other day I learned from a friend that he had left for ten days some fine plate glass amongst a strong solution of caustic soda. He told me he did not know what had happened, but the glass was marked and spoilt and had lost its polish. The real state of matters was simply that my friend had unwittingly made a partial solution of his plate glass, glass being appreciably soluble in caustic soda.

Then, again, we are all more or less troubled with the very active man who rushes into print with a new idea, and supports it with a flow of language of astonishing abundance and acrimoniousness. We do not require to go far to find instances. A writer in one of the journals not long ago asserted that light reflected from an orange surface affected a gelatine plate to a greater extent than light from a blue surface, and actually went the length of asserting that experiments supported him. Little matters of this kind are continually cropping up, showing the value of a knowledge of natural philosophy and chemistry to the photographer.

On the other hand, too much should not be expected from chemistry. When anything out of the common occurs during some of the processes connected with photography—such as some blotching, staining, or other occurrence entirely unexpected—chemistry more than points to a probable cause. The science for the moment might appear to be at fault, may be able to do very little—not because the blotching or staining is caused by something outside the domain of chemistry, but simply that the cause is so occult, so intangible, as to be difficult of approach.

Photography is an art above all others which is based upon occult or semi-occult causes. The whole art has always appeared to my mind to be a good example, in a chemical sense, of what Professor Tait, of Edinburgh, calls an incalculable machine—a machine whose motions, although following strictly the usual lines of cause and effect, are quite incalculable owing to the occult nature of the causes regulating its motion.

To illustrate more fully what I mean, we may instance an egg balanced on end near the edge of a table. This is a possible feat, especially if the egg be rough and the place very still and free from vibration. Even if the feat were impossible we could imagine such a state of matters. All conditions remaining the same, the egg will remain in position, and neither fall on the floor or turn over on the table. But on the slightest disturbance from without reaching the egg—if we as much as look at it, to use an expression—the egg will in all likelihood either fall to the floor or turn over on the table. We have reason to believe—nay, we know to a certainty—that the falling to the floor or the simply turning over on the table is the result of a specific cause, but that cause is so inappreciable in itself as to elude the most careful observation. The most careful scrutiny of the surroundings of the egg would not enable anyone to predict which way the egg would fall.

This balanced egg may be likened to some of the conditions surrounding the chemical substances used in photography. In their constitution they are so delicately constructed and so easily, so to speak, put off their balance, that it would require almost superhuman intelligence to predict what amount of force would put them off their balance.

Some of the actions which take place are beyond prediction and calculation, and the science of chemistry is able to give explanations the value of which only amount to probability.

During the practical working of a photographic method there may, therefore, be observed many phenomena, the causes of which are obscure and not directly explainable; and the individual with a knowledge of chemistry is only permitted to look at them, as it were, from over a fence and at a distance. Yet such, it must be admitted, has a better chance of making advances in photographic art than he who will not even come and look over the fence.

Photography, I have said, is an art based on actions which are semi-occult. It therefore follows that it is an art open in the highest degree to extension by experiment, because the more a thing is covered up the more there is to uncover. Some people, I know, hold the opinion that photographic matters have come to such a degree of perfection that any great improvement is not to be looked for. Some people, I doubt not, also thought so in the days of Fox Talbot. But we ought carefully to avoid cherishing such an idea. That such feelings are prevalent is proved by the fact that in one of this month's magazines there is to be found an article written in a sad strain. This writer thinks, in view of the enormous number of inventions recently made, that he is nearing the "fag end of sensation." This I hold to be equivalent to saying that man has very nearly exhausted or, as the Yankee would say, "topped" the universe. Now, even as photographers, do we not know enough of this universe and its subtilities to feel that there are plenty of undiscovered things lying close around? Especially in this art of photography, I say, we have but to ask ourselves a very few questions to find we are far off the fag end of sensation. I hold that experiment is in the future to do a great deal for photography, and that in the future photography will do a great deal for general science.

Unfortunately there are amongst the multitude of picture-makers few experimental workers. There are few who endeavour to trace out phenomena for the love of the thing; yet I am sure that, amongst the members of a large society such as this, there are some who might take an interest in experimental photography, involving questions in chemistry and natural philosophy. In a large society something might be done in the way of reading educational papers. I do not mean to suggest that we are behind other societies in this respect; but we might very easily place ourselves in the front of them by making a specialty of the application of chemistry, natural philosophy, and allied science to the practice of our art. If one member were to take up the subject of the changes that take place in a prepared plate by the action of light, another the changes that take place in the plate and developing solution during development, while a third took up lens matters, I think it would prove beneficial to the Society.

In making these suggestions I am speaking as a member of the Council, and one who shares the responsibility of doing what he can to make the meetings interesting. The adoption of this suggestion would not interfere with the regular evenings of the Society. Four or five lecturettes with experiments could be delivered by members of the Society very much to the benefit of those who have only recently begun the practice of the art.

I shall conclude by hoping that the session will prove an interesting one for the majority of the members; and that, while not neglecting the interesting routine of societies like our own, such as lantern and other meetings, we may find at the end of the session drawn into closer fellowship the sciences of chemistry and photography.

G. D. Macdougald.

WHERE TO GO WITH THE CAMERA.

ROUND THE ISLE OF WIGHT WITH A CAMERA.

Having decided to make a photographic tour round the Isle of Wight, I packed up my half-plate portable camera, with three double dark slides, rapid rectilinear lens, and three dozen dry plates in a light knapsack.

Taking train to Portsmouth Harbour Station, I soon found myself on board the "Duchess of Edinburgh," which is the finest boat I have seen used for such short trips. Looking around there were numberless things to be viewed with curiosity and wonder; but my thoughts were more intent on the beautiful isle we were to visit shortly. I have seen some magnificent scenery, but I confess I have seen nothing surpassing the view of the Garden Isle, on a bright summer's morning, as you gradually draw near to it. It is a sight that would make the most disheartened amateur or the most dejected professional take up his camera with renewed energy, determined either to transfer a little of natural beauty to a gelatino-bromide or end his miserable existence with one of Shakespeare's bodkins. Arriving on the beautiful pier at Ryde, which is the glory of the town, I got a splendid view, and I heartily reiterate the lines—

Ascending with the gentle slope
From the blue Solent's tide,
We know not of a fairer place
Than this our lovely Ryde.

The view from the pier of the prettily-planned town, with its tall church spires and charming white villas tapering away into the thickly wooded districts, seems more like an imaginary picture than a real one.

Making my way into the town I soon found there were far too many spots deserving of attention. But as I had set out with the determination of only taking the best I could find, I thought it prudent to make myself acquainted with the place before I decided upon the subjects for my camera. Here I was most fortunate in purchasing one of *Mason's Guides*, which is written by a local gentleman, and contained all the information I wished for. It gave me a complete route, and mentioned all the principal places of interest, together with the number of miles between each hotel, &c.

In taking a walk round Ryde I was pleased with its cleanliness and general aspect. Unlike some modern towns, it seemed to have all things appertaining to the comfort and the health of its visitors. After I had taken the principal parts of it I decided to spend the remainder of the day in wandering about its shady lanes and coppices.

In the evening a military band from Portsmouth enlivened the souls, and gave elasticity to the steps, of the promenaders on the Pier. It was a splendid evening, and I am sure the old men and widows, young men and maidens, enjoyed themselves indeed. What a shame it is that man and Nature cannot come to a satisfactory agreement for the production of moonlight instantaneous views. But, enough of this; I enjoyed it and retired to my hotel to change the plates I had exposed for new ones, which I successfully managed by closing the door, drawing-to the curtains, blowing out the light, and then getting under the bed, where it was totally dark, and where I was able to handle them without the slightest fear of fog. Rising at six o'clock I went down to enjoy a bathe and give one more look at the beautiful panorama from the Pier.

Leaving Ryde I took the road to St. Helen's, and from there to Brading, where I exposed a few plates upon the old church, the town hall, with the old stocks, which, of course, are not used now; also "Little Jane's" cottage and gravestone—"the humble peasant girl whom the pen of Legh Richmond has immortalised." Then I pushed forward to Saudown, and tried a plate on the view from the cliffs, which is very pretty. Next I came to the lovely village of Shanklin, where I found a little extra stir on account of the Crown Prince and Princess of Germany paying it a visit that afternoon, of whom I got two good negatives, by wading a little way into the water with my camera and using a quick drop-shutter, as they put off in the gig to the yacht which was lying in wait. I also took the coast guardsmen in their boat, and then I went up to the far-famed Chine, which for rustic beauty will be difficult to excel. Exposing my last plate here, I was obliged to be satisfied with only a look at Bonchurch—the spot M. Paul Bourget spoke so highly of—as I passed through on the way to Ventnor, where I intended to put up for the night, having walked a good twenty-one miles under a scorching sun.

After I had disposed of a good meal I wandered down the pier, which was alive with people. I managed to find a secluded seat, where I could watch all that was going on in peace. The band played some lively tunes, whilst a mild breeze was coming up from the sea, which kept most of the visitors on their feet; and as the evening wore on the moon arose in its full, casting its silver rays across the water, and showing up the pretty buildings on the hill, until all seemed full of life and spirit, and as fascinating as some old fairy tale.

In the morning I was up with the sun, and seven o'clock found me once more at the pierhead with my slides renewed, and in high spirits, ready to commence the second day of my walk. Sitting on the pier for a moment to drink in all the beauties which Nature, with unsparing hand, has bestowed around this little spot, the soul is stirred with an indescribable feeling of joy and admiration. Looking towards the south-west you have the very high hills capped here and there with Gothic cottages and beautiful palisadings; then a little below these, set into the sides of the hills, are the larger villas, with their charming gardens and evergreen-covered balconies, spread in a sort of lovely confusion until they reach the esplanade and beach, which is a very steep and pretty shingle-covered one, with the usual number of bathing machines, boats, and skiffs.

I selected the prettiest part as my next subject, and I tried my best to do it ample justice; but it is such a picture that any part of it, however carelessly selected, cannot fail to give satisfaction to the most fastidious love of photographs.

After finishing my desired number in that place I once more took up my knapsack and mounted to the top of the cliffs in order to push forward to St. Lawrence, Niton, Blackgang Chine, and the Needles; but I could scarcely get more than two hundred yards at a time without turning round to give another look from the various high points at the beautiful town I had left behind. The sun was shining very brightly, and by noon the heat was almost unbearable. At length I was forced to leave the coast and take to the downs, until I immerged into the main road for Carisbrooke; then pushing forward with a sharper step in about four hours I came in sight of the grand old castle, into which I soon entered. Here I saw the apartments in which Charles I. was incarcerated; also the garrison well, which has a shaft 150 feet in depth, with fifty feet of water, and the bucket is drawn up by a donkey inside a revolving fly-wheel. Leaving the castle I had just a mile to walk to the capital of the island, Newport, having earned a good supper and a sweet night's rest. Starting early in the morning I took the road for Osborne, and from there to East Cowes, where I saw the Queen's yacht, "Alberta," lying at the neat little coast-guard station. Then I took the steamer for Ryde again, which I reached about half-past two on the afternoon of Saturday, August 9th, having done a good seventy miles in three days, and bagged two dozen assorted negatives.

J. T. R.

SCRAPS FROM MY HOLIDAYS.

[Abstract of a communication to the Derby Photographic Society.]

My reason for taking up the art of photography was because I wanted lantern slides to illustrate subjects for lectures which were not to be found in any maker's catalogue. My first attempts—not of a very artistic character—were made with a rough camera composed of a wooden box, a dark slide, and the objective of my sciopticon lantern. This summer I took with me to Dolgelley, in North Wales (in addition to a half-plate camera, the negatives from which I have not yet developed), a sciopticon camera for plates three and a-quarter inches square, which, with lenses and four double dark slides in case, weighs about four pounds. I took also Mr. Smith's brattice and Manx stands, each weighing about one pound. The former I found very useful for hill work, especially in climbing Cader Idris. In such cases the stand becomes an alpenstock, and is not an useless weight for the time like a folding one.

The object of my holiday—not forgetting, of course, fresh air and exercise—was geology, and not photography, and most of the photographs I took were to illustrate that science. During the fortnight I walked 250 miles, collected over a hundredweight of specimens, and exposed twenty-five plates. The weight of the camera was of some importance to me. Four pounds is quite enough on a hot day on rough ground, in addition to several pounds' weight of iron in the hammer and chisel, and that of any specimens brought home. I found no difficulty in the packing of plates either before or after exposure. The plates were the Manchester rapid ones, which were taken in the boxes as supplied by the maker, and after exposure were replaced in a similar way. The changing I did under the bedclothes at night, wrapping each box up carefully in non-actinic paper, numbering each box, and taking notes of the plates replaced, so that on my return home I was able to pick out any plate required for development.

A few of my transparencies were printed on gelatine-albumen plates (Chapman's); but the majority on Edwards's gelatino-chloride plates. They were exposed by contact with the negatives to a bat's-wing burner, at a distance of two and a-half feet. The exposures varied from five to fifteen minutes. And here let me point out, in passing, what probably most photographers know, that light varies inversely as the square of the distance, so that an exposure of twelve seconds, at a distance of four feet from the light, would be equivalent to one of three seconds at a distance of two feet. A short calculation will enable us to obtain the same results from different distances with the same exposure as we can from different exposures at the same distance from the light; so that, instead of varying the exposure, we may vary the distance, thus saving time.

The developer used was the one supplied by Edwards—a long exposure and weak developer giving reddish tones; a short exposure and strong developer gave rich black tones—the latter making, I think, the best pictures.

[The remainder of the time was spent in showing the transparencies with the sciopticon lantern and explaining them, and in exhibiting the camera and stands.] H. Arnold Bemrose, M.A.

PHOTOGRAPHY IN COURT.

USING THE ROYAL ARMS WITHOUT AUTHORITY.

The case against the firm of Messrs. A. and G. Taylor for unlawful use of the royal arms in their business was again heard at the Malborough-street Police Court on Wednesday last, the 15th inst., before Mr. Newton.

Mr. St. John Wontner, who, as on the previous occasions, appeared for the defendants, stated that Messrs. Taylor had made use of the royal arms in the belief that they had a right to do so; but, as they were now aware that they did not possess this right, they had had them removed from their premises and business documents. This, he thought, would serve sufficiently as a reason for the infliction of merely a nominal penalty.

The magistrate also took this view of the matter, and, looking at it in the light of a test case, he inflicted the nominal fine of one shilling, with two shillings costs.

Seeing that much interest has been felt in the question of the right to use the royal arms in connection with business, we here append a letter which has recently been issued to the town clerks of the various provincial towns in England :—

"Board of Green Cloth, Buckingham Palace, September, 1884. Sir,—At the commencement of her Majesty's reign, and up to the year 1853, a great number of warrants of appointment were granted by the Lord Steward to tradesmen in different towns, some of whom served the Court, and others held merely an honorary title, according to the custom of that time, which has since been abolished. All these grants were personal to those named in the warrants, and could not be transferred to succeeding partners, so that it is probable that by far the greater number of these have lapsed by the retirement or decease of the persons to whom they were granted. The Patent and Designs Act of 1883, an extract of which is enclosed, enacts a penalty of £20 in the case of persons assuming the royal arms without authority; and, as the grant of a warrant of appointment is the only authority for using the arms so far as the Queen's household is concerned, it has become important to ascertain what tradesmen actually hold these warrants. I shall be much obliged if you will look over the enclosed list of warrants granted to tradesmen in ——, and give me any information in your power for the guidance of the Lord Steward as to the existence, or otherwise, of the persons named therein, or any of them. Trusting you will excuse this trouble, I have the honour to be, sir, your obedient servant, T. N. March."

IMPROVED APPARATUS FOR DISSOLVING AND CHANGING PICTURES IN THE MAGIC LANTERN.

COMPLETE SPECIFICATION. By B. J. EDWARDS.

MY invention relates to an improved method of, and apparatus for, exhibiting a series of slides or pictures in the optical instrument commonly known as the magic lantern, and has for its object the changing of the slides or pictures mechanically by one simple movement of a lever or handle without any movement being perceptible upon the screen. This effect is produced by means of my invention with one single lantern in a manner which is more pleasing and less fatiguing to the eyes than the usual method of dissolving views with two lanterns.

In order to accomplish this object I first shut off the light, and consequently the picture, from the screen by gradually closing or covering the front lens or objective of the lantern, and during the momentary interval of darkness thus produced I rapidly change the slide or view and substitute another one previously placed in position, and then by gradually uncovering the lens I allow the new picture to fall upon the screen. By means of my apparatus these various operations of closing the lens, changing the slide or view, and reopening the lens are performed mechanically by one single continuous movement of a simple arm or lever. The improved apparatus consists of a slideholder carrying two slides, which, by moving the handle or lever, are alternately placed in position in front of the condenser, in connection with a screen or dissolver which alternately closes and opens the lens.

In carrying out this invention in the simplest possible manner, I fix a short rod or spindle turning on its axis parallel to the optical axis of the lantern, and which spindle is rotated by a handle or lever. At the outer end of this rod I attach an opaque screen projecting in front of the lens so as to cover or close it, a certain portion of the screen being cut away, so that during a part of the revolution the lens is uncovered and the light, and consequently the picture, is allowed to fall upon the screen; and by means of suitable eccentric gearing I connect the rod carrying this opaque screen to a swinging or sliding frame carrying two slides or pictures arranged in such a position in the frame or carrier that, when the lens is not covered by the opaque screen or dissolver, one or other of the pictures shall be at rest in its proper position in front of the condenser. I arrange the gearing or eccentric motion, so that the sliding or swinging frame shall be set in motion, and the picture changed during the momentary interval of darkness caused by the passage of the opaque part of the screen or dissolver in front of the lens. In order that the darkening of the picture shall be gradual I make the aperture in the dissolving screen with serrated edges; but I prefer, instead of this revolving screen, to close and reopen the lens by means of two thin sliding plates or diaphragms working in grooves attached in front of the lens, and I make the sliding plates with both ends concave, and I suspend these plates by means of a cord passing over and once round a drum or pulley fixed to the rod in place of the opaque screen before described. One of these plates being attached to each end of the cord they balance each other, one rising and the other falling as the drum revolves. I make the plates of sufficient width to cover the opening of the lens, and of sufficient length to keep the light entirely shut off during the time the position of the slide carrier is being changed; and I arrange that, when the upper concave edge of the rising plate comes in contact with the drum, the lower concave end of that plate is just free of the upper end of the lens, while the upper concave end of the falling plate is just clear of the lower edge of the lens. For holding the slides or pictures in position I use a double carrier of the usual construction, but arranged by means of guides or runners to travel easily in metal grooves attached to a second frame, which is firmly fixed in the lantern immediately in front of the condenser. The slide holder or carrier carrying the slides or views is moved from side to side by means of a lever slotted at its lower end and working on a pin fixed to the central division of the double slide holder; the upper end of this lever is firmly fixed to a rod or spindle turning on its axis, and placed parallel to the spindle carrying the drum before described. In order to connect the rod and lever which work the slide holder with the handle and rod which works the drum and dissolving plates, I adapt and make use of a modification of the mechanism commonly used for regulating the winding of ordinary Swiss watches in the following manner:—To the drum-spindle I fix a circular disc of metal having a single tooth or pin working in a corresponding recess or depression in another disc or segment of a wheel fixed to the spindle which carries the slotted lever working the slide holder. This second wheel or segment of a wheel has a recess cut in it in which the tooth of the disc on the drum-spindle works, and on each side of this recess a concave indentation of the same radius as the disc on the drum-spindle. By this means the lever working the slideholder is not only not moved by the rotation of the drum-spindle (except during the time that the tooth is engaged in the recess), but is securely locked by the close contact of the periphery of the one disc with the circular indentations of the other. The apparatus is so arranged that during the first portion of the movement of the handle or lever the rotation of the drum causes the lens to be gradually closed and kept closed by the passage of the dissolving plates, one over the other, during the time the slide carrier is being shifted, when the latter portion of the rotation of the drum-spindle uncovers the lens, the handle or lever being arranged to describe about a semicircle during the completion of these movements. Should any adjustment of the distance travelled by the slide carrier be required it is readily increased by raising the position of the pin on the central position of the slide carrier or lessened by lowering it. During the time that the lens is uncovered, and a picture consequently being shown upon the screen, the other half of the slideholder is projected clear of the lantern so that the slide which is not being shown can be removed and another substituted in its place, the slideholder being by the action of my improved apparatus securely locked so that the operation of changing the slide does not disturb the slide being exhibited. By this means and by alternately moving the handle from one side to the other the lens is alternately covered and uncovered, and the slide or picture is changed invisibly during the moment of eclipse.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is:—1. The closing and opening of the lens or objective of the lantern, and mechanically or automatically changing the slides or pictures by one continuous movement of a lever or handle substantially as hereinbefore described.—2. The special arrangement above described for opening and closing the lens by means of plates or diaphragms worked by a cord and pulley or drum.—3. The adaptation or application of the mechanical contrivance employed in watches for the purpose of changing the slides in combination with the mechanism for covering and uncovering the front lens of the lantern substantially as hereinbefore described.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

" 22	Photographic Club	Anderton's Hotel, Fleet-street.
" 23	London and Provincial	Masons' Hall, Basinghall-street.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society, held on Thursday, the 9th instant, the chair was occupied by Mr. W. Ackland.

A letter from the Secretary of the Edinburgh Photographic Society was read, in which it was requested that members of the London and Provincial Photographic Association would act as judges in a competition that was shortly to be held amongst the members of the first-mentioned society. The Secretary was directed to write acceding to the proposition.

A letter was read from Mr. W. M. Ashman, who was to have delivered his lecturette on *Toning*, but who was confined to his room by indisposition. The lecturette was forwarded to be read by the Secretary, but it was decided to postpone the delivery until the 23rd instant, when it was hoped that Mr. Ashman would be able to read it and illustrate it by demonstrations personally.

Mr. WASHINGTON TEASDALE showed a number of transparencies printed upon commercial gelatine plates prepared expressly for this purpose. This led to a discussion on the best method of binding and fitting up transparencies for the lantern.

Mr. W. AYRES, for binding, used paper that had been coated with gum and sugar and dried. It was wetted for use with a postage-stamp damper.

Mr. TEASDALE preferred wheat glue. He thought it would be desirable to have metal rims instead of paper binding, so that the transparencies could easily be got at to clean off any dust or deposit that might invade them. He had had a few made on the plan of the rims called "preservers" that were used with glass positives, but they had to be made by hand, and were, therefore, expensive. If an order could be given for a quantity sufficient to justify the manufacturer in making dies to stamp them they could be made very cheaply.

Mr. AYRES remarked that dust could not be kept out by a metal rim as it was by an adhesive paper binding.

Mr. GEORGE SMITH used gum as cleanest for causing the paper binding to adhere. Some time since he had had metal rims for lantern slides, but found that it was necessary to use paper to keep the dust out.

Mr. J. BARKER preferred a mixture of flour paste with gelatine or glue. This set into a jelly, and was used cold.

Mr. W. K. BURTON referred to a developing agent recently introduced by Mr. C. Egli and Mr. A. Spiller—the hydrochlorate of hydroxylamine—and said that with the formula as published he had not been able to obtain an image; but by omitting the restrainer he had succeeded in obtaining an image of a beautiful colour and very clean. He would like to hear the results of experiments made by other members.

A MEMBER then inquired whether anyone could tell how a certain paper was prepared that was introduced more than twenty years ago, but for many years past had not been in the market. This paper was albumenised, and had to be sensitised in the ordinary way. After the usual treatment upon removal from the hypo. fixing solution into water the film of albumen separated from the paper, and could be transferred to anything required. He thought that lantern transparencies might be very satisfactorily produced by means of such a paper.

Another MEMBER, in reply, said that there were several methods of transferring an albumen film from the paper on which it had been printed. According to one plan the paper was coated before albumenising with india-rubber or gutta-percha. After printing, fixing, &c., the film was transferred by dissolving the india-rubber with benzole.

Mr. W. E. DEBENHAM remembered the paper referred to. It was introduced particularly for the purpose of making transfers on to ivory for colouring upon. The paper appeared to be coated with some starchy material before albumenising.

After the meeting Mr. A. L. HENDERSON invited the members and friends to stay to a supper which he had had prepared, and about forty sat down to a social and pleasant repast. The feasting over, after the usual loyal toasts,

Mr. DEBENHAM proposed that of the host, the delegate of the Society in the United States, the Ulysses returned from his travels—Mr. A. L. Henderson.

The toast was most heartily received, and was followed by that of "The Society," coupling with this that of the officers, which was proposed by Mr. J. TRAILL TAYLOR, who, in the course of his remarks, observed that he had been one of those concerned in the institution of the Edinburgh Society, now the largest photographic association in the world. He had also been present at the invitation of this Association, and he hoped for it a success similar to that enjoyed by its northern fellow society. One strong point in each was the fixing of the subscription at so low a figure as to be a hindrance to none, and it had been found in both cases that that small subscription was sufficient to cover all necessary expenses. In connection with the lecturette system, which had been suggested by the Curator, Mr. Haddon, and had been so successfully carried out, he observed that it was likely to be largely adopted in other societies. Mr. Henderson had started it in America by giving his lecture upon, and demonstration of, emulsion making, and he (Mr. Taylor) was aware, from correspondence with the President of the New York Society of Photographic Amateurs, that it was intended that the lecturette system should be made a leading feature in that Association.

The toast of the visitors, proposed by Mr. HADDON, was responded to by Mr. TEASDALE, who expressed the pleasure it gave him to see the faces of, and come into contact with, so many of those gentlemen with whose writings he was familiar in the pages of the journals and almanacs.

In the course of the evening

Mr. HENDERSON referred to the American Photographic Convention, which was to meet next year at Buffalo, and suggested that English photographers should make up a party to visit it. He felt sure that if this were arranged and known they would receive a most hearty welcome.

In reply to the toast of the honorary and foreign members,

Mr. TAYLOR remarked that with regard to the great American Convention that assembled once a year, and at the late meeting of which photography was scarcely ever mentioned, it needed "pulling together." It had even been said that its next meeting would be its last. He certainly thought that it would act as a stimulus to the American fraternity if it were known that a body of Englishmen were intending to pay them a visit. In a few weeks he would be in a position to convey personally to the photographic societies in New York the friendly feelings by which the members of the London and Provincial Photographic Association were actuated towards them.

The evening was then enlivened by songs and recitations. One song, given by Mr. William Cobb, made special reference to the host of the occasion.

PHOTOGRAPHIC SOCIETY OF IRELAND.

A MEETING of this Society was held in the Royal College of Science, Stephen's Green, on Friday, the 10th inst.,—Mr. Greenwood Pim, M.A., in the chair.

The minutes of the last meeting having been read and confirmed, Mr. A. G. Tagliaferro, of Malta, was elected a member of the Society. The following names were proposed for membership:—Messrs. S. Geoghegan, C.E., H. Magee, and Francis F. Hall.

Messrs. Samuel Baker and Thomas Curtis were elected to audit the yearly accounts before the next meeting.

Mr. C. W. WATSON gave an account of his recent trip through Derbyshire with the camera, and exhibited a large number of excellent views taken during the tour.

Mr. GEORGE MANSFIELD showed a series of 10 × 12 views which he had recently taken in France and Spain, all of which were much admired for their artistic and technical merits.

Mr. J. V. ROBINSON exhibited a patent instantaneous shutter the invention of Mr. F. W. Monsell, a member of the Society, and which formed the basis of a varied and interesting discussion on shutters in general.

Mr. THOMAS MAYNE showed a new expanding camera of great length, suitable for copying, &c.

Mr. JOHN L. ROBINSON'S paper, *A Week in Suffolk*, was, by consent, postponed until that gentleman's return.

The proceedings were then adjourned until the 9th November, when the annual meeting will be held.

ST. HELENS ASSOCIATION FOR THE PURSUIT OF SCIENCE, LITERATURE, AND ART.

PHOTOGRAPHIC SECTION.

A MEETING of this section was held on Wednesday, the 17th ult.,—Mr. Heather in the chair.

Mr. Bewley showed a number of views taken at Bettws-y-Coed during the month. Part of these were toned with platinum.

Mr. SHERLOCK said he preferred to use the platinum bath, as he could get as great a variety of tones with it as with gold, and the cost was only one-fourth that of the latter metal.

Mr. J. F. HOUGHTON showed a number of lantern slides of local scenery. Two (Chapman's albumen), developed by the pyro. sulphite method, from a formula given in Marion's *Photography*, were especially praised for their clearness. The remainder were developed by Cowan's solution; these tones were much admired.

Mr. THOMSON exhibited a number of lantern slides of some very pretty views near Buxton.

Mr. HEATHER showed about twelve prints toned with a solution made up of perchloride of iron, nitrate of silver, and hyposulphite of soda. The tones varied very much; some, however, had a very pleasing effect.

Mr. TAYLOR inquired if the prints were as permanent as the ordinary ones. He did not consider they would be, especially in a town like St. Helens.

Mr. HEATHER said his experience was limited to the few prints he had shown. He fully endorsed Mr. Taylor's remarks. He (Mr. Heather) then showed two negatives—one fogged, the other quite clear. He explained that while cooking the emulsion he found a series of small holes in the can, and consequently the emulsion was fogged. He then placed it in a ten-per-cent. solution of bichromate of potash for fourteen hours. After this treatment it was quite free from fog, but considerably slower.

After a discussion on emulsions, developers, &c., the meeting was adjourned.

BOLTON PHOTOGRAPHIC SOCIETY.

THE annual meeting of this Society was held at the Baths, Bridgman-street, on Thursday, the 2nd inst.,—Mr. E. N. Ashworth in the chair.

The minutes of the previous meeting having been read and confirmed, the following annual report was read by Mr. C. K. Dalton (Mr. Hawksworth, Hon. Secretary, being absent):—

ANNUAL REPORT.

IN presenting their fifth annual report your Council desire to congratulate you on the eminently satisfactory state of the Society. During the year 1883-4, there has been a large increase in the number of members; at no time since its formation has the Society stood on a sounder basis.

Your Council are happy to state that the balance in the hands of the Treasurer is steadily increasing.

The following demonstrations have been given during the session:—

On Toning and Fixing Silver Prints. By Mr. T. Parkinson.

On Enamelling Silver Prints. By Mr. J. Taylor.

On the Development of Platinotype Prints. By Mr. C. K. Dalton.

Lantern exhibitions have been given by Mr. W. Banks, Mr. R. Harwood, and Mr. T. Parkinson, and have undoubtedly added to the attractiveness of the Society.

The annual open meeting was held in April last, at the Baths, and was in every sense a success.

Your Council have again to regret the meagre attendance at the outdoor meetings. In fact, there has, strictly speaking, been only one meeting held during the summer months, although the weather has not been unfavourable. It is hoped that efforts will be made to render these meetings more attractive, and thus secure a better attendance.

The report having been accepted as read, a vote of thanks was passed to Mr. J. Hick, and regrets expressed as to his retirement from the presidency of the Society. Mr. Hawksworth having also desired to retire, the thanks of the Society were tendered for his energetic and valuable services as Hon. Secretary.

Messrs. Paiton and Taylor examined the voting papers. The following was the result:—*President:* Mr. J. R. Bridson.—*Vice-Presidents:* Messrs. Harwood, Ashworth, Parkinson, and Hawksworth.—*Council:* Messrs. Banks, Taylor, Knowles, and Slater.—*Treasurer:* Mr. J. C. Sewell.—*Hon. Secretary:* C. K. Dalton.

On the motion of Mr. B. ABRATT, a vote of thanks was passed to the retiring Council for their services during the past year.

SHEFFIELD PHOTOGRAPHIC SOCIETY.

THIS Society held its annual dinner and meeting at the Masonic Hall, on Tuesday, the 7th inst.,—Councillor T. Firth in the chair.

A very good muster of members sat down and did ample justice to a plentiful and well-selected meal, which, when over, gave place to the usual yearly routine of discussing and passing accounts, and electing new and re-electing other officers. The statement of accounts was read by the Treasurer, Mr. W. B. Hatfield, the most notable item in which was rather a serious loss on the last exhibition which was held in January of this year. Many remarks of noteworthy importance have from time to time been made by the members on the subject of exhibitions; but it is a fact that a great majority of them are unwilling to make another similar venture for some time.

After the accounts were passed the following officers were elected for the ensuing year:—*President:* Mr. W. B. Hatfield.—*Vice-Presidents:* Councillor Thomas Firth and Dr. T. H. Morton, M.D.—*Treasurer:* Mr. T. S. Yeomans.—*Secretary:* Mr. J. Taylor.—*Council:* Messrs. Bacon and Turner.

On vacating the chair Mr. FIRTH spoke of the prosperous condition of the Society. Although the exhibition had inflicted a loss on them, it had also called around them many who were now among them as members, contributing to their pleasure at each monthly meeting. They were now far more numerous and embraced a happy variety of careful workers, and he believed, with the new interest that was now being put into the working of the Society, good results might fairly be expected.

Dr. MORTON also declared his great satisfaction with the progress and improvement of the Society, and said he had felt sorry many times his business had prevented him taking part in the subject competitions, which had been the means of bringing so many good pictures to the meetings.

On taking the chair,

Mr. Hatfield said that it would be his study to maintain the interest and improvement the Society was now making, and he believed the only certain means to ensure that was a perfect arrangement of subjects for each night, and never to rely on chance conversation for the entertainment of the members. They did not want long and tedious papers filled with technical words and symbols, but short and pithy ones in plain and comprehensive everyday language; and when once a subject was announced for a night they should adhere to it, and all members do their best to make a complete discussion of every point bearing on that subject. After thanking the members for the honour they had conferred on him the business then proceeded.

The subject for this month's competition was the best picture of *Clouds*, and was won by Mr. Turner with a very beautiful half-plate of *Fleecy Summer Clouds.* These were round in their form, varied in light and shade, and filled with such an amount of charming and delicate detail that revealed in a moment you were looking on a truthful bit of Nature's glorious work.

Mr. H. Rawson brought a very rich print and negative of some clouds, which called forth great praise, and was a charming picture of another character of cloud, being dark and stormy, with a vivid light fringing the edges in artistic contrast. This was not for competition.

Mr. Turner had a number of good pictures of a summer's work on the table.

The subject for the November meeting will be ***Enlargements by Artificial Light on Argentic and other Sensitive Papers***, by Mr. Foxon.

DERBY PHOTOGRAPHIC SOCIETY.

The ordinary monthly meeting of this Society was held at the London Restaurant, Irongate, Derby, on Wednesday, the 1st instant,—Mr. Richard Keene in the chair.

The minutes of the previous meeting having been read and confirmed,

Mr. H. Arnold Bemrose, M.A., Vice-President, gave an address entitled *Scraps from my Holiday* [see page 667], which he illustrated with lantern transparencies by means of the sciopticon lantern.

A vote of thanks was passed to Mr. Bemrose for his interesting paper.

The report of the sub-committee appointed to consider the conditions of the subjects for study was, after a few slight alterations, adopted, the last day for sending in the prints being fixed for December 10th.

Mr. W. Haslam was elected a member of the Society. A cordial vote of thanks to the Chairman brought the proceedings to a close.

LEEDS PHOTOGRAPHIC SOCIETY.

The ordinary meeting of this Society was held on Thursday, October 2nd,—Dr. Thorpe, F.R.S., in the chair. There was a considerable attendance of members.

The following gentlemen were elected members:—Sir Percy Radcliffe, Rev. C. Courtenay, Mr. T. W. Harding, and Mr. R. T. McKay.—Messrs. S. Marshall and T. Dawson were elected auditors.

A large number of prints in silver and platinotype were shown by Messrs. Teasdale, Ramsden, Ward, Denham, McKay, Bothamley, and Pearson.

Dr. J. Walker exhibited a changing-bag of very simple construction, but most efficient, which elicited much admiration.

Mr. F. W. Branson exhibited a number of lantern slides to illustrate the effect of introducing sulphite of soda into the carbonate of soda developer, the result being great clearness, a warm brown tone, with great latitude in the exposure.

Mr. Pocklington exhibited a lantern slide toned with gold, in which the foreground was of a brown colour, the trees and middle distance green, and the sky a light blue. He (Mr. Pocklington) promised details of the process when he had made further experiments.

Messrs. Reynolds and Branson sent for exhibition a new lantern for the dark room with special features, which will meet with the approval of amateurs.

Mr. W. Teasdale, referring to a remark made by a member as to the manner in which he packed his exposed plates previous to development—that is, face to face without paper between—suggested that by this means the plates might be fogged. He based his opinion on the fact that, if paper were exposed to a strong light and then used for wrapping up sensitive plates, the plates so packed would be fogged. He was of opinion that the same result would be brought about—but, of course, not in so marked a manner—by packing exposed plates without anything between.

Dr. Thorpe intimated to the members that a committee had recently been appointed by the Leeds Philosophical Society for considering the question of furthering the interests of meteorology in some way, and he asked the attention of the members of the Leeds Photographic Society to this subject, as he thought they might be able to devise some method of determining the amount of solar energy sent down to us. This, he said, was one of the great problems of the present day. The subject had already been dealt with, and he described the various actinometers already in use. He said that what was required at present was not intricate and delicate apparatus, but some rough-and-ready method; and he expressed his opinion that this work might with advantage be undertaken by some members of the Society.

Several members made suggestions, and a general conversation on the subject ensued.

AMATEUR PHOTOGRAPHIC ASSOCIATION OF VICTORIA.

The monthly meeting of the above Association was held on Monday, the 1st ult., at the Royal Society's Hall,—Mr. E. C. Bell, Vice-President, occupying the chair.

After the election of new members and the nomination of two others for membership,

Mr. Baker proceeded to demonstrate the method of using Warnerke's sensitometer. He showed several of the sensitometers, and it was remarked by some members that if all those manufactured were similar to the samples exhibited very little reliance could be placed on them, so far as a general standard was concerned, as the density in no two of them was similar. When the development of the test plates was commenced, similar complaints were made by some of the members as to the coating of many of the makes of gelatine plates which reached this market, some samples, issued from the factory of a well-known maker, being conspicuous for uneven coating. [It was jocosely remarked by a member that gelatine emulsion must be exceedingly cheap, or the makers of plates could never afford to coat the backs of plates as freely as they do the faces, which was very often the case.] The result of the tests showed that some of Mr. Baker's make of plates registered as high numbers as the best makes of English plates which were tried.

The lecturer afterwards exposed and developed several opal plates of his own make, and a great deal of information was given, after which the meeting was adjourned.

Correspondence.

MARKINGS ON DRY PLATES.

To the Editors.

Gentlemen,—Some time ago I was much puzzled to find the cause of dark bands of fog on several negatives. A customer had sent to ask me the cause, affirming that it was the fault of the plates. I had already sent out several thousands of the same batch, and not having received any complaint you may guess that I was somewhat puzzled. On each negative, about half-an-inch from the right hand side, was a band of fog about two inches wide, exactly the same position and width on each plate.

The photographer also sent an unexposed plate of the same batch, but on developing it no trace whatever of fog was discernible. I knew very well that it would be difficult to produce fog always exactly in the same place even if I had wished to do so. The only reason I could give at that time was that the woodwork of the camera had become slightly smooth on the inside, and had reflected the light on to the plate.

The answer given remained without further explanation till last Thursday, when a gentleman called and asked me to develope a plate, as he thought there was something wrong with his dark slide. I developed the plate, and found a dark band on the right hand side of the plate, about one and a-half inch wide. On returning it to the dark slide I found that the mark corresponded exactly to the leather used for hinging the shutter of the slide. The leather smelled strongly, and had imparted a slight fog to the whole plate. The plate had remained in the slide for about one month, but during that time it had not been exposed to any white light.

I was informed that the plate if only kept in the slide for a short time was all right, but if kept for two or three days the band of fog was sure to appear. I am fully convinced now that the plates, the negatives of which had been sent back to me, had suffered from the same cause. The camera-makers should be more careful in selecting the leather they use for their slides, and save plates from being condemned through no fault of the plate-maker, as in the incident I have just related.—I am, yours, &c.,

21 and 23, Charles-street, Royal Crescent, Notting Hill, W., October 9, 1884. J. Désiré England.

TRICYCLES FOR PHOTOGRAPHERS.

To the Editors.

Gentlemen,—The letter in last week's Journal impels me to write and give my experience of the utility of a tricycle for the purpose of getting about and taking views, and to describe my own arrangement for the information of others.

The distance that can be ridden daily depends, of course, upon the physical powers of the rider; but it also depends, in some degree, upon the class of machine he rides. I may say, being guided in so doing by my twenty years' experience of cycling, that some of the machines mentioned from time to time in the press as being suitable for the photographer are about the worst of the tricycles before the public, being of a cheap, inferior, and improperly-contrived type. I will not particularise, but I have been sorely tempted to plunge into the arena several times, when I have seen letter after letter recommending machines for the purpose that I know full well would be sure to disappoint and disgust those who might be led to select them.

On a "sociable"—that is, a machine for two riders—I have found little difficulty in riding forty or fifty miles, carrying a complete set of apparatus, together with my own and my companion's luggage. On my "Carver"—a single machine—I can ride almost any distance within reason, either with a camera 8×5, made by Anthony, of New York, or my small tricyclist's quarter-plate set.

Undoubtedly the best machine for the photographer is the famous Humber type. That is ridden by all the best tricycle riders of the day, because its cross-handle bar serves as a sort of table. Of this type there are several good examples, viz., the Humber proper, the Carver, the Sandringham Club, the Traveller, and others; but the one that unquestionably seems to me to answer best for the photographer is the "Carver," made at the Alfred-street Mills, Nottingham. My reason for thinking the "Carver" the best is that, *while being well made and of the best material, it has a patent automatic brake which, at will, holds the whole machine perfectly rigid and still at any point, either on the slope of a hill or upon the level.* With this arrangement no tripod stand is needed at all, as the body of the camera can be placed on the saddle, and the fore-end rested upon the steering-bar handle, which is on a level with the saddle; and it is surprising how adroit one becomes with practice in placing the machine and the camera in proper position, and how rigid the whole affair is when done. I never carry a tripod at all, as with double swing-backs and a rising and lowering front almost any angle can be attained, and the tricycle can be led *anywhere*.

The apparatus is carried in a wicker basket upon the luggage carrier in front, and really seems to help rather than otherwise, as its weight serves to take much of the pressure from the trailing wheel. The enclosed photographs will show you my arrangement upon the "Carver."—I am, yours, &c.,

River Cottage, Hornsey, N, October 11, 1884. SIGMA SMITH.

[The arrangement shown in the photographs is excellent, but we prefer an open-fronted machine of the same type—that is, without the bicycle handle.—EDS.]

THE SODA DEVELOPER: A CORRECTION.

To the EDITORS.

GENTLEMEN,—On opening the Journal this morning I saw, with a feeling of dismay, that the formula for soda development, in the article to which my name is subscribed, contains a very serious error, which I hasten to correct, and at the same time beg of you to allow me space to apologise for my blunder to those readers, if any, who have been led astray by it.

The formula should be:—

No. I.

Pyro.	1 part.
Sulphurous acid	1 ,,
Water (distilled)	8 parts.

No. II.

Saturated solution of carbonate of soda	6 parts.
Sulphurous acid	$1\frac{1}{2}$ part.
Bichromate of potash (five-per-cent. solution)	$\frac{1}{4}$, $\frac{1}{2}$, or $\frac{3}{4}$,,
Water	18 parts.

It will be seen that the bichromate of potash is largely in excess in the former as compared with the corrected formula, and the sulphurous acid is deficient. This latter error is unimportant; but excess of the bichromate salt would decompose the pyro., and so destroy its developing power.

I may just add that the formula (in my hands) continues to work well, and it has been tested on several varieties of plates; but with one brand of very rapid, which produces a soft image, owing to the thinness of the gelatine film and lack of silver, it has been found needful to add one grain of bromide of potassium to each two ounces of developing mixture, in order to get density. Still the image was wanting in vigour; so the toning with iron was omitted, and the normal colour of the soda image utilised. These plates yield no better result with ammonia, and therefore soda is not to blame.—I am, yours, &c., W. HANSON.

Leeds, October 10, 1884.

A NEW DEVELOPING FORMULA.

To the EDITORS.

GENTLEMEN,—On reading the report of the Edinburgh Photographic Society, in your last issue, I felt somewhat "sorry I spoke," as the developer to which I alluded in my letter is certainly not quite as new in material as I supposed, although somewhat so in the combination. However, I had better say something, and say it as briefly as possible.

The first plate about which I made notes I developed with—

Hydrokinone	$1\frac{1}{2}$ grain,
Liq. potassæ, s.g. 1270	15 minims,
Water	3 ounces,

and got a very dense negative. I continued various experiments, adding carbonate of potash, citric acid, and mixing pyro. with the hydrokinone; but, after all, I found the following answer excellently for a $7\frac{1}{2} \times 5$ plate:—

Hydrokinone	$1\frac{1}{2}$ grain.
Citric acid	10 grains.
Liq. potassæ, s.g. 1270	20 minims.
Soft water	5 ounces.

Mix and filter.

Pour this over the plate and in half-a minute, or thereabouts, return to the developing cup and add from ten to thirty minims of liq. potassæ. The plate ought, on this being poured on, to come out well.

This developer appears to me to allow of great latitude of exposure, and not to sacrifice the high lights while the shadows are developing. Over-development is hardly possible. It gives great delicacy and softness in printing, and, at the same time, printing density, principally from the colour of the negative, which is a red shade, and not so visible by direct light as when viewed at an angle. I have noticed, and attribute it to the more perfect action of the hydrokinone over the pyro., that the white deposit in the hypo. (the free chlorides?) is scarcely present. In my last experiment I exposed two plates, one directly after the other. One of these I developed with Fry's sodic sulphite formula; the other with the above hydrokinone developer. I enclose prints from both. They will hardly, however, compare quite fairly, as the former was exposed thirty seconds and the latter twenty seconds.

I do not find that carbonate of potash in the developer makes any marked difference in the result; but I did not find I could develope without liq. potassæ added, and I like as simple a developer as possible. I venture to think this developer would well repay further experiment, as would also the examination of the active principles of other of the vegetable kingdom as developing agents. Before closing I may mention that I have obtained very pleasing toning results from carbonate of potash, twenty grains to one grain of gold.

In conclusion: I feel I owe your readers some apology for having made a claim in my former letter which a little delay and less enthusiasm would have prevented.—I am, yours, &c., W. T. F. M. INGALL.

Greenhithe, Kent, October 14, 1884.

THE MEDAL AWARDS AT THE PHOTOGRAPHIC EXHIBITION.

To the EDITORS.

GENTLEMEN,—I have just returned from the Photographic Exhibition, and cannot resist writing a line with reference to the recent awards, though I know full well that I lay myself open to remarks such as "the grapes are sour," &c.; but I can honestly say I have the best interests of the Society at heart in calling attention to the awards given.

I can conceive nothing so likely to bring the Society into disrepute as the awarding of medals to inferior work, &c. It will either end in members who can do good work not competing at all, or their sending in their works not for competition.

Take, first of all, the medal given for interiors, where all the lines converge. Surely this is not a specimen to be held up to the public as a sample of good photography.

Then a medal is given for scientific subjects — photomicrographs. Surely better work than this can be done to merit a medal.

Again: no medal is given for pure landscape photography, of which there are some splendid examples. I contend a great deal of skill is shown in the choice of a subject, so as to get it properly lighted, and avoid all movement of foliage, &c., which is not called forth by a mere snow-scene—beautiful as such photographs are.

Lastly: a medal is given for photo-engraving—entirely a mechanical process. This is certainly not photography.

I know there must always be dissatisfaction in the minds of some with the awards, but let us have a little less glaring faults to complain of.—I am, yours, &c., WM. WAINWRIGHT, JUN.

Hoe Place, Woking, October 14, 1884.

Notes and Queries.

W. H. WARNER writes, wishing to know the relative strengths as to restraining power of—1, nitric acid; 2, sulphuric acid; 3, sulphurous acid; 4, formic acid; 5, oxalic acid; 6, citric acid.——We shall be glad to have the opinions of our readers relative to this matter.

JOHN ROBERTSON says:—"I have commenced to make a lantern on the plan of M. Hutinet's for enlargements; but I find I want the information how I am to get ventilation at the bottom to cause the light to burn, and yet not to permit any light to escape. In the description of M. Hutinet's lantern in the JOURNAL and in the ALMANAC I do not find this named. I trust you will kindly give me the information. At the same time, perhaps, you will tell me the simplest method to reverse a negative."——In reply: We cannot anticipate any great difficulty in ventilating a lantern. A few holes covered over with a strip of tin bent at a right angle will prove the means of admitting air without allowing the egress of light.—To reverse a negative in the simplest manner: coat a glass plate with one of the dusting-on compounds to be found at page 227 of our last ALMANAC, expose under the negative, and develope by the application of powdered plumbago with a soft brush.

"1. HAVING constructed a magic lantern, four-inch condensers, I should feel much obliged at receiving your advice, in next issue, as to which is the best paraffine lamp to use to show a picture (sharp) on the screen about ten feet square.—2. Can I obtain better results with three condensers—namely, two plano convex and one double convex—than with the ordinary double condensers.—SOUTHENDON."——In reply: 1. A suitable paraffine lamp for the purpose (that is, giving a sharp image) is one which has a somewhat small circular wick, the flame of which is contracted by the chimney—one, in short, of the best argand form. A greater degree of luminosity may be secured by employing some of those lamps in which two, three, or even four flat wicks are presented with their ends towards the condensers, as in the sciopticon and lamps of the class which have been evolved therefrom. But, as a rule, the sharpest images are obtained when employing a very small flame.—2. We advise the employment of double condensers; but if a triple condenser be properly constructed it is likely to possess advantages greater than the double. Still, there is so much accuracy required in the construction of a high-class triple condenser that it is doubtful if, by any haphazard combination of three elements, such a good result would be obtained as if two only were employed.

ALPHA writes:—"Having a quantity of precipitated metallic silver which I wished to purify from any traces of the zinc with which it had been thrown down, I heated it in a porcelain basin with sulphuric acid. It was left to itself for a short time, and on my return I found the place full of such acrid fumes that I was unable to get into the room to turn off the gas, and had to wait until the whole had evaporated to dryness and the atmosphere had partially cleared itself by way of the chimney. I then found the cracked dish contained a considerable quantity of a yellowish white salt and but very little metallic silver. Can you tell me what this is, and what I have done wrong?"——In reply: It was wrong to *heat* the silver and sulphuric acid. The latter has no action upon silver at the ordinary temperature, but, when heated, converts it into silver sulphate. If concentrated sulphuric acid be employed, and the temperature raised to boiling point, the acid is decomposed and copious fumes of sulphurous anhydride are given off. This is what occurred in your case. During your absence the acid had become sufficiently concentrated through evaporation of the water, and then the evolution of sulphurous fumes commenced. The salt remaining is sulphate of silver, which, owing to its low degree of solubility (1 in 88 of boiling water), is very difficult of treatment. The simplest plan will be to boil it in a considerable quantity of water, adding, at intervals, chloride of sodium or hydrochloric acid until no further precipitate of chloride of silver is formed. In this manner successive portions of the sulphate are dissolved and converted into chloride, and the water left free to dissolve a fresh quantity; and so on, until the whole is converted.

"I HAVE been trying the collodion transfer process and experience some difficulty in getting the film to strip clean from the glass. According to the instructions I have received in writing from one who gives lessons *in absentia*, I have made the glass plate scrupulously clean, and complete the operation by rubbing it with the finest precipitated chalk; but still the film adheres so tenaciously as to produce patches all over the surface. What is wrong?—Yours, &c., FRANK B. WHITE."——In reply: Our correspondent has mistaken the nature of the chalk that must be applied to the plate after it has been made clean. It is not "precipitated" chalk but *French* chalk, which is an entirely different substance. Let this be well rubbed all over the surface, taking care that no part is omitted, and then wipe it all off again. If this be done previous to applying the collodion there is no fear of its adhesion to the glass at a subsequent stage in the process.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPHS REGISTERED.—

Thomas Roberts, Bradshawgate, Leigh, Lancashire.—*Photograph of Henry O'Connor, S.J.*

Edmund Eccles, Broad-street, Bury, Lancashire.—*Three Photographs of R. N. Phillips, Esq., M.P.*

Ambrose Copsey, 8, Sepulchre-street, Sudbury, Suffolk.—*Photograph of the Rev. Oliver Raymond, LL.B.*

William Baker, 7, Malva-road, St. Ann's-hill, Wandsworth, London.—*Photograph of Yoke of Oxen and Country Cart.*

Walter Lamb Knott, 68, King-street, North Shields.—*Photograph of the Lifeboat, "Co-operation," stationed at Callercoats.*

W. B. Allison, West-street, The Mount, Stoke-on-Trent.—*Photograph of the Venerable Archdeacon Sir Lovelace T. Stamer, Bart.; Two Photographs of Mr. Henry Broadhurst, M.P.*

VARNISH.—Rather too little body in the varnish.

B. D.—The Exhibition remains open until November 13.

H. JOLY (Lyons).—The subject will be treated in a leading article—most probably in our next.

C. PUMPHREY.—By the American term "sal soda" common washing soda of the oil shops is meant.

JERRY.—Consult our advertising columns. We cannot undertake to recommend any particular manufacturer.

SIDNEY.—Dissolve two or three grains of Castile soap in each ounce of alcohol, and employ that as a lubricant.

T. C. K.—Possibly you have rolled the prints before they were qu dr If not, probably you have employed too great a pressure.

T. J. R.—Write to the firm in question. Possibly they would prepare yo some plates specially—that is, if you order a sufficient quantity at a time

A. Z. O.—So many times as sensitive as "wet collodion" simply means nothing. What number does the plates show on the sensitometer screen That will be a guide as to their sensitiveness.

R. S. BELL.—We are by no means surprised that the dark tent realised so small a sum, notwithstanding its original cost. Indeed, we are more su prised that it sold at all. Who uses dark tents nowadays?

AMATEUR.—The five-inch lens is not sufficiently powerful to cause the rays to converge towards the object-glass in front. Try the effect of employing a second of the same character mounted close to the first.

A.—As you describe it, your method of washing should be sufficient, but, judging from the results, it is clear that it is not. Possibly too many negatives are washed at a time in a trough of insufficient size.

A. R. GILL.—The opal enclosed is not the kind generally used for opalotypes or "porcelain pictures." What you require is that kind which is known as "dead, smoothed pot opal." It is less expensive than your sample, which is "patent plate opal."

A. DENNY.—To copy the same size with your lens the camera must be capable of extending to seventeen and a-half inches. You had better have the cone made eight inches long, then with the sliding body of the camera you will have plenty of latitude.

J. G.—1. The sample of gelatine enclosed appears to be a good one, but without actually trying it it is impossible to say if it will be suitable for emulsion purposes.—2. See leading articles in our issues for March 14, 21, and 28 of the current year.—3. We regret we cannot spare time to accede to your wishes.

L. M. S. R.—1. B. is the more suitable.—2. Expediency must dictate which is the better system to adopt. If the proper effect can be obtained by raising or lowering the lens, it is, perhaps, better to have recourse to this.—3. The toning bath ought not to have become discoloured. When it becomes dark make a fresh one.

AN OPERATOR.—As a rule, so we are informed, the hours of employment are somewhat longer in provincial towns than in London; but yours appear to be unusually long even for the country. Of course there is no rule as to the hours that assistants are generally employed. This is always a special arrangement between the employer and the *employé*.

WM. HEYBRIDGE.—The mealiness or, as you term it, "leathery appearance" of the prints is due to their being over-toned. Some papers will not bear toning sufficiently to reach the purple stage, even if the negatives are of a suitable character to produce such tones. Tone less, and be content with warmer tones, or discard the paper altogether.

R. E. P.—All will depend upon the rapidity of the plates. What you term "medium rapidity" some would call "very slow," and others "rapid." Again: the exposure will be governed by the quality of the light and the amount admitted into the studio. The lens in question is much slower than an ordinary portrait lens, requiring about double the exposure.

ALEX. MCINTOSH.—The quantity of silver recovered certainly seems very small for so large a bulk of residues; but you must bear in mind that unless the metal were thin it could not be recovered. The weight of the residue and the time it took to accumulate is no criterion as to the amount of silver it contained. This can only be arrived at by making an assay.

IGNORANT.—Instead of relying on an intensifier, as you appear to do, you would do better to aim at attaining the requisite density in the development. The cause of the negatives fading or becoming spotty is that you have not sufficiently washed them between the different operations. The intensifier you have been using is a good one, if care be exercised in its employment.

J. WHISTLEY.—White hard varnish is not a good protection for negatives which are subject to hard usage, as it is too soft and pliable. If you require a cheap varnish, which will be more durable, you had better employ brown hard, diluted with methylated spirit. It is true that it is much darker in colour; but in the thin film on the negative it will not materially retard the printing.

LANTERN.—We have no means of knowing if the portrait be copyright or not, except by searching the register at Stationers' Hall. This you can do as easily as we can, as you reside very near. Supposing the picture be copyright, it will be an infringement of it if you copy it as a transparency for the lantern. By so doing you will render yourself liable to a penalty of ten pounds for every copy you sell.

*** Several correspondents' communications and notices are unavoidably left over till our next.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 22nd inst., the subject for discussion will be—*Reversed Negatives.*—All notices affecting the annual general meeting must be given in on or before the 22nd inst.

CONTENTS.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1277. Vol. XXXI.—OCTOBER 24, 1884.

THE COLLODIO-ALBUMEN OR THE ALBUMEN PROCESS FOR LANTERN SLIDES.

The lantern season is now fast approaching, and many amateurs will be setting about producing transparencies from the negatives secured during the past summer, so that they can exhibit the results to their friends on winter evenings. Naturally they will be anxious that their work should appear to the best advantage; therefore any information as to the best method of securing this end will just now be most acceptable.

At the last meeting but one of the Photographic Club Mr. Wm. Ackland (a veteran in transparency making) described the collodio-albumen process for producing lantern slides, and also demonstrated certain portions of the process, more particularly those wherein the beginner is most likely to fail. The details of the process, as described by Mr. Ackland, were so simple and the results exhibited by him so perfect that the Club decided, in accordance with one of its rules, that the different formulæ should, with Mr. Ackland's permission, be published.* It may be mentioned that the simplicity of the process appeared to take most of the members by surprise, as they, in common with many others, seemed to imagine the collodio-albumen process was one of considerable complication.

We here propose to offer a few remarks on Mr. Ackland's communication to the Club. Although, unfortunately, we were prevented from being at the meeting, we have the advantage of learning what took place from a gentleman who himself is an experienced worker of the process.

In the first place, it may be well to explain wherein the method described by Mr. Ackland differs from the old collodio-albumen process of Taupenôt. In the latter process the plate is first coated with an ordinary iodised collodion and then sensitised in a silver bath, precisely as in the wet collodion process. It is afterwards washed to free it from nitrate of silver; then, after draining for a short time, it is coated with iodised albumen and dried. It is again sensitised—this time in a bath strongly acidified with acetic acid—washed, and dried. The plate is then ready for use. In the former process the plate is coated with iodised collodion as in the other; but, instead of being sensitised in a silver bath, it is simply washed in water to free it from the collodion solvents and, at the same time, the iodising salts. When the whole of the ether and alcohol is washed away the plate is coated with iodised albumen, and afterwards treated exactly as in the Taupenôt process.

Although this at the Club was entitled the "collodio-albumen process," we cannot avoid thinking that the "albumen process" would be a more correct designation, inasmuch as the collodion acts entirely mechanically and takes no part whatever in the formation of the picture; in fact, it is simply a substratum, as it were, to hold the albumen upon which the image is formed.

It may be remembered that towards the close of last year we directed special attention to the albumen process for producing lantern slides, and subsequently [see page 783 of our last volume and page 3 of the current one] we gave the full working details of the process. These differ in no material degree from those given by Mr. Ackland—at least, in so far as the preparation of the plate is concerned—and very little in the after manipulations.

It may be well to explain the part the collodion plays in the process, so that those who may take it up will the better comprehend its functions. An even film on the plate is, of course, at least as great an essential in the albumen as it is in the gelatine process, and the old method of obtaining this was to pour on the albumen and then place the plate in a perfectly horizontal position—the same as is now done with gelatine. But albumen, unlike gelatine, does not "set" or gelatinise, and, therefore, cannot be reared up on end to dry. Hence, the plate had to be dried while in the horizontal position, and, unfortunately, during the time the film is moist, it has a singular affinity for dust; the most minute particle of which settling on the plate invariably produces a spot or blemish in the finished picture. It was found, however, that this difficulty could be obviated by the following method of procedure:—

The plate is first coated with a collodion of a porous character—such as that yielded by a sample which has been kept for a long period after iodising. It is then washed to free it from the alcohol, ether, and the iodiser; then on this washed film the iodised albumen is applied. The albumen permeates the porous collodion, and sufficient is retained by it, sponge-like, even when the plate is reared on end while drying, to form the image. By this simple expedient an even and uniform coating is secured. But this is not the only advantage gained; for if, perchance, a particle of foreign matter—such as dust—should happen to come in contact with the film, the albumen as it dries appears to force it into the collodion substratum, where it remains practically inert.

After our articles on this process appeared we received several communications from correspondents who had failed in obtaining the albumen in a clear and workable condition. This simply arose from not following the instructions as we gave them. The impression on many minds appears to be that, in order to obtain albumen in a state of limpidity, it is essential that it should be converted into a froth, and the more perfectly this is done the better will be the result. Now, this is precisely what is to be avoided in the preparation of it for this process; for if froth be formed it is sure to give rise to more or less trouble, as several of our correspondents have already discovered. The importance of this fact was, we are informed, strongly dwelt upon by Mr. Ackland.

It may be explained that when the acetic acid is added to the albumen the whole must be gently stirred with a glass rod, so as to mix them without the formation of air-bubbles or froth. As the acid mixes with the albumen a flocculent deposit is formed, which, after standing a few hours, collects on the top in a compact mass, and can then be easily removed, leaving the albumen comparatively clear, and so limpid that it will readily pass through filtering-paper. If, however, in mixing the acid froth be formed, the precipitate will not collect into one mass, but remain diffused in a more or less fine state of division; and it will be found quite impossible to separate it by straining or filtration, so as to render the albumen fit for use. The after addition of the ammonia restores, to an extent, the viscosity which the acid destroyed.

Another matter of importance in the preparation of the plate is that of its sensitising. It should receive but a very short immer-

* Mr. Ackland's communication, embracing the formulæ, will be found on page 680 in the current number.

sion in the silver bath—much shorter than many beginners are inclined to think sufficient. The maximum time for immersion should on no account exceed a minute, and it is only in very cold weather that this time should be allowed; for under ordinary conditions half-a-minute, or even less, will be ample.

The albumen, or collodio-albumen, process—whichever it may be termed—is one which, by reason of the exceeding transparency of the lights and depth, without opacity, of the shadows it yields, is capable of producing transparencies of the highest possible standard of excellence, as witness the admirable productions of MM. Ferrier and Soulier. We shall take an early opportunity of recurring to the subject, and shall add a few remarks on the other details of the manipulations.

ENLARGEMENTS ON CANVAS.

What is the best and cheapest method of producing an enlarged photograph from a small negative on canvas for the use of the colourist in oils? This is a query that comes to us with a certain degree of frequency. The question is one which admits of some latitude. It presupposes the existence of several methods, some of which are cheap; others—irrespective of cost—good. Having a small negative of a portrait, how are we to enlarge it in a cheap, yet good, style?

One of several methods which forces its attention upon us at the present time is that by the transfer of a collodion film from the glass plate upon which it has been taken to the canvas upon which it finds a final resting-place.

Let us suppose that an artist is desirous of having a certain face and bust transferred to canvas. It is first of all necessary that the apparatus for producing a large image of the original be at hand. If daylight be the luminant employed, then the question is reduced to one of extreme simplicity. The negative is erected in such a manner as to have the sky as its background, and at a right angle to it is placed the lens by which an image is to be formed. A screen for receiving this image is erectd at the other side of the lens, and the optical conditions are thus rendered complete.

We will now presume that the enlarged image has been obtained in a collodionised glass plate of any reasonable dimension—such as twenty or thirty inches in length by a proportionate breadth—and that it has been treated in such a manner as to ensure permanence as well as the requisite amount of detail. What then? While the collodion image is being washed let us turn our attention to the canvas upon which it is to be placed as a final support.

Canvas prepared for painters is readily procurable from those artists' colourmen who make a specialty of this department of artistic requirements; and we now take it for granted that a sheet of such canvas has been obtained. The first thing to do with it is to sponge it all over with soda (mono-carbonate) and water until every trace of greasiness has quite disappeared, allowing the water to flow freely over the surface. When this is the case a moderately-strong solution of gelatine, containing a feeble admixture of chrome alum, is sponged over or otherwise applied to the surface of the canvas, and allowed to become quite dry. It is, indeed, better that such canvases should be kept in stock ready for use.

Let us now revert to the collodion image upon the glass plate. When it is found to be well developed and still clear in the shadows, the plate is laid, glass side down, upon a block or tablet which has been erected at one side of the sink at which the development and washing have been effected. The canvas, previously sponged over with water until plastic, is laid face down upon the collodion film, and pressed into close contact by means of the squeegee.

It is, of course, understood that the glass plate, previous to receiving its coating of collodion, shall have been thoroughly wiped over with a rubber charged with finely-powdered French chalk, or with a solution of bees'-wax in turpentine or other solvent. We find in our own practice that French chalk answers the purpose admirably, and, as it is cleanly and easily applied, we commend its use to all who try this process.

The plastic canvas, now quite wet, must be pressed into intimate contact with the equally-wet collodion film containing the image, and the plate is then laid down upon a flat table, a few folds of blotting-paper, backed by a thick pad, being superposed. This must remain undisturbed for a short time, after which a trial may be made at one corner to see if the canvas when raised carries with it the collodion film, which becomes detached from the glass in favour of the textile fabric. If the film be found to attach itself to the canvas the latter should be carefully raised from the glass.

The great advantage of effecting the transfer previous to the canvas and film becoming dry is that the film adheres in a most perfect manner to the canvas—certainly adapts itself more perfectly to the textile character of the fabric—and dries *flat;* whereas, if the transfer be not made until the film has become quite dry, the surface is of a shining and glossy character, being, indeed, then a transcript in regard to mechanical smoothness of the surface of the glass, which from an artistic point of view is somewhat offensive.

When the canvas is stretched out so as to become quite dry the collodion film will, upon being dried, be found to have become "part and parcel" of its surface. There will be no gloss, but the interstices of the textile fabric will be as plainly shown through the thin collodion image-bearing film as if no such pellicle were superposed upon its surface.

THE MEASUREMENT OF EXPOSURES.

We lately received an inquiry from a correspondent in France as to the best mode of ascertaining the duration of exposure when a guillotine shutter was employed; and seeing that, during the present year and its predecessor, the ranks of photography have been recruited by such large numbers of amateurs, it may serve a good purpose if we briefly allude to some of the methods that have been proposed for measuring the times of exposures, the subject having been rather fully treated on various occasions anterior to this period.

At the outset it may be said that the guillotine shutter offers the greatest facilities of any for obtaining the required data, seeing that, theoretically, a simple calculation without the employment of any apparatus will furnish the desired information, the laws of falling bodies being so simple and easily understood. Such a shutter, however, unless made in a manner more nearly approaching perfection than has yet been done, does not in practice move with the rapidity of perfectly-free bodies, and, in consequence, the dictates of theory have to be modified by the logic of facts as indicated by practice. Nevertheless, for comparatively small distances, when the motion is not very quick, it is quite possible by mere calculation to learn the time occupied by the shutter in falling a certain distance.

The shape of the aperture also governs the time the plate is subjected to the action of the light, seeing that it varies from the proportion of a true square to that of an extremely elongated rectangle; hence, any rates of rapidity given must be corrected by finding a mean of the times occupied in passing the lens by the upper and lower edge of the aperture.

Disregarding, as we may safely do for short distances, the resistance of the air, and for the nonce leaving aside the frictional retardation we have alluded to, we may say in round numbers that in a second of time any body falls through sixteen feet of space. At the expiration of that time it would be moving at such a rate as, if continued neither checked nor increased, would be thirty-two feet per second; but in a body falling we know the motion is continually being accelerated. Drop shutters, however, do not fall through such spaces as these, and we may deal with small distances.

But the acceleration continues from the very moment that the shutter begins to drop, so that it would be quite wrong to assume that, because a second of time is occupied by an object in falling sixteen feet, it will fall eight feet in half a second, or four feet in a quarter of a second, and so on, for such is not the case. Of any two consecutive equal periods of time taken during the falling the distance traversed is always greater in the latter. It is thus obvious that to ascertain the time of exposure from the distance fallen through, or *vice versâ*, is not the simple piece of division that at first might be imagined. Still the actual calculation is easily performed, as the ratio is a simple one.

Thus, if we know how far a body falls in one second, for example, we get the distance traversed in a certain number of seconds by squaring that number and multiplying the result by the given distance. Thus, a body will fall, as we have said, about sixteen feet in one second; therefore, in three seconds it will fall not three times sixteen feet, but sixteen multiplied by three times three, or one hundred and forty-four feet, and so on. The same rule holds good for smaller periods than one second. To give a practical character to these remarks, and to save trouble in calculation, we here reproduce a table given in a leading article in this Journal a number of years ago, showing the space fallen through by a freely-moving body in each tenth of a second up to one second:—

In $\frac{1}{10}$	of a second	the object will	fall through	$\frac{4}{25}$	foot.
„ $\frac{2}{10}$	„	„	„	$\frac{16}{25}$	„
„ $\frac{3}{10}$	„	„	„	$1\frac{11}{25}$	„
„ $\frac{4}{10}$	„	„	„	$2\frac{14}{25}$	feet.
„ $\frac{5}{10}$	„	„	„	4	„
„ $\frac{6}{10}$	„	„	„	$5\frac{19}{25}$	„
„ $\frac{7}{10}$	„	„	„	$7\frac{21}{25}$	„
„ $\frac{8}{10}$	„	„	„	$10\frac{6}{25}$	„
„ $\frac{9}{10}$	„	„	„	$12\frac{24}{25}$	„
„ $\frac{10}{10}$, or one second		„	„	16	„

Smaller distances than $\frac{4}{25}$ of a foot—that is, less than two inches—are not likely to be made use of, increased rapidity being gained by a spring, in which case other means for ascertaining its rate would need to be made use of. It has been proposed to photograph a falling weight, but when spaces of a few inches only were in question it may be readily seen that micrometer measures would be required, and these would be undesirable for popular use.

Most of the other methods proposed involve the photographing of moving bodies, and vary as regards the construction of the moving arrangements and the manner of recording them. One general principle runs through the multitude of plans proposed—that is, a brightly-illuminated object moves in a circumscribed path, and is photographed at some stage of its career. The image shown on the plates after exposure and development—whether in the form of a circular arc or a straight line—shows the extent of path traversed during exposure, either with or without calculation. Among the objects recommended are a moving pendulum, its length enabling exact calculations to be made; a hand moved by special clockwork round a dial; the swing of a metronome; a revolving opaque disc, with an aperture through which light passes to the lens; and a handkerchief held at arm's length by an assistant, and moved quickly in circles, a little practice enabling him to do this with a fair approach to accuracy.

Finally: we may name one most ingenious method by means of a vibrating fork. The shutter is blackened by camphor smoke, and while it is falling a hair attached to a tuning fork touches it and thus records the vibrations, which are readily calculated and converted into time measurements.

We may caution those who attempt to carry out any of these ingenious experiments that they usually give equal value to any particular period of the exposure, if it be divided into a number of equal periods, although the moment when a drop shutter is opening, as also that of closing, is of far less value than the central periods. This, however, forms matter for investigation of another class and we believe that the query of our correspondent is fully answered, at the same time that a brief *résumé* of interesting matter is given to our readers in general.

THE PHOTOGRAPHIC EXHIBITION.

[Third Notice.]

Mr. T. M. Brownrigg is, as usual, represented by a number of his well-known landscapes of large size, chiefly woodland scenery. Both in selection and in the rendering of the foliage these are admirable examples of work, though the effectiveness of *A Lane at Waverley* (No. 113) is slightly marred by a trace of halation. *In a Wood at Cobham*, in the same frame, is a nearly perfect composition.

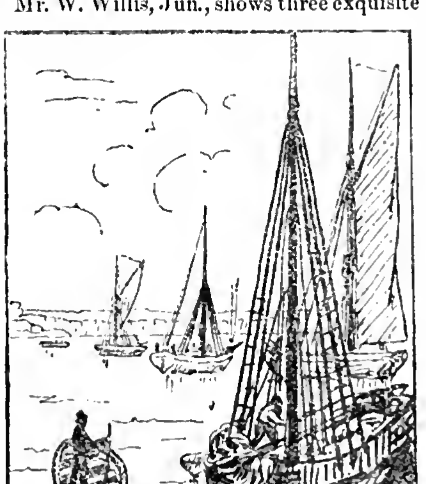
We have so frequently spoken of Mr. W. F. Donkin's Alpine views that it is scarcely possible to say more in their praise. We are probably expressing the general opinion when we state that Mr. Donkin has this year perhaps surpassed his previous efforts, though, in consequence of being one of the judges, he was unable to compete. In addition to the magnificent enlargements, prints are shown from the original $7\frac{1}{2} \times 5$ negatives, and it is interesting to note how little of the quality is lost in the process of amplification. *The Rothhorn, from Lo Besso* (No. 63), an autotype enlargement, gives one of the most marvellous renderings of snow we have ever seen; and a careful examination of the small print of the same subject in frame No. 375 cannot fail to impress one with a belief in the capabilities of the gelatine plate in combining vigour and softness under the most difficult conditions. Where all are so good it is difficult to particularise, but the mammoth proportions of *The Matterhorn, from the Hörnli* (No. 178) single it out for special notice. This is one of the few instances in which the gigantic size of the enlargement does not detract from its pictorial value.

Mr. Luke Berry exhibits a large number of frames of subjects very diverse in character, including portraiture, architecture, and group studies, the last being most noteworthy. With the exception of *Fountains Abbey* (No. 128) none of the first two classes call for special notice, but this is a very fine piece of work. *An Autumn*

No. 213—*An Autumn Morning*. By Luke Berry.

Morning (No. 213), selected for illustration, is a very effective bit from the harvest field. *The Last Load* (No. 349) and *Daddy's Coming* (No. 395) are also good.

Mr. W. Willis, Jun., shows three exquisite little platinotype prints, which have more the appearance of fine mezzotint engravings than of photographs. The best of these, *Shipping, Rochester* (No. 210), is well chosen and admirably executed.



No. 210—*Shipping, Rochester*. By W. Willis, Jun.

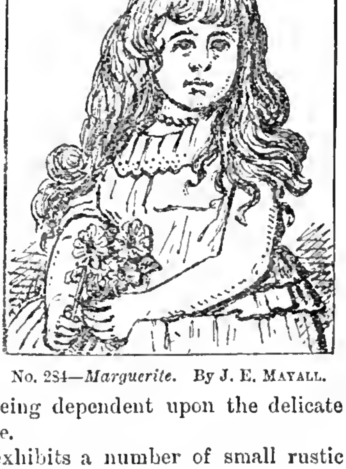
Mr. W. P. Marsh has received a medal for a frame of *Instantaneous Sea Studies* (No. 43), consisting of waves breaking on the beach at Bognor. While these are clever of their kind, there are other instantaneous works on the walls equally deserving.

Lieut. C. E. Gladstone's *Botanical Gardens, Palermo* (No. 50), makes a very effective picture, the style and colour of the platinotype print being eminently suited to the subject. Nearly the reverse of this, however, may be said of his

In Moor Park (No. 80), which appears weak and flat. The remaining exhibit, *Cedar Tree, Moor Park* (No. 439), is a vigorous and well-selected picture.

Mr. F. Beasley's *Studies of Cattle* (No. 55), exhibit all this artist's old power of selection and treatment. The centre picture, a group of cows browsing beside a willow-skirted stream, is a truly charming study. *A Folkestone Fisherman* (No. 74) is good, as is also the little group entitled *A Morning Chat* (No. 73). Mr. Beasley's landscapes are, as usual, remarkable for their delicacy and softness, his *Rydal Water* (No. 84) being specially so.

The veteran J. E. Mayall is to the fore again with several fine works, prominent amongst which at the present time is his *Portrait of Sir Moses Montefiore* (No. 195). *Marguerite* (284), selected for illustration, is a pleasing child portrait, and Nos. 526 and 546, portraits respectively of Mr. Henry Irving and the President of the Photographic Society, are characteristic and successful. From another of Mr. Mayall's photographs of Mr. Glaisher we have taken our supplement of this week.



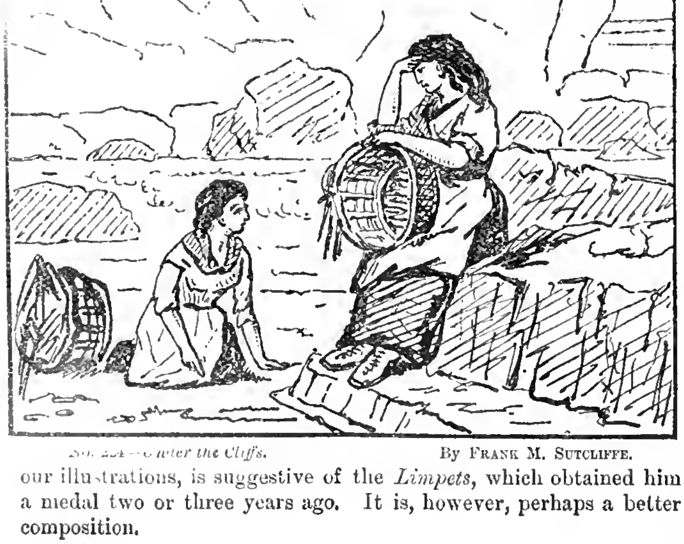
No. 284—*Marguerite*. By J. E. Mayall.

One of the few lady exhibitors, the Hon. Mrs. Holden-Hambrough, exhibits this year pictures of large size (12 × 10), of which the best are the two architectural studies of *Haddon Hall* (Nos. 85 and 86). The two "bits" from *Ashwood Dale* (Nos. 56 and 57) are spoilt by imperfect definition, the whole artistic value of the subjects being dependent upon the delicate rendering of the luxuriant foliage.

Mr. B. G. Wilkinson, Jun., exhibits a number of small rustic studies, of which the best is *Luncheon Time* (No. 76); also a couple of views *On the Mole, Betchworth Park* (Nos. 192 and 193).

Mr. H. Pointer's frame of *Cats and Dogs* (No. 380) contains a class of subject that is becoming rather monotonous, and, as it is now-a-days by no means a difficult one, might well be dispensed with in our exhibitions. No. 78, an enlargement of a white Persian cat, is, however, worth notice.

Mr. Frank M. Sutcliffe is not so well represented as usual—so far, at least, as quantity is concerned—though the quality is up to his standard. His *Under the Cliffs* (No. 224), which forms one of



No. 224—*Under the Cliffs*. By Frank M. Sutcliffe.

our illustrations, is suggestive of the *Limpets*, which obtained him a medal two or three years ago. It is, however, perhaps a better composition.

Mr. J. Milman Brown contributes a few little views of the Isle of Wight, and also a study of landscape and cattle, entitled *Repose* (No. 81), which is good, though the distant landscape is over-exposed.

Mr. C. Allan Ferneley's framed *Views in Surrey* (Nos. 537 and 558), though small in size, contain some very good work. His *Hampshire Cottage* (No. 87) is a pretty picture, the picturesqueness of the subject being enhanced by a judicious introduction of clouds.

Mr. J. Bracebridge Hillditch's *Study of Pampas Grass* (No. 88) is the most noticeable of that gentleman's exhibits; while his *Can I Trust You?* (No. 102) is of such small dimensions that it requires some search ere it can be found. There appears to be but slender connection between subject and title.

Mr. J. Hubbard's *Mother's Love* (No. 282) is a picture which, though it is some years since we first saw it, has lost none of its

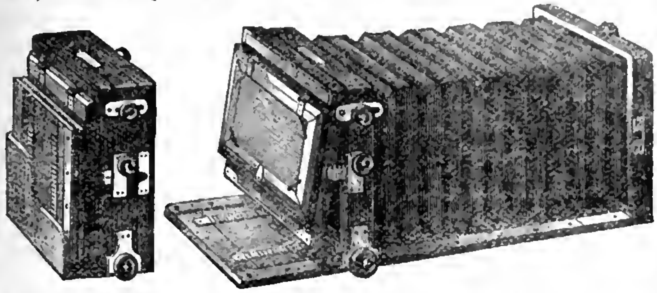
No. 282—*Mother's Love*. By J. Hubbard.

charms. Scarcely equal in result to the same artist's well-known *Stolen Moments*, the conception is a more happy one, and the picture will fairly take rank amongst successful composition work.

APPARATUS.

A departure from the regular routine employed in the construction of cameras has been made by Messrs. J. F. Shew and Co., who exhibit a "camera adapter." This invention, for which a patent has been obtained, has for its object the means of enabling the operator to work a plate one or two sizes larger than that for which his camera is constructed; thus by employing an adapter to a half-plate camera it may be converted into a whole-plate camera. The specimen exhibited effects the conversion of a whole-plate into a 12 × 10 camera—no small boon, it must be admitted, as it enables the amateur of limited means, who commences with a camera the dimensions of which are proportionate to his finances and, perchance, his manipulative skill, to aspire towards greater things with increased experience. With this invention he has only to have an adapter fitted to his camera, which will enable him, by using the single combination of his lens, to take pictures on the one or two sizes larger at a small outlay and with but slight addition to weight and bulk, with the extra advantage of being able to remove and dispense with the adapter and use the camera as usual when found desirable. The adapter is connected with the camera by means analogous to that employed with the dark slide or the lens front.

The long-focus camera of these makers, which we described last year, is again placed for examination in the Exhibition; but it has been improved since our description appeared by a lever clamp, dispensing with rackwork, saving time in opening, and provided with a very short rack which serves the part of a fine adjustment such as we have advocated in the Journal. The back of this camera can be instantly run out to any extent demanded by the focus of the lens, then clamped, and the back placed under the control of the

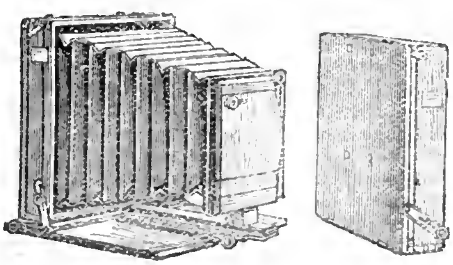


short rack already mentioned, by which the focussing is finally effected. The above diagram represents this camera.

Shew's eclipse shutter, too, comes under improved conditions from those which prevailed last year; for it is now fitted so as to be situated midway between the lenses in a compound objective—an undoubted advantage. Another improvement in the exhibits of last year by this firm is to be found in their small portmanteau or tricycle stand, which, like those pieces of apparatus referred to, has been brought under the influence of evolutionary principles, for it is still better this year than it was at the previous Exhibition. We are glad to report this firm (Messrs. J. F. Shew and Co.) as being the first to manufacture on a commercial basis the reversing camera-stand top, which has more than once been strongly recommended as a decidedly good thing. The idea is of American inception, and its special advantages have been during the past year urged upon the members of the metropolitan clubs and societies. It provides the means of enabling a photographer, after having focussed a view upon the plate lengthwise, to instantly turn the camera upon its end, so as to provide for any tall steeple which might not be got into the view as it originally appeared upon the ground glass, and this without the necessity for undoing any screw.

Messrs. W. W. Rouch and Co. exhibit an elegant little instantaneous shutter constructed of wood, yet so thin and light as to be capable of easily being carried in one's pocket-book. It consists of a flap fitted, of course, in a frame. The flap, when liberated by pressing a button at the foot, flies open, and, similarly to that which we described last week, permits, when open, a shutter to descend and cover the lens. This shutter is propelled downwards by a spring which imparts an initial velocity. The exposure given is uniform in the sense of not being adjustable.—A "war," or "special," correspondent's photographic outfit, exhibited by Messrs. Rouch and Co., consists of a camera and dark slides packed in neat cases capable of being slung over the back when the user is riding. It shows in a striking manner in what way photography may be made to aid the pen by way of supplying a description of interesting scenes.

There is also an excellent specimen of Rouch's patent portable camera exhibited by this firm. It possesses such mechanical features (shown in the adjoining figure) as combine the requirements of rigidity and portability, and and these qualities are conjoined with the extreme of lightness. Our diagram shows it both packed up and extended. When packed, the ground glass is protected



by a hinged wooden cover which folds over it. This cover, when moved upon its hinges, turns right round under the camera and forms the base-board, which can by the action of a screw be clamped either at a right angle to the ground glass or at any desired angle, forming in this respect an efficacious means for swinging the back so as to allow of tilting, for the purpose either of securing sharpness in the foreground of a landscape or accuracy in the delineation of an architectural view. To provide for the extension and focussing of the camera there is a movable central framework, which can be attached without screws to the base-board in a few seconds. This carries a rack and pinion, affording such a degree of extension as to permit of a lens of very long focus being employed, if required.

Leather as a material for the bellows of folding cameras has long held the first place in the estimation of manufacturers of apparatus of the highest class; indeed, they consider "there is nothing like leather." When, however, the expense of the material stands in the way, the substitutes proposed are most numerous. A material that struck us as being most serviceable in use was a "black sateen cloth" which a Manchester amateur had employed for the purpose, and he informed us that he had found it to wear excellently, his camera having seen plenty of service, and still being light-tight and sound at the time of our inspection. Possibly he may have been prejudiced in favour of the staple products of his neighbourhood; but we must say the appearance of the camera belied the existence of any such bias.

"Swing-back, Sir! No such fads for me. I do quite well without!" Upon our mildly suggesting that there was at times a real benefit to be obtained from tilting the back from the perpendicular, we were gruffly informed that he was well aware of the fact and frequently adopted the expedient. A request for an explanation elicited the manner of doing it. The back of the camera, attached, somewhat after the style of the Kinnear, by a pair of loose screws, was first placed firmly, *in situ*, in a vertical position by screwing it up tight; then both screws were loosened, a black lead pencil slipped between the loosened back and the base-board, screws tightened again, and, *presto!* the back had a strong tilt, which could be modified by placing the pencil nearer to or further from the screws. Every end was served and the process was not a long one.

Accounts are to hand from observers in all quarters of the recent eclipse of the moon (which occurred, as our readers will remember, upon the evening of the *conversazione* of the Photographic Society of Great Britain), and they appear to be unanimous in describing it as possessing features of a rather unusual character, particularly in the almost complete invisibility of the orb during the period of totality. Usually the moon is quite visible during the phase of greatest obscuration, but in this instance it was only by a close scrutiny of the part of the heavens where it was known to be that it could at all be found by the naked eye.

It has been suggested that a connection may be discovered between this unusual appearance and the remarkable sky-glows which have several times of late been again observed in the heavens—possessing a brilliancy almost, if not entirely, equal to that which characterised the displays of last autumn.

With regard to this latter suggestion a singular observation of Mr. Lewis Swift, Director of the Warner Observatory at Rochester, New York, which was read at the American Association, may be here referred to. He stated that since the sky-glows appeared last year there had not been a single first-rate clear sky for observational purposes, and his experience, it was stated, was borne out by the generality of other observers.

Nevertheless, it has apparently not interfered with lunar photography at Paris during the eclipse; for our contemporary, *La Nature*, has a series of interesting photo-engravings direct from negatives of the moon taken by MM. Paul and Prosper Henry, who succeeded in securing a large number of negatives of the phenomena at various stages of progress.

Photographers should know something about the working up of residues, although many still persistently reject any mode of treating hypo. residues. We wonder if it be possible for these most conservative workers to be convinced by describing the method adopted at the large mines in Nevada for extracting the silver from some very impure ores. After crushing and drying the ore, and passing it through a pipe lined with magnets to extract the iron, it is mixed with three per cent. of common salt and then roasted—a treatment which converts the silver into chloride. It is then, after transference to a lixiviating vessel, washed with hot and cold water, and afterwards treated with a seven and a-half per cent. solution of hypo., from which it is recovered by the plan despised by so many photographers—that of precipitating with a soluble sulphide. Quantities so large were worked that it pays to adopt measures to collect the sulphur expelled during a final roasting to bring the precipitate to the metallic state.

Bisulphide of carbon is familiar to photographers from its suitability for dissolving india-rubber and gutta-percha, removing traces of grease, resin, &c.; but to employ it as an antiseptic for preserving paste, glue, &c., would be thought as unlikely a purpose as could well be conceived. According to a writer in *Comptes Rendus*, however, it possesses antiseptic powers of a remarkable kind, as its solution in water (which takes it up to the extent of ·05 per cent.) arrests fermentation and kills all microbia. If his statements should prove to be correct it will be difficult to imagine a more useful material for a variety of photographic purposes. Being inert chemically, it could be used in a mountant for the most delicate print without fear of injurious chemical reaction, such as must always be suspected with carbolic, salicylic, or thymic acids, often used for the purpose. Its great volatility would lead to all traces of its presence rapidly passing away as soon as its purpose was served, and the mounting material had parted with all its water.

The important part which the mounting material plays in the permanency of photographs is, usually at least, appreciated by the photographer, and he generally uses materials in accordance with the dictates of science; but with the bookbinder, for instance, to whose tender mercies many hundreds of photographs are confided in the course of a year for mounting and binding into book form, the matter assumes a different aspect. Bookbinders' paste is a most tenacious and highly-adhesive compound; but the materials that often compose it are by no means neutral in the matter of photographic prints. There are pastes *and* pastes, and from alum to bichloride of mercury is a wide leap; yet neither substance is unknown for the purpose, and it is impossible to say what other compounds gain admission. The result of their use upon the back of a photograph it would not be difficult to foretell. At the same time we do not wish for one moment to insinuate a single word against the professional photographic mounter, who makes a business of the work. We only allude to the occasional mounting given to a binder, who does not profess any knowledge of the science.

That our readers may fully understand the possibilities which exist in that direction, we append a recently-published method of making paste, glue, &c.:—Five pounds of potato starch is placed in six pounds of water, a-quarter of a pound of pure nitric acid added, the whole kept in a warm place, and frequently stirred for forty-eight hours. The mixture is then to be boiled until it forms a thick, translucent substance, and is afterwards diluted and filtered, if desired, through a cloth. Our readers can imagine the effect of using such a compound to paste pictures into the leaves of a book; though for ordinary purposes it would be, no doubt, a most serviceable pasting or glueing material.

JAMES GLAISHER, F.R.S., F.R.A.S.

The subject of our portrait this week requires little introduction from us. Mr. Glaisher's long and intimate connection with the Photographic Society has brought him, if not into actual contact, at least within the boundaries of acquaintanceship, with most, if not all, of the leading photographers of the present period and of past years.

Outside photography Mr. Glaisher is best known in connection with meteorology, having been from his earliest days interested in that branch of science. At the age of twenty he was charged with certain meteorological observations in connection with the Ordnance Survey in Ireland. After a brief connection with the Cambridge Observatory he was appointed to the Astronomical Department of the Greenwich Observatory; but on the establishment of the Meteorological Department, in 1840, he assumed the position of superintendent. In the interests of meteorology Mr. Glaisher has gained a name as one of the most intrepid of aëronauts, and has probably been instrumental in adding much knowledge to that science that would have long been wanting but for his pluck and daring. Some thirty ascents, all in the interest of science, were made by Mr. Glaisher, in one of which, accompanied by Mr. Coxwell, a height of nearly seven miles was attained.

In addition to numerous other works, Mr. Glaisher has been engaged, since his retirement from Greenwich Observatory, on the compilation of a series of Factor Tables for the fourth, fifth, and sixth millions—a work requiring unexampled patience, and for which he has received the recognition of the British Association.

What Mr. Glaisher has done for the Photographic Society only those who regularly attend the meetings are aware. Seldom—practically *never*—absent from a meeting the President seems to form a necessary portion of the Society; and we trust that he may long be spared to fill his present post.

Our portrait is from a recent photograph by Mr. J. E. Mayall, of Bond-street.

NOTES ON SILVER PRINTING.

I have to thank Mr. Dunmore for his kindness in telling me how to observe when the chloride of silver has been removed by fixing from albumenised paper. Certainly it was new to me.

I am well aware that albumenised paper, when it is sensitised, becomes impregnated with chloride of silver through the whole of its thickness; but, even at this, the film is a very thin one compared to what we are accustomed to have, for example, in a gelatine plate. The film is comparatively thin, and the quantity of haloid silver salt contained in it is comparatively *very* small. I imagine that if we deduct the free silver nitrate there is not in a given area of albumenised paper more than an eighth part as much silver as there is in the same area of film on a gelatine dry plate. The thin film comparatively weak in silver is, moreover, porous, and of such a nature that it can be attacked by the fixing solution from both sides; whereas a gelatine film may only be attacked from one side.

Taking all this into consideration, we might very naturally assume that a silver print would be fixed in a very much shorter space of time than would a gelatine plate; yet we should be astonished to find gelatine plates—at least such as did not contain a large quantity of iodide of silver in the film—requiring anything like the time to fix that we usually give silver prints in the hypo. bath. Moreover, if I have observed properly the instructions which Mr. Dunmore gives for determining, by ocular observation, when a print is fixed—when, that is, the chloride of silver has been dissolved out of it—a very few seconds suffice.

However, I should be far from wishing to advocate that a shorter time be allowed to silver prints in the fixing bath than is usually given. To wait a quarter of an hour or twenty minutes is no great hardship; but it seems to me that we might, with advantage, use a much weaker fixing bath for our prints than we commonly do. I find that the quantity of hyposulphite usually advocated for fixing prints is from two and a-half to five ounces per pint. With the latter quantity I have frequently found the tone to be degraded, and even with the former, weak prints—which, it is true, should not exist, but which, nevertheless, sometimes do—often lose something.

I am quite aware that a *very* weak solution of hyposulphite of soda used for fixing may produce an insoluble hyposulphite of silver and sodium which may be dangerous to the permanency of prints, but I do not think it is likely that any solution used in practice will be weak enough for this.

Mr. W. M. Ayres, who is well known as a most skilful printer, and against whose prints want of permanence is the last thing that could be urged, has frequently told me that he never uses a fixing bath stronger than one ounce of hypo. to the pint. It seems to me that if there is no danger in using so weak a bath it is a great advantage to do so, if for no other reason than that it reduces the likelihood of there remaining any hypo. in the prints after washing.

We are commonly told that hyposulphite of soda is very soluble in water, but that it clings with great pertinacity to paper, and that from this fact arises the necessity for giving prints so long a washing after fixing. As a matter of fact, I do not believe that hyposulphite of soda clings with more pertinacity to paper than do many other chemicals—for example, nitrate of silver. I wonder how many photographers have tried how much washing it requires to remove the last trace of silver nitrate from paper. I have been astonished myself at the length of time required. I am convinced that the washing usually given to prints after fixing would not be sufficient were it given to them before toning to remove every trace of silver nitrate.

It is most difficult to wash all the free silver out of prints, and it is, moreover, not a very easy thing to reduce all the free silver nitrate to chloride by the action of a weak solution of common salt,

SUPPLEMENT TO THE BRITISH JOURNAL OF PHOTOGRAPHY, OCTOBER 24TH 1884.

JAMES GLAISHER, F.R.S. F.R.A.S.
President of the Photographic Society of Great Britain.

INK-PHOTO, SPRAGUE & Co LONDON

such as many photographers use before toning. I was under the impression until lately that the result of treating untoned prints with a weak solution of common salt was to get rid of *all* the silver nitrate. I found this not to be the case, however, as the following experience will prove.

I had occasion recently to tone and fix half-a-quire of paper in the form of prints. I wished to wash out the greater portion of the silver nitrate; and, for this reason, having no large tub available for washing, I proceeded in the following manner:—The prints were placed in a large, flat dish filled with water. The water was drained off and fresh was supplied. The prints were then removed, one by one, to a second dish of fresh water, and when they were all there the water was drained from this second dish. The operation was repeatedly performed. It will be evident that an excellent test for the complete removal of the silver nitrate is to be found by catching the last small quantity of the water drained off the prints, and observing if there be any milkiness in it or not.

The first washing was continued for an hour. The prints were then soaked for five minutes in a salt solution containing one ounce of salt per gallon. They were kept in constant motion during the soaking. They were then washed in the manner already described for half-an-hour to remove the salt. Even at the end of this washing there were distinct traces of silver in the drainings of the prints. Toning was, however, gone on with. The time taken for the colour to change was very long, which, I think (as the solution was not cold), indicated that there was much less free silver in the paper than there usually is when the toning process is commenced. After toning, half-an-hour more washing was given to get rid of the toning solution. At the end of the last washing there were still traces of silver nitrate remaining in the paper. Be it observed that this experiment was made with ready-sensitised paper, in which the quantity of free silver nitrate is even initially very small.

Certainly, if hyposulphite of soda adhere to paper with even as much persistence as nitrate of silver does, and if it be the case that the presence of a small quantity of hypo. in a print means want of permanence, we may hail with pleasure the idea of using less of it, and, therefore, of having less to wash out.

Concerning a solution of salt: I may say that with one considerably stronger than that mentioned the decomposition of the silver nitrate appears to be complete in a very short time. After treating prints with a solution of salt, containing an ounce to the pint, for three minutes, all free silver nitrate seemed to have disappeared, and the prints refused to tone *at all*. Is it not possibly the case that a *little* free silver nitrate is necessary to the toning process? I think it will be found that without any prints will altogether refuse to tone.

I believe the action of a toning solution is not at all understood yet. We are told that it consists in covering the metallic silver forming the image with a thin film of gold—in gilding it, in fact. If this be so, how is it that no change of colour takes place when a mass of silver—say a silver spoon—is placed in a toning bath, even if the spoon be first dipped in silver nitrate solution?

W. K. Burton.

AN INSTANTANEOUS SHUTTER OF THIRTY YEARS AGO.

[A communication to the Manchester Photographic Society.]

The shutter I have brought before you this evening is probably one of the oldest and, as I think, for absolutely instantaneous work the best form of shutter extant. It was given to me some years ago by my friend Mr. Joseph Sidebotham, but for want of time and opportunity I have never, until quite recently, put it to a practical test.

It was made by Dallmeyer about 1856-7, Mr. Sidebotham having taken part in developing the principle, which is extremely simple. It consists of two light laths of mahogany, in each of which I will say, for simplicity, is a square opening (although in this particular shutter there are two openings in each lathe because it is a double one for stereoscopic work). When the focussing is done and everything ready, the exposure is made by touching a light trigger, when the two laths are instantaneously pulled in opposite directions, one square opening passing across the other, consequently giving the centre of the lens the greatest benefit, as it is there the shutter first opens and last closes.

It will thus be seen that, however quickly a shutter may be made to work simply by a movable opening passing a stationary opening fixed to the front or inside the lens tube, as in the case of the drop shutter, if the stationary opening be converted into a movable one, and in an opposite direction, the exposure in the latter case will only be half the duration of that in the former case. It is precisely analogous to the passing of two express trains in opposite directions. Any slight opening between the trains seen by a person standing on the platform of a railway station at the time will be exceedingly brief as compared with an opening seen between a single train and a stationary object, such as the end of a building which may happen to be on the other side of the line of railway on which the train runs.

My object is not to depreciate any other form of shutter, for there are many excellent and deservedly popular ones now in the market; but I thought it would interest many to see an efficient instantaneous shutter which was made nearly thirty years ago, and I further think it will be admitted that the results I am showing you are sufficient proofs of the value of the principle for what may be called extra-rapid work.

I must, however, point out that the details of construction are bad in two important particulars. The source of motion is an india-rubber band attached to each lath, the elasticity of which, when the trigger is liberated, draws them in opposite directions; and as each elastic band works on its own account, and quite independently of the other, there is a danger, by reason of the difficulty of getting the tension in both cases equal, that one lath may travel quicker than the other, which, in fact, I found on one occasion to be the case, when one half of the plate was better exposed than the other half.

In the first place, therefore, I would have no india-rubber; it is an untrustworthy and perishable material, and liable to break or become useless when one has no chance of renewing it. In the second place, I would connect the two laths in such a way that one source of motion only, instead of two independent ones, would be required. Both of these alterations, I believe, could be readily accomplished by connecting the laths with a strong silk cord passing over a small ivory roller, and using as the source of motion a good watch or small clock spring. The speed of the shutter could, I think, also be altered within certain limits by means of the introduction of a brake action.

It may be asked if there are any examples now in existence of work done by this shutter at the early period above referred to. Regarding this I may say that Mr. Sidebotham informs me he was at that time working hard to perfect a dry process which gave him some encouragement, and by which he succeeded in taking good negatives of such subjects as donkey races and a merry-go-round on the sands at Southport; but the process turned out very unreliable, and in so many apparently unaccountable ways, that he afterwards gave it up in disgust. As that gentleman is at present residing in the south for the benefit of his health, I am unable to show you any of the results of that period, even if they are still preserved. I should, however, imagine that for the most rapid wet-plate work the action of the shutter would be found much too quick, which was probably the reason why it fell into desuetude.

J. S Pollitt.

THE SODA DEVELOPER, &c.

With the indulgence of the Editors I will venture a few practical remarks on the subject of the very able leading article in the last issue of the Journal, with special reference to two points in my former communication to which exception is taken, namely, the alleged restraining power of sulphites in the developer and the probable cause of green fog being a mixture of alkalies.

First, then, the accuracy of my deduction that sulphites act as restrainers is questioned on the ground that pyro. and sulphite of soda alone are capable of developing the latent image of a properly-exposed gelatine plate. But does it necessarily follow, because an image can *slowly* be brought out by the aid of sulphite of soda, that, therefore, it accelerates development when used in conjunction with one or other of the alkalies? Let experiment answer this question to all who are interested in it. To me experiment seems to prove that sulphites not only do *not* accelerate, but positively *retard*, the operation of development.

I confess that this is quite contrary from what would be expected of a reducing agent, but cannot disregard the evidence of facts. When the Editors of the British Journal of Photography first made known the interesting and important fact that pyro. and sulphite of soda were sufficient of themselves for development, I thought it conclusive proof of the accelerating tendency of the sulphite salt; but further experience of its use has induced me to change my opinion concerning its real function in the developer. When things of an opposite character are joined together a medium product is generally the outcome of the union. Now let sulphite of soda be allowed to represent extreme slowness in the operation of development, and ammonia (of the right strength) extreme quickness, then a combination of the two, according to the above general rule, ought to yield a mean ratio of speed depending upon the proportions in which they are mixed. And in practice I find this to be so, for the more sulphite there is present in the developer the slower it works; and this is particularly true of the sulphite of ammonia, which exercises greater restraining power than the corresponding soda salt. I am, of course, speaking of its use in conjunction with free ammonia. In the case of soda development the conditions are not the same, because sulphite of ammonia cannot exist in the society of soda, this latter base having a stronger affinity for the sulphurous acid.

The other objection is against my supposition that the combination of ammonia and soda in the same developer is the cause of green fog; but the Editors are scarcely accurate in saying—"The fact that Mr. Hanson obtained green fog with a *carbonate of soda* developer *containing sulphite of soda* is no more surprising than that an ammonia developer should produce the same result." I did not say, or imply, that I had obtained green fog with that combination, as a reference to my communication (page 648) will show; but that the green fog spoken of resulted from a very different combination, namely, *soda* and *ammonia* in the same developer. It was this fact which excited my surprise, and in the end led me to exclude ammonia from the formula I gave for soda development.

I now repeat, what was clearly implied before, that a developer composed of pyro., carbonate of soda, and a well-balanced proportion of sulphide of *soda*, yields plates absolutely free from green fog; but the same combination, with a little *ammonia* added, induces the fog at once. It matters little whether the required proportion of sulphite be supplied by adding sulphurous acid to the carbonate of soda used in the developer or by dissolving the pure salt, provided a sufficiency of the alkali remain to ensure energetic development.

From the concluding words of the Editors' excellent article I must beg leave to dissent. They are these:— * * * "But so long as either ammonia or soda or both may be used, so long will it be impossible to guard against green fog." I find it quite possible to develope plates prone to fog by treating them in accordance with the theory advocated. If I develope with pyro. and ammonio-bromide I use pyro. kept by sulphite of ammonia, as before described; but when pyro. and carbonate of soda are employed I then use pyro. kept by means of sulphurous acid, as shown in the formula. But sulphite of soda may be substituted, and, on the whole, it is perhaps better, because the salt does not evaporate and has no smell.

The stock pyro. may be prepared as follows:—Dissolve one part of pyro. in (say) nine parts of sulphurous acid (strength nine per cent.); then add saturated solution of carbonate of soda gradually, until the yellow colour of the dissolved pyro. disappears. Should it be found that a larger proportion of sulphite of soda is desirable—a circumstance to be determined by the energy of development and colour of the image—sulphurous acid may be added to the stock solution of carbonate of soda and bichromate of potash. The proportions of the developer must, of course, be adjusted to the particular requirements of the plates used—one make or brand, perhaps, needing a larger, another a smaller, proportion of alkali.

I find for the majority of plates that four parts of a saturated solution of carbonate of soda, instead of six, as indicated in the formula, is sufficient, unless a full dose of sulphurous acid be deemed expedient. W. Hanson.

THE PRODUCTION OF LANTERN TRANSPARENCIES.

[A communication to the Photographic Club.]

In attempting to produce a suitable transparency for the lantern, or for enlargement, the amateur must be under some difficulty as to the choice of what process to employ among the varied published formulæ for the purpose, and he may entirely overlook a process capable of yielding results at least equal, if not superior, to any other. To such I would say try the collodio-albumen process, and in order to aid his endeavour I will give such full particulars as to render success certain and failure impossible. The necessary solutions are—

Iodised collodion.
Iodised albumen.
Aceto-nitrate exciting bath.
Pyrogallic solution.
Silver developing solution.
Fixing solution.
Toning solution.

The iodised collodion may be made as follows:—

Any good soluble pyroxyline	10 grains.
Iodide of ammonium	10 ,,
Tincture of iodine	10 drops.
Alcohol, ·830	1 ounce.
Ether, ·720	1 ,,

The tincture of iodine being made by dissolving thirty grains of iodine in one ounce of alcohol, strict adherence to this formula is not needed. Any old and otherwise useless solution may be used, provided it possess sufficient tenacity to adhere firmly to the plate and bear the subsequent washing.

The iodised albumen requires more careful attention to minutiæ in its preparation, and is best made as follows:—Break any number of eggs, and, having separated the yolks, add to each eight ounces of albumen and twenty-four drops of glacial acetic acid previously diluted with one ounce of water. *Stir gently together* with a glass rod for about one minute, or until the rod when drawn up from the side of the mixing vessel fails to bring up a viscid and unmixed mass with it; then let it rest one hour to separate. This plan of mixing the albumen is important, as what we require for this process is a thin, transparent albumen totally unlike the result obtained by the "beating-up" process adopted when the material is required to coat paper for printing, as for such a purpose a viscid albumen is needed, which is useless in the collodio-albumen process.

The albumen mixture having rested one hour, when properly prepared will be found to have separated into two layers—the upper curdy, white, and glutinous, and the lower bright, clear, and limped. The upper layer is most easily removed by slightly inclining the vessel, and with one finger passed down its upper side withdraw the adherent mass in one solid lump. This, if neatly done, leaves the albumen clear and bright, with but a stray particle or so of the upper scum floating in it. If at this stage the albumen is opalescent throw it away as useless, and try again. Now strain the albumen through muslin to remove any slight white particles that may be present, and to the strained liquid add forty drops of the strongest liquor ammonia, forty-two grains of iodide of ammonium, six grains of bromide of ammonium, and your iodised albumen is complete. This will be found to keep for twelve months provided the ammonia be prevented from escaping by careful corking. I may say that I usually make sufficient in spring to last during the year.

The aceto-nitrate bath is made by dissolving one ounce of nitrate of silver in ten ounces of water, and then adding one ounce of glacial acetic acid.

The pyro. solution is three grains of pyrogallic acid to one ounce of water.

The silver developing solution is nitrate of silver five grains, citric acid five grains, and distilled water one ounce.

The fixing solution is hyposulphite of soda two ounces, water ten ounces.

The toning bath is made as follows:—

Water	10 ounces.
Hyposulphite of soda	2 ,,

Dissolve, and then add to it—

Chloride of gold	4 grains,

dissolved in one ounce of water; and, lastly, add chloride of silver, blackened in the light, sixty grains. The blackened chloride of silver, if not at hand, may be omitted, but it is certainly an improvement in the richness of tone obtained.

This forms the solution necessary, and the mode of proceeding to prepare the plates is as follows:—Coat the glass plate with the iodised collodion in the usual manner, and allow it to set until the drop that forms at the lowest corner is sufficiently dry to receive the impress of the finger; then plunge it into a vessel of cold water, and allow it to soak for about five minutes whilst other plates are being coated and immersed. Now rinse it under the tap or in another vessel of water until all greasiness is removed, and it is then ready to receive the albumen coating.

The iodised albumen requires filtering through a small pledget of sponge pressed into the neck of the funnel before being used. To apply it attach the plate to a plate-holder, pour a little of the iodised albumen at the upper edge, incline the plate so as to cause it to flow over the entire surface, and run off into the sink. A second quantity of iodised albumen is then poured on so as to cover every part, and drained off and poured on three or four times; then drain and stand up with one corner resting on three or four thicknesses of blotting-paper to drain. Dry plates thus prepared will keep for any length of time if preserved from damp and noxious vapours, and are excited when required for use by being immersed for half-a-minute in the aceto-nitrate bath, using yellow light for this purpose. It is found advisable not to exceed this time. The plate being excited, is washed thoroughly in water so as to remove all the aceto-nitrate solution from the surface, and is, after draining, set up to dry in a perfectly-dark room, box, or cupboard, and should then be closely packed to prevent access of noxious vapours, if not required for immediate use. These plates are intended for transparences to be printed by contact, and daylight is preferable to artificial light.

The exposure varies according to the density and colour of the negative, and may be from five to thirty seconds in a moderately-subdued light, or from one to five minutes to gaslight with the pressure-frame eight inches from the gas burner.

The picture may be slowly developed with a saturated solution of gallic acid and the addition of two or three drops of the silver developing solution to each ounce, or, more rapidly, by covering the entire surface of the plate with water to which a single drop of silver developing solution has been added; and, after soaking for two or three minutes, to thoroughly permeate the film, then drain closely and pour on a mixture of four drops of silver developing solution to one ounce of pyrogallic solution, and let it rest for about one minute, when, if the plate has been rightly exposed, the high lights should begin to show themselves. Again pour off and on until the details are plainly visible by the yellow reflected light, but thin and faint by transmitted light. Now pour off the developing mixture (which should still be clear and bright), and add to it half-a-drachm of the silver developing solution. Pour this mixture on and off until the required intensity is gained, which, under ordinary circumstances, takes place in about two minutes, the developing fluid being still moderately free from deposit. Should it become thick, mix fresh quantities of the pyro. and silver developing solutions.

The required intensity being gained, the plate is fixed by immersion in the fixing solution, and when thoroughly clear it is ready for toning; but prior to being toned any surface deposit must be removed by holding the plate under the tap and applying friction with a pledget of cotton wool, and the surface will be found hard enough to remain uninjured under this rough treatment.

The positive is now of a brownish-green tint, and to give it a pleasing colour it is immersed in the toning bath until it changes to a grey tint, which may take from half-an-hour to two hours. On drying it will be found to darken considerably, and, with a little practice, various tints may be produced to suit the fancy of the operator. After toning wash well and dry. The excellence of this process depends on the fact that the picture is made up of stained albumen without the slightest grain.

In most other processes for producing transparencies the formation of the picture is due to an opaque deposit on or in the film, but in the collodio-albumen process the picture is produced by a staining of the albumen; hence its superior transparency, crispness, and brightness.

In conclusion: this process has had the merit of a long trial, having been used by myself for a quarter of a century. W. Ackland.

ON THINGS IN GENERAL.

"To err is human," and picture-hangers and judges have no claim to be otherwise, though, sometimes, we hear them termed "inhuman" when the pet product of some unfortunate's brain is "skied" out of all possibility of examination. At the present Exhibition in Pall Mall, however, I am inclined to think that hangers and judges have met with fewer complaints than is commonly the case, and have managed to hit the general taste with unusual success. There are, as the necessities of the case must always bring about, some lapses in hanging, and some verdicts not popularly endorsed; but that there are fewer grumblers than usual all will admit. Having stated this much by way of commendation, I must give expression to some of my views of which praise does not form a part. I wish to know how it comes that there should be in a conspicuous position, on the line, two large opal busts which are most elaborately painted upon in monochrome, while one of the regulations of the Exhibition distinctly states that such works will not be admitted. It is an accident, perhaps; but if this rule cannot be better carried out it should be entirely expunged. This is not the first time that it has been ignored. The same thing happens on another wall, but in this instance the subject is not a portrait but a study of boats. The whole effect is obtained by unsparing use of the brush.

This sort of thing should not pass unchallenged. I do hope that in another year, if the rule should still remain in force, no one may have occasion to find fault with such glaring disregard of a very proper regulation. Perhaps the hangers were aghast at their own temerity in rejecting so large a number of photographs as they did. I believe the number of massacred innocents is on the present occasion very large. It was whispered that, at least in one instance, the verdict of the judges necessitated a diving into the cellar to bring up a frame that could not consistently with the judges' awards be left out in the cold.

History repeats itself, and such is the case with medalled pictures. The number of yachts sailing about the room was something remarkable; and, as to fair ladies, each with arm elevated to a level with their shoulders and supporting a head, I started at the *conversazione* to count them, but I found my paper was not sufficiently large to hold the marks.

If the managers of the Exhibition arrangements could only have secured the presence of the latest photographic wonder what a crowd they would have had! A sufficient number of spectators would have been drawn from the general public to have paid all expenses, I feel assured. I refer, as my readers may guess, to the photograph of the tiger attacking the buffalo, as narrated some little time ago in the *Daily Telegraph*, which devoted a leader to the incident. The story goes that some natives holding a tiger in a leash were bargained with to let him kill a buffalo, and a photographer arranged his camera within a few yards ready to seize the opportunity. The buffalo was tied to a tree, the camera placed in position, and the tiger loosed. He "went in" for that buffalo, and in the act of striking him down the spring shutter was released and the mortal operation recorded on the sensitive plate. This is all very well so far as it goes, but we are not told how the tiger was carried off again by the "party of natives" when the entertainment was over; nor, further, how the tiger—said to be photographed with his forearms literally embracing the buffalo's neck—was induced to step aside for a moment, as he must have done, if we are to believe the further account of the natives cutting the buffalo's throat to save their conscience. *Si non e vero e ben trovato!*

The papers "have much to answer for." It is only a short time since the *Evening Standard* described the exploits of an American photographer who, being denied the pleasure of photographing at his studio in New York a certain American actress, and, determined to make her sit to him, followed her to "Frisco," chartered a bathing-van, photographed her just as she emerged dripping from the water, and then used the photograph to compel her to sit for a "proper" photograph, which, of course, she did. Cowhides are not exhausted yet in America, if we are to believe what we read, and surely cowhides by the dozen would have been extended towards a brute who disgraced himself in such a manner. Americans are chivalrous to their women, and the life of a man who behaved in such a manner would not be worth a day's purchase. Flatly, I do not believe the story.

Photography on its part has much to answer for. On the one hand I read Dr. Brudenell Carter's remarks on the effect upon the eye of close occupations in a dull light—such, for example, as retouching and dark-room work must necessarily include. On the other hand, I read Mr. E. Cocking's complaint of the effect of ammoniacal fumes upon his physical organisation. Not only do they cause him temporary discomfort—they also induce catarrh in the nose, deafness, and general nervousness to such an extent that he was induced to ask if anyone could suggest a remedy. Mr. Ashman suggested something akin to the old "aromatic vinegar." Mr. Cocking is not the only sufferer. Another gentleman has been taking up his pen upon the same topic, and he also suffered frequently from severe attacks of influenza in the head and chest. His remedy is the use of a snuff-box at intervals during dark-room work. Surely photography is not going to resuscitate this habit. Many photographers indulge in the pernicious habit of smoking; if snuff-taking also is to be adopted, what unpleasant people they will become! Yellow noses and purple fingers! Free Lance.

TRANSPARENCIES.

[A communication to the Newcastle-on-Tyne and Northern Counties' Photographic Association.]

The subject of transparency making is a very large one, and to treat it thoroughly—that is, by a description of all the various known processes—would take up not one evening, but three or four. However, I think, we may limit ourselves to two or three processes, and consider—1st, the carbon method; 2nd, the collodion, wet and dry; and, 3rd, the gelatino-chloride.

Those who have negatives small enough will find the carbon process by no means difficult. Briefly, a special transparency tissue is sensitised with bichromate of potash in the usual way; it is then squeegeed upon a piece of very clean collodionised glass. When dry (which process must take place in the dark) it is peeled off, cut into the proper sizes, and exposed under the negative. The usual circular, dome-shaped, cushion, or square masks, serve very well for the "safe edge" always used in carbon printing. The exposure is rather longer than that given for prints. The exposed tissue is then immersed in water until it softens, squeegeed on to a piece of very clear and clean glass, and developed as for prints. Plenty of time should be taken over this operation, and the water used should not be too hot. Carbon transparencies may be intensified by pouring over the still wet film a solution of pyrogallic acid, followed, after slight washing, by a solution of sulphate of iron.

Wet collodion I have not tried, but I am told that, provided the "bath" be in good condition and ordinary care used, there is nothing to prevent anyone from achieving success in this direction. A "bath" may be purchased ready made and in the best condition. The collodion rather old and high coloured is preferred, as it works cleaner. Mr. Hedley Robinson, whose paper on *Transparencies* will be remembered by most of us, recommends that the "bath" be decidedly acid, and suggests as a developer a solution containing—

Ammonio sulphate of iron	15 grains.
Glacial acetic acid	½ drachm.
Lump sugar	15 grains.
Water	1 ounce.

The older the solution the better. Mr. Robinson also recommends as a toning solution—

Ferridcyanide of potassium	2 grains,
Nitrate of uranium	2 ,,
Chloride of gold	$\frac{1}{10}$th grain,
Water	1 ounce,

which, he says, gives a colour nearly approaching that of a Woodbury slide.

Dry collodion plates will probably be used by some of us. In this case, doubtless, the Beechey emulsion plates will be generally preferred. Their advantages have been summed up by Mr. Robinson as follows:—"Considerable latitude of exposure, good colour of image, perfect control of density, and comfort in developing. They bear forcing with ammonia, and are not easily fogged." The emulsion can be bought ready made, all that is then necessary being to coat properly-cleaned and prepared glass plates.

Good results have been obtained on gelatino-bromide plates. I have one or two samples of work on ordinary gelatine plates, but there is great risk of veil and fog. The ferrous oxalate developer gives about the best results, and the proportion of oxalate of potash solution to that of iron sulphate should be increased slightly, using bromide.

We are now able to get gelatino-chloride plates, and with these we can do all that we require without much difficulty. They are rather slow. If printing by contact five minutes, twelve inches distant from an ordinary fishtail gas jet is not more than enough for a negative of ordinary density. I will show later on a few negatives of varying density, and exhibit transparencies taken from these on gelatino-chloride plates. This will give some idea of the exposure requisite. The developer I succeed best with is one containing carbonate of ammonia, citric acid, and a solution of sulphate of iron. This is Cowan's second formula. The plate should be fully exposed, and the development must not be prolonged. A variety of tones are produced by varying the developers, three of which are given.

I find them very slow when taking transparencies through the camera in daylight, ten minutes being the shortest exposure with a rather thin negative. This was, however, in very dull weather. The lens used was a six-inch Ross' symmetrical, full aperture, the transparency being made from a whole-plate negative. Care must be taken in mixing the developer. The iron solution should always be *added* to the potash or ammonia solution. I use as a clearing solution a mixture containing one ounce of alum and one ounce of citric acid to one pint of water. The developer may be used for several plates, and the same amount of density may be had with the last plate as the first.

J. Pike.

THE PHOTOGRAPHIC PROGRESS OF THE CURRENT YEAR.

[A communication to the Glasgow and West of Scotland Amateur Photographic Association.]

By way of preface to the paper which I now have the pleasure of bringing before the Association, I should perhaps state that those members who follow the course of photographic events, as detailed from time to time in the various journals, will find nothing very new or original in the facts communicated. There are, however, doubtless many of our members who are not quite so well posted up, and to those the different matters touched upon may not be without acceptance.

I do not think that this year, so far as it has gone, can be said to have produced any great photographic discovery. It is more a working up of details that has been going on. Perhaps the most important fact to notice first is Dr. Vogel's method of reproducing colours in their true colour intensity. We all know how, in photographing a blue object, the print from the resulting negative brings that colour out as if it were white in the original, while yellow and red come out more or less dark. A photograph of an oil painting, for instance, does not represent the colours in what may be called their relative tone as seen by the human eye. The addition of a dye to a sensitised film to diminish the action of the blue and violet rays, and increase that of the red and yellow, is by no means a new one. Dr. Vogel himself was working in this direction as far back as 1873. It was only this spring, however, that details which would enable anyone to work out the process for himself were published by Dr. Vogel. Translations of Dr. Vogel's original papers are to be found in The British Journal of Photography for May 30th and June 6th. The dye used by Dr. Vogel for collodion plates is eosine, and for gelatine plates azaline. Through the kindness of Mr. Bolas I am enabled to show specimens of the work done by these plates; and the fact that they have been prepared by Dr. Vogel himself lends an additional interest. The rather formidable term "isochromatic" has been applied to plates treated with the before-mentioned or similar dyes, and already they are an article of commerce.

Passing from the work done by a continental investigator, it would have seemed an anomaly had we had nothing put forward by Captain Abney. He proves from experimental evidence that heat causes greater sensitiveness in a gelatine plate, while cold diminishes it. Should any of our members be contemplating a photographic tour on the continent, or any country where dust is prevalent, he would do well to avail himself of a "wrinkle" of Captain Abney's, namely, to rub the inside and grooves of the dark slide with a glycerine rag, which prevents the fine dust from settling on the plate. A series of six lectures, on *Photography Considered as the Work of Radiation*, was delivered at the Royal Institution last spring by Captain Abney, and, as they have been reported in our two leading journals, all of our members who are interested in the scientific aspect of photography could not do better than read what is given of these lectures. Another very interesting series of lectures was delivered early in the year, under the auspices of the Society of Arts, by Mr. Bolas, the subject being *Recent Improvements in Photomechanical Printing Methods.* The journals do not give these lectures so full as they might have done, but they were to have been printed *in extenso* in the *Journal of the Society of Arts.* However, up to the present they have not made their appearance.

It may interest members to know that a very successful method of photo-engraving is being carried on in Glasgow at the present moment. The process is one devised by an Austrian, Herr Klick, who spent several years in perfecting it. Messrs. Annan, of this town have acquired the right to work the process in this country, and I am indebted to Mr. J. Craig Annan for the numerous specimens shown this evening. I may mention, on the assurance of Mr. Annan, that in no single instance has the tool of an engraver touched the plates from which these prints have been produced. The process is at present a secret one. Under an arrangement with Messrs. Annan, Messrs. Maclure and Macdonald are now producing work done by Herr Klick's method. It says a good deal for the enterprise of our Glasgow men that they have been the first to secure a process giving such excellent results.

Passing from photo-engraving: let us consider for a few minutes what has been exercising a good number of minds these last few years, namely, the production of printing photo.-blocks to be used in letterpress printing. I think the day is not very far off now when our illustrated magazines will avail themselves of some of the processes that have been lately brought forward. The conversion of the gradations of an ordinary photograph into a black and white grain or stipple, with the lights and shades of the same intensity as the original, is perhaps more a mechanical problem than a photographic one. I would especially call your attention to two processes that have been quite recently introduced, namely, Meisenbach's, of Munich, and Ives, of Philadelphia. Specimens of printing by these respective processes are here for your inspection. Judging from the results obtained it seems to me that the days of the wood engraver are considerably on the wane, if they be not about numbered. The starting-point of Ives' original method is a Woodbury relief. This is covered with ink, and a peculiarly-prepared paper is pressed against it. The higher portions of the relief crush down the grain of the paper forming the blacks of the picture, while the gradations—the half-tones of the relief—are rendered by this crushing being not so complete. The print thus obtained can either be photographed or used as a transfer. Ives' latest improvement is to take a plaster cast from the relief picture, and by means of an elastic stamp impress an ink stipple on its surface. Where the relief is highest and the pressure greatest there the ink spots unite and form the blacks, while in the deeper portions of the cast the spots are exceedingly minute. The merit of the invention lies in the application of the elastic stamp.

Let us discuss for a little what has been said and done regarding developers during the period we are considering—a subject that cannot fail to be of interest to us amateurs. Every one has a certain pet formula of his own, and from the enormous number of formulæ published from time to time it would be no invidious task were the amateur to tackle each one in succession. Hence, perhaps, the wisest plan, after all, is, after having a formula giving good results, to stick to it. There is no doubt, however, but that the soda developer has been coming to the front. The negatives produced have a green, unhealthy hue, which would prejudice many against its use, accustomed, as most of us are, to the blacks of the ammonia pyro. developer. The prints are, however, all that can be desired. One of our members who uses this developer regularly has given me some negatives and prints, which will be examined with interest. The formula to be recommended is that of Mr. Bassano, given by him in The British Journal of Photography of May 16th:—

Pyro.	4 grains.
Sodic sulphite	30 ,,
Water	1 ounce.
Anhydrous sodium carbonate	40 grains.
Water	1 ounce.

For every ounce of pyro. solution one drachm of soda solution to be added—best, in my experience, in two portions. The negatives have very much the appearance of the old collodion plate. There are one or two negatives on the table, which have been developed according to the above formula. I developed a good number of negatives this summer with the developer in question, and, with the exception of some plates lost through frilling during the hot weather, I had no reason to be dissatisfied with it. I question if at the time the plates I refer to were developed they would have stood the ordinary ammonia developer.

Solutions in the room showed a temperature of 70° Fahr., and the water from the tap a constant temperature of 60° Fahr. The doing away with the odour of ammonia in the developing-room is certainly an improvement, while a solution of sodium carbonate is much more reliable as to its original strength being retained than a solution of the very volatile alkali ammonia. One thing should be borne in mind when using sodium sulphite: that it is by no means a stable salt in solution. Fresh solutions are indispensable in order to obtain the best results.

Here I should like to bring before your notice some remarkable facts connected with this salt, which the Editors of The British Journal of Photography laid before their readers last April. From experiments they then made it was found that development of negatives could be made by using pyro. and sulphite of soda, ammonia being entirely dispensed with. The development was a protracted one, fifteen to twenty minutes being required, but one thing was distinctly proved by the experiments, namely, that the sulphite acted as no restrainer or retarder of development, as those using this salt had been wont to allege. It is very easy to see how this character had been given to it. In the original formula, where sulphite was used—a formula due to Mr. H. B. Berkeley—citric acid was recommended to be added till the solution showed an acid reaction, sodium sulphite being by constitution a salt showing an alkaline reaction. The result of this was the formation of a definite quantity of citrate of soda—

a substance known to possess strong restraining properties. Another fact brought out in the experiments referred to was that the merest trace of a bromide showed the development to a very great extent. Why this should be I am at a loss to understand. It is clear, therefore, from these experiments that formulæ in which sodium sulphite is employed should have neither citric acid nor a bromide present. Bassano's formula meets this requirement.

Regarding the potash developer, where potassic carbonate replaces sodium carbonate: I am informed by one of our members who has experimented with it that frilling can scarcely be prevented. This is hardly to be wondered at, seeing potassic carbonate is much more strongly alkaline in its character than the corresponding sodium salt. A mixture of the carbonate has also been recommended to be used. I do not know whether any of our members have tried it. I fail to see wherein a combination of these two alkalies should have anything special in itself for it to be recommended.

Hydrokinone as a developer will never, I think, be adopted by professional photographers to any large extent, its action being slow as compared with the universally-used pyro. This fault, if fault it be, is one that does not affect the amateur in the same manner as the professional photographer. Inasmuch as hydrogen does its work without requiring the presence of a restraining bromide it is, *par excellence*, the developer. Mr. Goodwin, who developes largely with hydrokinene, informs me that for some time he was troubled with thin images. This he overcame by giving a second application of fresh hydrokinone when the details were out. With the exception of enlargement work ferrous oxalate does not seem to be much employed, either by professionals or amateurs, in this country. It is, however, largely employed on the continent, where the conditions of light are much more uniform than with us. The ferrous oxalate does not allow the same latitude of exposure. The inky black tones of the image developed by oxalate are all that can be desired.

A word or two regarding our old friend "hypo.:" while developers increase and multiply it remains the photographer's fixing agent. One thing is certain: it will be difficult to find a substance that would act better than hypo. and at such a low rate of cost. The hyposulphite of the photographer, however, is not the hyposulphite of the chemist, and already in several treatises on photography we find its true chemical name given to it, namely, "sodium thiosulphate." It is, therefore, not at all improbable that instead of the familiar hypo. we shall have to accustom ourselves to the use of the term "thio," that being, I take it, the natural abbreviation of "thiosulphate."

In the month of July, in the short article on *Mercurial Intensification*, THE BRITISH JOURNAL OF PHOTOGRAPHY makes reference to a suggestion received from one of its correspondents regarding the employment of a solution of sodium sulphite to the bleached image instead of ammonia. This method of intensifying I have tried on several negatives, and can testify to its excellent character. There is this difference between it and the usual formula advocated—that there are no insoluble products formed in the film; hence the washing to eliminate the mercuric chloride that may happen to remain in the film does not require to be of the usual thorough character. The plate for that part may be taken out of the mercuric chloride solution and plunged directly into the sodium sulphite solution without staining the film. I have brought the necessary solutions so that members may judge for themselves the effect of this intensifier on a thin negative. I should mention that a very convenient strength for the solution of the sulphite is one of ten per cent. It may seem superfluous to state the fact—but for the benefit of our less-experienced members it may be as well to do so—that the complete removal of the hypo. is necessary before commencing this or any other method of intensification, otherwise sulphides are formed with the film and the picture hopelessly stained.

Coming, now, to the counterpart of intensification—that of reduction: the method for reducing an over-dense negative that has found most favour is one devised by Mr. E. Howard Farmer. Two solutions are required—a five-per-cent. solution of ferricyanide of potassium, a red prussiate of potash, and a five-per-cent. solution of hyposulphite of soda. The negative to be reduced is immersed in the hypo., to which a few drops of the ferricyanide solution have been added. Reduction then takes very evenly and gradually, and when carried to the extent desired all that is necessary is to take the plate out of the solution and finish up with a good washing. I purpose demonstrating the action of this very perfect reducer before you. I trust, therefore, that you have, as requested in the billet announcing this evening's meeting, brought forward a goodly number of dense negatives for me to experiment upon. I have brought some over-printed prints, and you will find that these can be made quite presentable after an immersion more or less prolonged in this reducing solution.

W. LANG, Jun.

OPINIONS OF THE LONDON PRESS ON THE PHOTOGRAPHIC EXHIBITION.

THE popular notion of photography is still very generally confined to a predominant sense of its exactness and truth. The photograph was for long accepted as something, beyond all dispute, literal. That a photograph should contain much that is grotesque, or appertaining to caricature, and therefore essentially unliteral, was never a popular view. Truth and photography were almost convertible terms. This view of photography was natural enough in the infancy of the art, and when the method of Daguerre was being displaced by one more perfect, and the future of photography was not less brilliant because it was absolutely undefined. Now that the dry plate, with its intransient developing power, has driven from the field the old "wet" process, photography has become more of an art, even while the method of production is more than ever mechanical. It is now judged from another standpoint than formerly, and we hear less of its truth and literal force than of the artistic qualities—the light and shade and tone values. This combined increase in the perfection of the mechanical process and in sound views of its functions as an art is a singular feature in the history of photography. It would seem that the very facility of production, the perfection to which chemists and mechanists have raised it, has actually awakened the æsthetic impulse, instead of resulting in a dead level of execution and the discouragement of artistic effort.

The exhibition of the Photographic Society of Great Britain, now open in Pall Mall East, is full of interest and suggestion. It is not altogether so striking and representative as the last; it does not include any pre-eminent examples, nor, in the collection of mechanical apparatus, new special features of novelty or invention, but it marks a distinct advance. There is still far too much work that is merely skilful, or experimental, or expressive of dexterity and the feats of the admirer of instantaneous effects; yet there are several exhibitors whose ideals are worthy, even though their achievements are not altogether successful. It is satisfactory to note that, despite the genuine merits of much amateur photography, there is a great gulf fixed between the artist and the man who is content to take a view and give a mere literal transcript. The facility of development does not tend to confuse their diverse aims in one common result. The variety of quality in the Exhibition is one of its chief merits. There is, of course, a fair supply of landscape views, woodlands, and river scenery that are full of the falsity of photographic realism, where the literal quality is an exaggeration of nature, where atmosphere does not exist, and the delicate *nuances* of tone are absolutely lost. In such the excessive detail is brought out with a precision that some photographers admire. There is in some instances a foreground admirably delineated and a distance, but no intermediary tones, no gradations, no true harmonising relations. There is no light and shade, but a uniform distribution of black and white touches, hard and speckly in effect, and far more removed from nature than a bad woodcut. Beyond noting its presence such work need not detain us.

Foremost in technical merit are M. Vittorio Sella's *Views in Switzerland*—four studies of the Lyskamm, the Märjelen See, Mont Blanc, and Monte Rosa. These beautiful examples of science and skill reproduce with exquisite purity of tone and atmosphere the visionary aspect of the Alps, the pure, serene, and boundless vacuity of the scene. The texture of the great sweep of the glacier, the snowy boulders in its sinuous course, the lone shadows and desolate aiguilles are rendered with admirable atmospheric truth. They do not suggest geological studies, nor have they the impressiveness of clouds and storms—effects familiar enough in larger photographs. The impression they convey is more rare, because less conventional. In another class of nature studies that evince the artist's powers of selection are two *Winter Scenes*, by Mr. G. Renwick. Of these No. 167 is a very tender and subtle realisation of hoar-frost and mist. Among works that display a deliberate pictorial intention, that are animated by a *motif*, and are more or less studied compositions, Mr. H. P. Robinson's series of landscapes and figures is prominent. In some of these the effort to compose is transparent, the figures are self-conscious, and do not represent the artless rustics innocent of their picturesque attraction. The difficulty of introducing figures free from conscious pose is well overcome in other subjects by Mr. Robinson. In *He Loves Me—He Loves Me Not* and in *The Cuckoo* the *motif* is very prettily illustrated. In *He Never Told His Love* the group of figures is excellently disposed, and the sentiment is displayed with much force and humour. Another admirable study is *The Gillyflower*, where a girl, in a graceful, natural attitude, is studying a flower with a child on her arm. Allied in aim to these, though distinct in technical quality, are some vivid and pleasing studies by Mr. Lyddell Sawyer. Specimens of platinotype prints are not very numerous; but these by Mr. H. B. Berkeley and Mr. W. Willis, Jun., are of rare excellence, and suggest a great future for this valuable and easily-manipulated process. Mr. Berkeley's *The Thames at Pangbourne* and Mr. Willis's *New Wareham* are two vignettes of remarkable beauty and finish. In the former the effect of dry point is striking. The more mechanical form of photo-engraving is fully exhibited by Messrs. T. and R. Annan, and also in some book illustrations printed in platinotype. The autotype and Woodburytype methods are shown in some fine enlargements from negatives. The enlargement from a negative, by Mr. J. G. Sinclair, *Cattle at Noontide, Ulswater*, executed by the Autotype Company, is a very successful example.

In portraiture Mr. H. S. Mendelssohn shows some refined and highly-finished examples, of which the *Mrs. Duppa* and the beautiful platinotype *The Lady Brooke* are of high merit. Portraiture, in its more conventional aspect, is well represented by Mr. Lafayette, the London Stereoscopic Company, the Autotype Company, and others, though there are few portraits in the exhibition that call for remark. Mr. Gillard's clever character-portrait, *The Miser*, is very expressive of the powers of photography. *A Siesta*, by Mr. Valentine Blanchard, is one of the most distinctly-artistic conceptions in the gallery; the sentiment of lassitude and repose is most happily rendered, and the composition is graceful and poetic. It is impossible to speak in high commendation of the so-called instantaneous photography. The transcripts of sea, whether raging or at rest, are more curious than felicitous, and there is nothing comparable to the really impressive enlargement exhibited lately by the Autotype Company. Mr. C. Grassin shows an *Express Train*, from a plate exposed $\frac{1}{350}$th of a second, which should move no one to admiration; and Mr. W. P. Marsh has a *Series of Instantaneous Sea Studies*, in which the phenomena of breaking and receding waves are curiously caricatured. This must needs be, seeing that the eye cannot perceive the whole phenomena and receive the impression with the swiftness and completeness with which it is fixed in the camera. Among other attractions in the exhibition, which we have only space to indicate, are Mr. Henry Stevens's *Studies of Flowers*, Mr. R. H. Lord's series of the performers in *The Birds* at Cambridge, Mr. Andrew Pringle's interesting studies in the Yosemite and elsewhere, the Alpine views of Mr. W. F. Donkin, the series of yachts under canvas by Messrs. G. West and Son, and some excellent scenes on the Cherwell by Captain Abney, R.E.—*Saturday Review*.

IMPROVED METHOD OF, AND APPARATUS FOR, TAKING PHOTOGRAPHS BY ARTIFICIAL LIGHT.

By EUGEN HIMLY, Berlin, Germany.

FOR producing good photographs it is necessary to have the object to be photographed in a light in which it is most distinctly visible and most usually seen.

This light is, as is well known, best afforded by diffused daylight, which may either be afforded naturally, giving more light on the one side than the other, according to the time of day chosen, or artificially by means of screens, blinds, mirrors, and the like, so as to illuminate the object from all sides to a moderately varying extent.

In the same manner that it is necessary to prevent the direct or regularly reflected rays of the sun from striking the object to be illuminated (unless special effects are desired to be produced), it is also requisite to a still greater degree to prevent the direct or regularly reflected rays of light from a powerful artificial source of light from striking the object to be photographed.

For obtaining the irregular reflection of rays from powerful sources of light, so as to produce an artifically diffused light analogous to that of daylight, it has hitherto been customary to employ as the most perfect means attainable intensely illuminated white surfaces, either plane or concave, not acting as mirrors, which reflect the rays divergently in the general direction of the object to be illuminated. These illuminated surfaces can also consist in dulled sheets of glass, through which the rays from a number of sources of light are caused to pass divergently.

The diffusion thus obtained is, however, but little analogous to that of daylight, as the direction of the rays still remains more or less one-sided, and consequently the photographic pictures obtained by these means have easily-discernible strongly one-sided illumination.

Another usual method of a comparatively perfect nature for obtaining an illumination analogous to that of daylight consists in the use of several sources of light, shaded by opal globes arranged round the object to be photographed, which, together with the photographic apparatus, is mounted on a revolving turn-table.

Independently of the question of the expensive nature of this arrangement, requiring specially careful attention to the several sources of light, it is not free from imperfections of illumination, due to the fact that in addition to the rays that are irregularly reflected in the desired manner by the small surfaces, produced by the clouding of a glass globe, many rays pass through the glass which, in consequence of the varying absorbing or refracting powers of the glass, and also in consequence of the want of parallelism of the glass surfaces, produce light and dark spots on the object.

My present invention relates to a method of and appliances for producing artificial illumination as analogous as possible to the action of daylight, consisting mainly in the employment of a mechanically-moved illuminating screen, which reflects the rays from one or more powerful sources of light irregularly in the direction of the object to be photographed, but which entirely diverts the direct or regularly reflected rays of such sources of light from such object, the movement of the said screen being effected during the whole time of exposure either through a certain arc round the stationary object to be photographed, or through a straight line past the same. By this method I obtain, firstly, by means of the construction of the illuminating screen an illuminating effect analogous to the action of diffused daylight, and free from shadows or excessively strong shadows; and, secondly, owing to the quicker or slower advancing motion of the screen regulated according to requirements, I obtain a moderate lateral gradation of the illumination of the object similar to that of daylight. In particular, I am enabled by this method to prevent the too powerful illumination of one side of the object, while another side has to be exposed for a longer time in order to develope deeper shadows.

The appliances which I employ for carrying out my said process consist, firstly, in the illuminating screen, and, secondly, in the mode of applying and actuating the same. (We omit the drawings.) The illuminating screen forms a large semicircular niche with domed top, which is closed at bottom by a semicircular reflecting surface adjustable on a horizontal axis, and in which two separate lateral niches are formed by means of vertical dwarf walls, such niches containing the two powerful sources of artificial light.

Consequently, direct rays or rays reflected from the mirrors do not pass outwards, but only on to the surfaces of the illuminating screen, as also upon the more or less inclined adjustable bottom surface, these surfaces being throughout of a dull white colour so that they can only reflect the rays irregularly.

The exclusively diffused rays of light passing from the illuminating screen consequently surround more or less the object to be illuminated according to its distance from the screen, while there is no central less-illuminated core in such rays of light, such as is produced in illuminating screens of present construction with a single source of light in the axis thereof by the use of a shield or disc for intercepting the direct rays of light, and which causes difficulties in the choice of position of the object to be illuminated.

The number of sources of light employed in combination with my illuminating screen is not limited; there may be only one, or two, or more, arranged in an analogous manner. The adjustment of the bottom surface on a horizontal axis has for its object to distribute the light to a greater or less degree to the lower parts of the object to be illuminated.

The object to be illuminated is situated near to and underneath the centre of motion of the crane, so that the illuminating screen is caused to move in a circular path round the object by means of any suitable mechanism. Or, according to the arrangement, a semicircular rail is suspended from the ceiling of the studio, on which rail the screen is made to run by means of rollers being moved to and fro by cords. The path in which the screen is caused to travel may be of a variously-curved or more or less straight or inclined form.

For particular purposes I also employ an arrangement by which the illuminating screen, while moving along its path, also has a motion round a vertical axis imparted to it, so that it may maintain a parallel position at every point of its path.

I also in some cases employ as an auxillary to the above-described method and appliances a lateral reflecting screen of a conical or concave form, mounted so as to turn on a vertical axis, which is employed to assist the action of the travelling screen in causing that side of the object on which such lateral screen is situated to be more strongly illuminated. As only diffused rays fall upon this screen, it may consist either of actual mirror or of a deadened surface for irregular reflection.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is:—

1. The method of illuminating photographic objects during the exposal by means of irregularly reflected rays of light from one or more moving sources of artifical light, substantially as herein described.

2. The construction of the illuminating screen such as shown in the drawings, operating in combination with one or more sources of light, arranged behind lateral screens, whose direct rays of light, or whose rays regularly reflected from mirrors, can only pass by irregular reflection from the illuminating screen to the object to be illuminated; also, in combination with the said screen the use of a flap with irregular reflecting surface, adjustable on pivots and forming the bottom surface of the screen.

3. The use of a rectilinear, or semicircle, or otherwise curved path or rail upon which the illuminating screen is moved by mechanical means during the time of exposure.

4. The use of a crane or swinging arm for imparting the required motion to the illuminating screen.

5. The use, in combination with the method of illuminating set forth in the first claim, of a stationary adjustable lateral auxiliary screen, having a perfectly or irregulary-reflecting surface, and which is caused to reflect more or less of the irregularly-reflected rays of the travelling illuminating screen according to the momentary position occupied by the latter.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Association, held on Thursday, the 16th instant, the chair was occupied by Mr. A. Mackie.

Dr. Schleussner, of Frankfort-on-the-Maine, was introduced to the meeting, and it being understood that he was engaged in the manufacture of gelatino-bromide plates, some questions were asked of him relating to the employment of these plates in Germany. In reply to a question as to whether Warnerke's sensitometer was adopted as a standard for speed on the continent, and, if so, what was the register number which plates were expected to show?—

Dr. SCHLEUSSNER replied that it was used, and that the number registered by the plates that he manufactured was 22. He further stated that that was the number given with the ferrous oxalate developer, which was almost exclusively used in Germany. With pyro. developer there was less sensitiveness, but for the colour given to the negative he preferred pyro., which gave an image more resembling that of collodion. In making oxalate developer he used seventeen parts of sulphate of iron and forty-five parts of oxalate of potash.

Mr. A. L. HENDERSON said, with reference to the speed of emulsion plates, that if gelatine were added in large quantity to emulsion without first neutralising or washing away the acid that most gelatines contained the emulsion was very much slower.

Dr. SCHLEUSSNER, in answer to further questions, said that he did not use iodide in his emulsion, nor was it employed in the manufacture of Monckhoven's plates. He also stated that it was no use to compare two emulsions with different sensitometers, as these were made of varying strength, and one would register a higher number than another.

Mr. BELL'S experience with sensitometers was similar to that of Dr. Schleussner's.

Mr. HENDERSON said that he had been experimenting in a new direction, which he believed would be a very useful one, with the manufacture of emulsion. The idea was to use as little water as possible, and to substitute the greater part of this solvent by alcohol. So little water was employed that the gelatine would only dissolve when hot, and on cooling would separate from the solution, taking the water with it. The alcohol could then be poured off and used again in the manufacture of a subsequent batch. A great portion of the soluble salts, the nitrates, would be found crystallised on the top of the cake of precipitated emulsion, from which it could be washed off, and the remainder was removed by washing in the usual way. The actual formula he had employed was as follows:—180 grains of bromide of potassium and five grains of gelatine were dissolved in half-an-ounce of water. This was heated and made up with hot alcohol to five ounces. 240 grains of nitrate of silver were also dissolved in half-an-ounce of water and made up to five ounces with alcohol. Half the silver was converted into ammonio-nitrate. The solutions were then mixed and placed in water at 120° Fahr. Half-an-ounce of dry gelatine was next stirred in. For a little time the flakes were crisp and brittle, but then they dissolved and the solution was allowed to cool, when the emulsion would be found to be precipitated as mentioned.

Mr. A. Cowan had been experimenting in another direction with emulsion by the boiling method. He had found that if an emulsion were made slightly acid during mixture it might be neutralised with carbonate of lime, and then, although neutral, it might be boiled for a long time without fogging. He had gone up to three hours' boiling without having a trace of fog.

Mr. G. T. Grammer was elected a member of the Association.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The first meeting for the present session of this Society was held in the Manchester Technical Schools on Thursday, the 11th ult.,—Mr. John S. Pollitt, President, in the chair. The minutes of the previous meeting were read and confirmed.

The Chairman made reference to a subject that had been under discussion at the Council meeting, namely, the scarcity of papers that were being read by members. In response to his call Mr. A. Brothers, F.R.A.S., volunteered a paper, and gave a practical demonstration of the daguerreotype process.

Mr. Alan Garnett exhibited a charming collection of small landscapes taken during a recent tour in Normandy, and showed a mask which he introduced in his camera, enabling him to make four exposures on one plate; also a series of four or five prints, forming a panoramic picture, in which the joinings were scarcely perceptible.

Mr. Wilson exhibited some prints from negatives, taken at the outdoor meetings of the Society.

Mr. S. D. McKellen showed a fine series of photographs taken on the occasion of the Society's visit to Kirkstall Abbey.

The Hon. Secretary exhibited a new lantern carrier, made by Mr. Steward, of London, by which slides of various sizes were automatically registered.

The meeting was brought to a close by a lantern exhibition, by Mr. J. A. Chadwick, consisting of Parisian and other views.

The annual meeting of this Society took place in the rooms of the Society, at the Manchester Technical Schools, on Thursday, the 9th instant,—Mr. John S. Pollitt, President, in the chair. The minutes of the previous meeting were read and confirmed.

The Hon. Secretary read the following

Annual Report.

This being the twenty-ninth annual meeting of the Society, your Council have to congratulate you upon the very successful year we have just passed through. It is satisfactory to be in a position to state that, notwithstanding the heavy calls which have been made upon our exchequer this year by the Exhibition in December last, our funds have increased beyond all expectations, our present position being better than has ever been known since the Society first came into existence.

Although we have had 32 new members added to the list, we have to record several resignations, our numerical strength being now 130 against 113 last year. It is satisfactory to find that the average attendance at our monthly meetings has increased to 59 against 51 last year. We are, however, sorry we cannot boast of the number of papers read during the present session; but it is with pleasure we reflect upon the general interest which has pervaded our gatherings.

Undoubtedly, the principal event of the year was the exhibition in December last, being chiefly the work of our own members, together with the choicest work of the leading photographers in Great Britain, and supplemented by a unique collection of photographic work collected from all parts of the world by our esteemed member, Mr. Charles Harris, F.R.G.S., who also contributed to the interest of the exhibition by a short recital of his experiences of the photographic brethren in America, India, China, and Japan.

Not the least interesting event of the year was the presentation of a testimonial to the Hon. Secretary, Mr. W. I. Chadwick. That gentleman having filled the office for the past seven or eight years with so much ability and tact, besides having some time previously matured and carried into effect a scheme for placing the finances of the Society on a much sounder basis than had ever before existed, it was thought by many of the members that some substantial recognition of such long-continued, active, and purely voluntary services should be made. It was not intended, however, from the first that the funds of the Society should be drained upon for the purpose; nor was it intended, beyond the mere sending out of circulars to members apprising them of what was proposed to be done, that any solicitations for subscriptions should be made or any canvassing resorted to. The matter was entertained in a spirit of great liberality by a large proportion of the members, and the testimonial took the form of a very handsome gold watch and guard, which was presented by the President, on behalf of the subscribers, on the occasion of the *soirée* by which the December exhibition was inaugurated. The ceremony took place in the presence of a large and select company of visitors, and Mr. Chadwick, labouring under some emotion, made a graceful acknowledgment of the gift.

On the same occasion our valued friend and old member, Mr. John Holding, artist, presented the Hon. Secretary, on his own account, with a beautifully-executed water-colour drawing from his own pencil.

We must not omit mention of our old member Mr. W. B. Woodbury, who came down from London specially to exhibit to us and demonstrate the working details and manipulation of the stannotype process.

We have also to record amongst the papers read one from the President, *On The Attitude of Our Society, Past, Present, and Future*, and another from the Hon. Secretary, being a series of suggestions of subjects that might be advantageously taken up by most of the members for research and demonstration at our meetings.

Mr. Rishton read an interesting paper *On Swing-Backs and Swing-Fronts*, illustrating his remarks by an ingenious model of a camera in section, which he afterwards presented to the Society.

The Hon. Secretary gave another short communication *On Landscape Lenses and Diaphragms*, with a few elementary remarks for the benefit of the younger members of the Society.

Mr. Greatorex gave an interesting and highly-amusing paper, entitled *A Summer Holiday*, consisting of notes taken during a recent tour in Switzerland.

Mr. Edwards followed by a paper advocating the importance of rising-fronts, and exhibited several negatives intended to demonstrate the superiority of rising-fronts over swing-backs.

The President dealt very ably with the same subject in another communication, and conclusively proved to the members that the rising-front was a more valuable addition to a camera than a swing-back.

Besides the above, many other subjects of interest have been brought before the members, including a demonstration of the manipulation of gelatino-bromide paper, by Mr. McKellen.

The lantern has upon more than one occasion been successfully handled by the Hon. Secretary and his brother, Mr. J. A. Chadwick, and generally the meetings have been well supplied with novelties in apparatus and members' work, amongst which may be mentioned a series of large pictures, by Mr. McKellen, and some charming smaller studies by Mr. Alan Garnett.

Mr. A. Brothers, F.R.A.S., also exhibited some fine microphotographs, taken by the aid of the electric light.

Before closing this retrospective survey of the past year's proceedings, we must acknowledge the unprecedented success of our outdoor meetings, which have been with few exceptions well attended and enjoyed by all present.

And now, in resigning our respective offices, we again congratulate you on the satisfactory condition of the Society—not only in its financial status, but also upon the harmonious feeling which has characterised the whole proceedings.

Mr. Wm. Watts said he thought a very important event had been omitted from the report, namely, the presentation to the Hon. Secretary of a testimonial for his past services.

The Hon. Secretary acknowledged that it had been omitted, but, being a testimonial from the *members* of the Society, and not really a gift of the *Society as a body*, he did not mention it in his report. However, as so many of the members expressed a wish that the subject should be included in the report, the Hon. Secretary said he would prefer that the President receive the report from his hands as it now read, and that he (the President) might add whatever he thought best. With this understanding the report was accepted.

A printed copy of the annual balance sheet was next handed round to the members; and, in proposing the same be accepted,

Mr. Wm. Watts complimented the Council upon their able management of the Society's affairs during the past year.

The election of officers next took place by ballot, resulting as follows:—*President:* Mr. J. S. Pollitt.—*Vice-Presidents:* the Rev. Canon Beechy, Dr. C. P. Bahin, Mr. A. Brothers, F.R.A.S., John Dale, and J. W. Leigh.—*Council:* R. Atherton, Alan Garnett, Jos. Greatorex, Charles Harris, F.R.G.S., John Kershaw, S. D. McKellen, E. Openshaw, John Schofield, John Warburton, and N. Wright.—*Hon. Treasurer:* W. G. Coote.—*Hon. Secretary:* W. I. Chadwick.

During the scrutinising of the voting papers,

Mr. J. Greatorex exhibited a negative much fogged, with patched, dense markings. This was one of a batch of excellent (commercial) plates and the only one found defective. No explanation was offered, but many members said they had met with similar experiences.

Mr. W. Blakeley exhibited a number of excellent prints, the work of a friend, who was desirous of becoming a member of the Society, and whom he would propose at the next meeting.

Mr. Livesey exhibited a number of splendid photographs, 10 × 8, very neatly mounted. They composed a series of views in Scotland.

The Chairman exhibited an instantaneous shutter, made more than thirty years ago, and read a short paper describing the same. [See page 679.] He also exhibited some charming stereoscopic views and lantern slides from instantaneous negatives taken by the aid of this shutter.

Mr. Alfred Brothers exhibited a portrait taken about 1856 or 1857, and which he supposed was the second *carte* portrait taken in Manchester.

A general discussion took place on shutters and instantaneous exposures, in which the Chairman, Messrs. John Chadwick, Sen., S. D. McKellen, Schofield, and others joined, resulting in the general approval of shutters of the Noton type.

Mr. Wm. Watts exhibited a walking-stick camera tripod stand, which opened out to five feet three inches in height, and was so firm and rigid that it supported easily a weight of thirty pounds. When closed it resembled a bamboo walking-stick, with buckhorn handle, silver mounted. Its weight was one pound to one pound seven ounces.

Mr. Jos. Greatorex exhibited a number of lantern slides by the wet collodion process, Cowan's plates, and collodio-bromide.

Owing to the lateness of the hour the lantern was not used, but the Hon. Secretary said he would arrange to have the lantern working at the November meeting, and hoped all members who intended to send slides would confine them to the standard size, namely, three and a-quarter inches square, accompanied by a list of number of slides and exhibitor's name. He desired that members would send up their slides before the *last minute*, in order to ensure their safe return, as it was extremely perplexing for a lanternist to have slides put into his hands during the exhibition by two or three different people, ensuring each a safe return.

The next meeting will take place on November 13, at which, besides the lantern exhibition, Mr. Alfred Brothers will demonstrate the daguerreotype process.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

The first ordinary meeting of the session was held in the College of Physical Science, Newcastle, on Tuesday, the 14th inst., at 7.30 p.m.,—Mr. J. P. Gibson in the chair.

The minutes of the previous meeting were read and passed, and Mr. T. G. Gibson and Mr. Ruddock, of Tynemouth, were elected members of the Society.

Mr. J. Pike (Hon Secretary) said:—A notice with reference to the exhibition has been issued to members, and you will observe that mention is made of the transparency competition. It has been very wisely decided to postpone the holding of this competition until December or January. This will allow us to devote our whole time to the arrangement of our pictures for the exhibition next month, and will then leave ample time for the preparation of slides. It has occurred to me (more especially as no paper has been formally put down for this evening) that we might very profitably have a discussion on the best methods of making transparencies, and that those of us who have had any experience of this branch of the photographic art might be induced to allow their information to circulate amongst their less favoured brethren. He (Mr. Pike) then read a short paper on *Transparencies* [see page 681], with special reference to the forthcoming competition. Hints were given and remarks made on the preparation of carbon transparencies and those prepared on gelatino-chloride plates, samples of which were shown, together with the negatives from which they were taken. Speaking of the wet and dry collodion methods, he (Mr. Pike) said he had had no practical experience, but he had asked Mr. Templeton, of Gateshead, to bring a few samples of wet-plate work, and that gentleman very kindly gave his experience of this method, remarking that he used the developer and toning solution mentioned in his (Mr. Pike's) paper.

Several questions were asked and replied to.

Mr. Pike recommended intending competitors to read Mr. Robinson's paper; also a full description of various processes in The British Journal Photographic Almanac of this year.

Mr. Downey, of South Shields, showed a large number of stereoscopic pictures and slides, which were highly appreciated.

Votes of thanks were passed to Mr. Pike and to Mr. Downey.

The Chairman said he hoped that all members would be able to send pictures to the exhibition next month, not only for competition but for decorative purposes.

The Society's exhibition this year, of members' work only, will be held in November, at the Art Gallery. A presentation print is to be selected and the medal and prize, offered by Mr. Borrow and Mr. Gibson respectively, competed for. The transparency competition is postponed till December or January.

GLASGOW AND WEST OF SCOTLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

The usual monthly meeting of the above Association was held at their rooms, 180, West Regent-street, on Tuesday, the 14th inst.,—Mr. Hugh Reid, President, in the chair.

After the approval of the minutes the following new members were admitted:—Messrs. William Orr, Henry Leask, H. M. Fraser, William Leiper, John McKissack, and George W. Gray.

It was agreed to hold weekly informal meetings each Tuesday during the winter.

Mr. W. Lang, Jun., then read his paper on *The Photographic Progress of the Current Year.* [See page 682.] Mr. Lang's interesting paper was illustrated by a number of specimens of the various methods of photo-mechanical printing, kindly lent by Mr. J. Craig Annan and others. Mr. Lang afterwards demonstrated the value of some of the new methods, and reduced and intensified a number of negatives in a completely successful manner.

After some general conversation the meeting was adjourned.

Correspondence.

TRANSFERABLE ALBUMEN FILMS ON PAPER.

To the Editors.

Gentlemen,—I notice in your issue of this date an inquiry, from a member of the London and Provincial Photographic Association, "whether anyone can tell how a certain paper was prepared that was introduced more than twenty years ago, but for many years past had not been in the market. This paper was albumenised and had to be sensitised in the ordinary way. After the usual treatment, upon removal from the hypo.-fixing solution into water, the film of albumen separated from the paper and could be transferred to anything required. He thought that lantern transparencies might be very satisfactorily produced by such a paper."

As an old amateur of more than thirty years' standing I think I can throw a light upon this subject. In plain sensitive paper it was found that a coating of whey before the floating of the silver solution greatly increased its sensitiveness, and one of the continental manufacturers of albumenised paper thought it would add value to his albumenised paper. Under that conviction he manufactured a large quantity for the English market. When the paper came to be immersed in the hypo. bath the film separated from the paper, and then was discovered a twofold impression, namely, one of a very foggy appearance on the plain paper and another on the albumenised film. This was always more faint than the paper impression, but much finer in its delineation (the print had to be somewhat over-exposed to obtain the finest results on the albumen). I bought some of this paper, and the failure of the manufacturer caused me to consider if this circumstance could not be advantageously utilised. Finding the film remarkable for its cohesion whilst the print was in the hypo., I transferred the film on to opal glass, and the effect was very much admired; but amateurs did not think it was a field sufficiently attractive to follow up. At that period transparencies were not the fashion, and hence it fell away.

I may state that I have specimens by me that were made twenty-five years ago, and still show not the least sign of decay. I would further remark that I used a substratum ot gum before placing the film on the glass. I carried this out whilst the film floated on the water, the glass being placed under the water and tho film stretched over it, and then taken out to dry spontaneously. This could be easily done upon carbon transfer paper or paper made transparent.

I shall be glad to find that some enterprising amateur will again take up this interesting branch of the art-science.—I am, yours, &c.,

Liverpool, October 17, 1884. Jas. Alex. Forrest.

MARKINGS ON DRY PLATES.

To the Editors.

Gentlemen,—Since I wrote to you in July, as to the markings on the negatives caused by the American leather cloth used for the hinges of the slides, I have again used the cameras, believing that the leather must have become seasoned, but have been again troubled, although I took every care to keep the slides cool and to leave the plates in them as short a time as possible.

I believe the whole plate is affected, and that in slight cases one end of the plate is simply more or less dense or fogged. It is curious that with Swan's plates the bar is transparent or nearly so, while with Wratten's and other plates it is more or less opaque. It would be interesting to know what it is that has an entirely opposite effect with different makes of plates.

I am pleased to find my experience confirmed by Mr. J. D. England, as I failed to convince the maker of the camera or the readers of your Journal. I note that it is only in hot weather that any effect is produced, and think that, if investigated, it might be utilised.—I am, yours, &c.,

Silvermere, Woodberry Down, N., October 20, 1884. D. W. Hill.

MR. BANKART'S CAMERA.

To the Editors.

Gentlemen,—I was much interested in reading Mr. George Bankart's ideas on *The Camera of the Future* in your last issue.

According to the description his proposed camera is, in the main, very much like the one patented by Mr. George Smith, except perhaps that the latter has a rack and pinion for focussing, and a swing-back which can be clamped in any position.—I am, yours, &c., H. Arnold Bemrose.

Irongate, Derby, October 21, 1884.

PHOTOGRAPHIC BRASS-WORK.

To the Editors.

Gentlemen,—Recent utterances show what a field there is for firms who will execute desirable photographic brass-work.

Mr. A. Pringle's design for fixing lenses expeditiously is one example. Another is that mounts which allow front and back lenses by different makers to be interchangeable, and to be placed at any desired distance from each other, will give great extra pictorial power to the photographer, with no more extra expense than the cost of the universal mount.—I am, yours, &c., A. B.

October 21, 1884.

MEDAL AWARDS AT THE PHOTOGRAPHIC EXHIBITION.

To the Editors.

Gentlemen,—I entirely agree with the criticisms made by Mr. W. Wainwright, Jun., in your last issue. I also note the stale sarcasm of calling the grapes sour.

I made a special visit from my parish in Cheshire to the Photographic Exhibition last week, and gave the most accurate and conscientious attention to most of the exhibits hanging in its gallery, and I hesitate not to say that the adjudication of medal awards was not at all satisfactory; and, even at the risk of being called a soured and disappointed amateur exhibitor, I stoutly affirm that work of the highest merit has been ignored. What could the judges have been thinking about when they elected to overlook the *landscape* works in the Exhibition. Some of them are the most beautiful and clever compositions it has ever been my lot to see. It would be almost impossible to produce more splendid examples of really artistic work.

Mr. Wainwright has referred to the medal given for interiors as an award given for inferior work. I suppose this was done in spite of the straits the artist's camera was put to to get such a wonderful display of converging lines. I have always understood that a fault of this kind was a *cardinal* one, and that even under the manipulation of a mere tyro' hands was entirely inexcusable; but as the judges have decided otherwise I presume I must be in error.

And, may I ask, who is responsible for the *hanging* of the pictures? Here there has been to my mind the most ridiculous "miscarriage of justice." If (by what obtains in the Royal Academy) special honour is always supposed to be attached to works which hangs "on the line"—if this be the rule which was supposed to guide the decisions of the Council, it certainly, to my mind, was "more honoured in the breach than in the observance." By the merest accident and at considerable bodily inconvenience I found a very clever frame of first-class work, placed not "on the line," but very far indeed *below* it. I do not hesitate to mention both the number and the name, namely, *Interiors* (No. 293), by Edwin Fox. Anybody who has made a speciality of studies of this nature must know how difficult it always is to get full harmony of illumination and detail. Either there is too much illumination, causing halation in the highest lights, and too great density in the shadows, or other eccentricities of an equally inartistic kind. In this example there is nothing of the kind. And where, think you, was this frame placed by the judges? Well, right behind a large heap of tripods, &c., sent by Messrs. J. F. Shew and Co. for exhibition purposes, and certainly blocked out from the public view effectively. This is only one out of many instances. I will not say it was intentional mismanagement, but it was unfortunate, and unjust to the exhibitor for all that.

Again; may I ask if the judges considered that the work shown by Mr. W. P. Marsh, and awarded a medal, had any special claims on their selection because it bore all the distinct traces of very indifferent retouching? At least it fixed that full impression upon my mind.

May I again ask why was Mr. G. Renwick awarded a medal for his snowscapes, and the exhibits (No. 369) by Mr. B. Wyles overlooked? *Why* was No. 362 medalled? Why was No. 440 placed on the line and No. 443 placed off it, and very much off it? Why, in the name of art, were Nos. 406 and 407 not medalled? These are just one or two instances of what I would venture to call very hasty and immature decisions on the part of the authorities.

I envy Mr. Forsyth his genius and resignation. My own studies of "outdoor portraiture" were placed as near the carpet as they could possibly be; but this was because they richly deserved it, the exception in this kind of just treatment proving the rule.

Just one point more. It is a very significant fact that scarcely any amateur has this year secured a medal. The Council is composed of both amateur and professional judges—the latter in a *majority*. Now I do not consider this fair, when the majority of the exhibitors are amateurs. I think that there ought to be a sharp distinction drawn between the two, and no professional worker should be allowed to compete with the amateur, and *vice versâ*. Either let there be two separate classes or do away with medals altogether, and let the Exhibition be worked on the same lines as our Royal Academy. The present state of things is most unsatisfactory, and sooner or later must be remedied.—I am, yours, &c.,

The Vicarage, Cheadle Hulme, Cheshire, H. VICTOR MACDONA, M.A.
October 20, 1884.

Notes and Queries.

D. E. F. wishes us to recommend a special form of lens; but we make a point of declining to do so. He must read the various advertisements emanating from manufacturers of and dealers in lenses, and use his own judgment in making a selection.

SELF TAUGHT inquires if a *carte* lens can be utilised for reproducing a few small photographs for pasting on Christmas cards.——Certainly it can. The photographs may either be copied the size of the original or be reduced. In reply to a second query, the distance in the enclosed photograph is well rendered.

"BY what means can I produce a red or reddish-brown colour in a photograph, such as characterise some very old engravings which I have often seen?—OLD EBOR."——In reply: Try silver printing on plain paper, without any toning. Or try the uranium and red prussiate process, exciting the paper with a solution of nitrate of uranium, and developing with a solution of ferridcyanide of potassium.

W. A. WALKER writes:—"I have a complete and successful zinc-etching apparatus, used in combination with transfers from drawings upon lithographic stones. I am told that photographs can be transferred to stone, and then a transfer from that be obtained, so as to use it in combination with the zinc-etching process. Could any of your readers oblige me with details as to this photolithographic process, particularly as to how the photograph is transferred to the stone?"

"A LONDON AND PROVINCIAL PHOTO." inquires by what means the true focus of a combination of lenses can be ascertained when it is composed of one of the spectacle glasses of which some mention has been made of late united with an achromatic such as the front of a portrait lens.——In reply: Having ascertained the focus of each of the lenses, and determined upon the distance at which they are to be mounted apart, multiply the focus of one by that of the other, and divide by the sum of their foci less the distance of separation. This gives the equivalent focus of the combination.

C. F. B. writes:—"Could you kindly tell me if there is any process by which I could print Woodbury prints on to paper and then transfer them from the paper to glass or wood? I have been trying a collodionised glass, but it will not leave the mould without breaking away in places. I have been endeavouring to accomplish it in several ways, but cannot get anything to work right. If you could give me any assistance through the Journal I should be very thankful."——We publish this query in order to elicit the experience of any who may have worked in this direction; but would remark that Woodbury lantern slides and transparences, of every class, are usually, if not invariably, printed upon the glass direct.

"CAN you inform me if there is in the market any emulsion or plates that will take a positive picture? Would prepared porcelain plates do? I have no silver bath, and printing from a negative when only one copy is required takes up a good deal of time. It would be a great boon to most, especially to amateurs, to be able to purchase plates for positives, and a large sale might be expected.—J. CLARK."——In reply: If our correspondent desire a plate upon which to take a positive direct in the camera, nothing of the kind can be had ready prepared. The plate—whether porcelain, glass, or metal—must be black, so as to form the blacks of the photograph. Let our correspondent try his hand at coating ferrotype plates with an iodised collodion emulsion and see what amount of success will reward his efforts.

S. HYAMS writes:—"Can you kindly give me a reply to the following:—I wish to take a group in a room which must be lighted by artificial light. Will you tell me the best to use? Electricity is out of the question. I find magnesium likely to drop and go out; and how to convey the fumes from white fire composition I hardly know. Can you enlighten me on the subject? Do you think a Ross' rapid symmetrical suitable for such a subject? I have tried the oxymagnesium, and have failed through the ribbon breaking off and going out."——In reply: A common stove pipe, or one formed of calico kept distended by wire, will suffice to carry off the fumes from the white-fire composition. With respect to the lens: we would recommend one of the portrait form for employment in preference to the rapid symmetrical.

Exchange Column.

No charge is made for inserting these announcements; but in no case do we insert any article merely OFFERED FOR SALE, *that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a* NOM DE PLUME *be thought desirable), otherwise the notice will not appear.*

What offers in exchange for 100 10 × 14 ferrotype plates?—Address, PHOTOGRAPHER, 21, Bartholomew-street, St. Olave's, Exeter.

What offers for cabinet burnisher, Hunt's *Photography and Silver Sunbeam?* Wanted, anything useful in photography.—Address, A. ATKINS, 61, Ainsworth-street, Mill-road, Cambridge.

Wanted, a large, heavy rolling-press, if out of condition will do, in exchange for microphotographic apparatus, lot of electrical affairs, printing-frames, &c., &c.—Address, C. R. TRUEMAN, Southwold.

I will exchange a set of nine Victoria lenses on one brass plate, perfect instruments, or a thorough good *carte* lens, by Burr, for any useful accessory or scenic background for studio, posing-chair, &c., &c.—Address, S. HYAMS, 5, Pollet, Guernsey.

I will exchange a posing-chair with four changing-backs, exterior background, ditto (Bull's) and rustic chair, rolling-press, for 12 × 10 pictures, by Knox, of Glasgow, nearly new, for a whole-plate camera and lens.—Address, W. WESTOBY, Goole, Yorks.

Wanted, a quarter-plate tourist camera with lens and stand, in exchange for a whole-plate folding camera, with three double slides and stand (by Billcliffe), with whole-plate view lens by Grubb.—Address, A. B. BARLOW, Cornbrook Works, Chester-road, Manchester.

I will exchange a stereo. camera, $6\frac{1}{2} \times 4\frac{1}{4}$, and two lenses, double combination, for same, all equal to new, for half-plate square bellows-body camera and good lens; must be in good condition.—Address, FRANK COLBOURNE, *Journal* Office, Lansdown, Stroud, Gloucestershire.

I will exchange a long-focus half-plate camera, swing-back, rise- fall- and slide-front, leather bellows, screw focus, very light, complete with three double backs, only used a few times, for a $7\frac{1}{2} \times 5$ Dallmeyer's rapid rectilinear lens or offers.—Address, H. RICHARDS, South-terrace, Broadwater, Worthing.

I will exchange a second-hand portable 12 × 10 Kinnear camera, of Spanish mahogany, brass bound, bellows-body of morocco leather, brass-bound dark slide and carriers, size when closed $14\frac{1}{2} \times 14\frac{1}{2} \times 4$ inches; also a mahogany 15 × 15 square sliding-body camera and dark slide, 14 × 12 carrier. Wanted, a studio camera, with repeating-back, for *cartes* and cabinets, with screw focussing arrangement, must be in good condition. Will also exchange backgrounds, some by Seavey, for coloured and other backgrounds of different designs, photographs on applications: send particulars.—Address, W. W. WINTER, photographer, Derby.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

NOTICE.—*Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a* NOM DE PLUME *as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.*

PHOTOGRAPHS REGISTERED.—

Abraham Squibbs, Wembdon-road, Bridgewater.—*Photograph of Sir James Dalrymple Elphinstone; Photograph of the "Flying Dutchman" going at full speed.*

WM. COLES.—Received. In our next.

E. V. B.—Mr. Warnerke mentions ten as being equivalent.

Geo. A. Rushton.—It is not necessary that the condensers be achromatic.

W. C.—Mr. J. J. Ayling, Crane-court, Fleet-street, E.C., will supply what you need.

F. W. W. B.—Messrs. Marion and Co., Soho-square, will, no doubt, furnish the mounts.

Lime Light.—Messrs. Lancaster and Son, of your town, will be able to meet your requirements.

T. Pool.—Without knowing your requirement, and the space at your disposal, it is impossible to afford you any useful information.

Amateur.—The Council of the Society, having on previous occasions duly considered the question, arrived at the conclusion that the present system is the best.

Photolitho.—The paper is not an article of commerce in this country. Dr. Liesegang, Dusseldorf, will, no doubt, supply it. Silk velvet: you will have to make them for yourself.

Positive.—The only plan is to dissolve off the varnish with benzole. But we fear that you will not be able to remove it without injury to the film, particularly if the picture be an old one.

F. E.—1. About the same proportion as in the preparation of plates.—2. Not suitable, unless the albumen be coagulated.—3. Why not make the experiment?—4. The usual iodide of starch test is the best.

T. M. Lowcock.—All will depend upon the number of prints you wish to wash at a time. Better have the trough too large than too small. There is no objection to washing *carte* and cabinet prints at the same time.

Silver.—1. The spots on the prints do not appear to be "metal spots," but are caused by something in the preparation of the paper. Without knowing more of this we are unable to account for them.—2. If the bath be too alkaline it may cause a dulness in the prints.—3. Should the bath be too alkaline neutralise it with nitric acid.

E. S. D.—Either will answer. If your camera have a sliding front the extending one may be made to slide in the rabbets. If it have not, the opening in the front will have to be made larger, as the less aperture will not be sufficiently large. The pressure does not produce the blisters. All so called "doubly-albumenised papers" are more or less prone to blistering.

Rev. A. Malan, M.A.—Make the toning solution as you do at present, and add gold from time to time as required, without a further addition of acetate of soda. Occasionally a little fresh acetate may be added, but it is not necessary with each fresh addition of gold. The gold should be added some hours before the bath is required for use. Thanks for the cutting, which is highly amusing.

Ferrotype.—It is somewhat doubtful if you will succeed in converting your old printing bath into a "first-rate" sensitising bath for collodion plates. However, the best method for you to pursue is to dilute it down to the proper strength and then add carbonate of soda until a decided precipitate remains after well shaking. Now expose it to strong sunlight for several days; after which filter, and make decidedly acid with nitric acid.

Northampton.—1. According to the formula the developer should keep very well. Perhaps you have been over-exposing your plates; hence the lack of density.—2. One ounce.—3. This is purely a legal question. However, we know that such agreements are made, but generally only for a stipulated time. We question if an agreement phohibiting you from taking other employment for an indefinite period would be a legal one; but if it were stipulated that within a certain limited time you should not, then the case might be very different. Better consult a respectable solicitor.

Received.—H. N. Atkins; Herbert S. Starnes; John Nicol, Ph.D.; "X.X.X." In our next.

Photographic Club.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 29th inst., the subject for discussion will be—*On Reversed Negatives.*

Photographic Society of Great Britain.—The next monthly technical meeting of this Society will be held in the Gallery (Exhibition), 5 a, Pall Mall East, on Tuesday next, the 28th inst., at eight p.m., when the apparatus now in the Exhibition will be brought forward and fully explained.

A Dark Slide.—At the present period much attention is being directed towards the improvement of the camera and its slide. We, therefore, direct attention to a specimen of the latter, which we have had submitted for examination by Mr. S. Sidey. Instead of there being a draw-shutter to admit the light to the plate, the same purpose is here effected by a flap-door which, when closed, prevents the ingress of light. By means of a short metallic arm, which projects outside, the door is opened after the slide has been inserted in the camera. The examination of this slide suggests that of Daguerre's camera, in which a pair of doors that closed over the plates in front were pushed open by a slip of brass after the slide had been inserted in the camera. There are some ingenious points about Mr. Sidey's slide.

Audra's Blue Intensifier.—Husnik's Iodine Plates.—In the *Correspondenz* Dr. Eder calls attention to the fact that the universal intensifier, which Herr Audra seeks to patent, is substantially the same as that published by himself eight years ago in the *Correspondenz*, after he had described his lead and uranium intensifiers. Dr. Eder's blue intensifier gave the reaction:—Ferridcyanide of potassium + silver = ferrocyanide of potassium + ferrocyanide of silver

$$(2\,K_6\,Fe_2\,Cy_{12} + 4\,Ag = 3\,K_4\,Fe\,Cy_6 + Ag_4\,Fe\,Cy_6).$$

The whole of Dr. Eder's elaborate article was reproduced at the time in The British Journal of Photography, and anyone who may have a fancy for blue intensification may there find full directions how to proceed, and may mix his own intensifier at less than three shillings a litre. Dr. Eder's formula was briefly:—100 to 300 parts water, 6 parts red prussiate of potash (ferricyanide of potash), 4 parts of iron alum.—The same gentleman also reports that a short time ago Professor Husnik began to prepare gelatine emulsion containing ten per cent. of iodide as a commercial product. Herr Scolik did the same more than a year ago, but gave it up again on account of the difficulty most practical photographers found in getting powerful negatives with it when using the ferrous oxalate developer. Professor Husnik tries to overcome the fault of slowness of development and fixing by using as little gelatine as possible in proportion to the iodo-bromide of silver and developing with ferrous oxalate. Dr. Eder feels bound to correct the opinion expressed by Professor Husnik that the Monckhoven plates now prepared contain ten per cent. of iodine. They are free from iodide, or, at least, if they do contain any the trace of it is so slight that Dr. Eder has been unable to detect it. Dr. Eder, also, in the course of his remarks, reminds his readers that though the varnish may be removed from collodion plates by a solution of caustic potash, alcohol, and water, that mixture is not suited to gelatine plates, as it is apt to cause blisters. He says it is much safer to lay the plate from which the varnish is to be removed in alcohol of 94°, to rub it with a soft linen rag, and then to wash it again in pure alcohol. He also recommends that, after the varnish has been removed as well as may be by the alcohol, the plate should be flooded for a few seconds with a mixture of one or two parts of a concentrated ley of caustic potash to 100 parts of alcohol, and then thoroughly rinsed in water. The object of this last application is to free the plate perfectly from any remainder of adherent varnish that might cause spots when the plate was subsequently intensified or reduced.

LONDON GAZETTE, *Friday, October* 17, 1884.

Partnership Dissolved.

George Taylor, Andrew Taylor, and George Marshall Scammel, trading as A. and G. Taylor, Baldwin-chambers, Baldwin-street, Bristol, and the Arcade Studio, High-street, Newport, Mon., photographers; as regards G. M. Scammel, who retires.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician,

For four Weeks ending October 22, 1884.

These Observations are Taken at 8.30 a.m.

JOURNAL OF PHOTOGRAPHY.

No. 1278. Vol. XXXI.—OCTOBER 31, 1884.

THE COLLODIO-ALBUMEN OR THE ALBUMEN PROCESS FOR LANTERN SLIDES.

At the conclusion of the leading article on the above process last week we intimated that on some future occasion we should recur to it for the purpose of offering some further remarks on the manipulations. At that time it was not our intention to do so thus early, but, as Mr. W. Ackland's communication to the Photographic Club is now before the public, and the time is rapidly approaching when amateurs will require their slides for exhibition, we lose no time in redeeming our promise.

It will be remembered that our previous observations were principally directed to the preliminary stages of the operations, namely, to the preparation of the plates, the object of coating with collodion, the preparation of the albumen itself, the method of its application, and its afterwards being made sensitive. We shall here assume that the plate has already been prepared according to the instructions given by Mr. Ackland at the Club (or in accordance with our former articles on the albumen process, for in practice there is really no material difference between the two), and that it is now ready for exposure. This may be made either by contact printing or by camera printing.

If camera printing be adopted lenses of large angular aperture, such as the so-called "quick-acting" portrait combinations, must be used. Even with them in good daylight a very prolonged exposure will be necessary; for it must be clearly understood that the albumen process as compared with the gelatine is an exceedingly slow one, and if this method of printing be adopted an exposure of from eight to fifteen minutes, according to the intensity of the light and the aperture of the lens, will be necessary. In our own practice we prefer contact printing, as, apart from the tediousness of the long exposure, we have noticed that the tones we obtained when working with the camera were not so satisfactory as with contact printing. Therefore, it is the latter method which is to be recommended in practice.

The exposure may be made either to diffused daylight, or to the light from a gas flame or a paraffine lamp. On the whole, perhaps, artificial light is the one to be recommended to the beginner, on account of its being more constant than daylight, which is ever varying. As a rough guide to the exposure it may be mentioned that, with a moderate light from a fishtail gas burner at (say) a foot from the flame, and a negative of medium intensity, from three to eight minutes will be necessary. If diffused daylight be employed, from five seconds to half-a-minute will generally be sufficient. We mention these times only as a very rough guide; for, as we have already said, the collodio-albumen process as compared with the gelatine is an exceedingly slow one, and the beginner, who may only be familiar with the latter, might imagine that it is less slow than it really is, and thus be misled as to the time actually required to get a fully-exposed transparency.

Although we have intimated that the beginner may possibly get on better by working with artificial light, yet as he gains experience he will probably prefer diffused daylight. At least we do so ourselves, because we have noticed, and we believe it is a general opinion, that whenever the time of exposure has been long the tones of the resulting transparency are not so satisfactory as when an equally-exposed print can be obtained in a shorter period; that is, by printing in a more actinic light.

We now come to the development of the image. The method we described in our article in the first number of the current volume differs somewhat from that given by Mr. Ackland, inasmuch as that gentleman recommends the solution to be used cold, while we suggest that it should be employed warm. Yet, after all, there will be but little difference in the finished result; only, in using the solution warm, the development is more rapid, and, as a rule, the colour of the image partakes less of the olive tint. However, by using the developer cold, as Mr. Ackland does, a greater latitude in the exposure is allowable; for, should the plate prove to be under-exposed, it may sometimes be saved by throwing off the cold solution and immediately applying warm. Furthermore: with the cold solution certain portions of the image (which may be over-dense in the negative) may have the detail coaxed or forced out by applying heat locally to that portion, either with the flame of a spirit lamp or a hot iron placed beneath the plate. Before now we have utilised a heated kitchen poker for the purpose. The light from the spirit lamp will not fog the plate when once the image is fairly brought out.

A particular feature in connection with the albumen or collodion process is that during the development, particularly if it be prolonged or it has to be much forced, a veil or stains of a marbled character may make their appearance on the film. However, they are of little moment, as they are entirely confined to the surface and can easily be removed by rubbing them off with a pledget of cotton wool, holding the plate under a running tap at the time. The novice need be in no fear of injuring the film by this operation, as it is hard enough to resist any moderate amount of scrubbing—at least with cotton wool.

The image, as left by the developer, is of a very unpleasant colour, partaking more or less, according as the development was prolonged or the solution used cold or warm, of an olive-brown. Hence, to get the pleasing tones seen in albumen slides by the best makers, the pictures must be toned. Mr. Ackland prefers to fix the image and tone it afterwards. We, in our previous articles, recommended fixing and toning in one operation, as was customary in the old method of fixing and toning paper prints.

It may be well to mention that while the image is fixing the film may blister. This arises from employing a collodion which is too new, or one which is made with a cotton of too horny a nature. However, the stock of plates already prepared need not be wasted if, previous to sensitising, they be made thoroughly hot over a spirit lamp or in front of a fire, and afterwards allowed to cool. Unless the collodion be very unsuitable indeed this will be an effectual remedy.

The method of development described above differs materially from the one with which many amateurs are alone familiar, namely, the alkaline. But this method *may* be used with the collodio-albumen process, though it is not to be recommended, inasmuch as it impairs to some extent the transparency of the lights, which is one of the great charms of an albumen transparency when projected upon the screen.

In concluding this notice of the albumen or collodio-albumen process, we may add that if plates, ready-prepared could be purchased commercially, as gelatine plates can, we feel assured that, owing to the simplicity of working, together with the latitude allowable both in the exposure and development, this process would soon supersede all others for making lantern slides amongst amateurs.

Although the plates may not be procurable in commerce the amateur need not be deterred by imaginary difficulties from preparing them for himself. It involves but little trouble or inconvenience, as up to the sensitising all the operations may be performed in broad daylight. If the instructions which have been given are carefully adhered to, very little practice will ensure success in the production of slides which cannot be surpassed by any other process extant.

SULPHUR TONING.

Among the numerous topics arising, as side issues, in the course of the discussion on the lecturette on *Toning*, delivered by Mr. W. M. Ashman, at the meeting of the London and Provincial Photographic Association last week, was that of sulphur toning and the liability to fading of prints which have been so unfortunate as to have been subjected to the action of this powerful toning agent.

But sufficient attention was not then, and never has been, paid to the fact that, in addition to gold-toned and sulphur-toned prints, there is a third class, namely, those which have never been toned at all, and yet the colour of which is not by any means bad or inartistic. No one who examines the prints in a fairly good copy of Talbot's *Pencil of Nature*—the first work ever issued which was illustrated by photography—will undertake to say that the tones of these prints are bad; nor, subject to an exception, will they venture to say that they have faded—at least in any appreciable degree. Yet they were produced at a date long anterior to gold toning, and even to the recognition of any toning action at all being required.

We have referred to an exception: that is to be found in the margins of the prints by which they were attached, by ordinary bookbinders' paste containing alum, to the mounting boards. It would appear as if Talbot had a premonition to the effect that the paste might prove a deleterious element in the mounting of silver prints, and that, therefore, the less used the better. It is on record that so disgusted was he at the action of the paste upon his prints that he decided upon discontinuing silver printing entirely, as far as was practicable. This example proves that to ensure either good tones (in particular those of a brown hue) or a reasonable degree of permanency, toning, as a distinctive feature in or portion of the photographic process, is not absolutely necessary, more particularly when plain-salted and well-sized paper is employed instead of albumenised paper.

The case as we have described it is applicable to plain printing upon plain paper. By "plain paper" here we mean that which has been sized by starch, gelatine, or any other agent usually employed for such purpose, with the exception of albumen. But we are by no means certain that when upon such paper a print is toned by sulphur—in the ordinary acceptation of the term as understood by the image having been converted into sulphide of silver—it is not entitled to be considered, if not quite permanent, at least as permanent as the majority of the so-called "gold-toned" photographs of the present time. We possess sulphur-toned prints twenty-seven years' old which are still quite presentable, and we do not imagine that they will undergo much further change for a long period.

We recollect that, in 1857, a former editor of The British Journal of Photography, Mr. George Shadbolt, brought before the notice of the Photographic Society a process of printing, in which was recognised the well-understood stability of sulphide of silver. Seeing that excellent results have been obtained by this process we append details.

Plain paper is floated for about a minute upon a solution composed of one grain of gelatine and ten grains of ammonium chloride in an ounce of water. This, after being dried, is excited on a bath of nitrate of silver. The printing is carried on until the shadows are well bronzed and the half-tones much darker than they are required. After removal from the frame the prints are washed for five minutes, so as to effect the removal of the free nitrate of silver. Now comes the special novelty. The print while still wet is placed in a deep dish, and a dilute solution of ammonia (one part of ammonia to four of water) poured upon it, a plate of glass being then laid upon the dish so as to cover it completely. This, by rocking the vessel, is caused to flow over the print backwards and forwards for about a minute, after which it is poured off and the print subjected to a thorough washing with plain water, this being changed two or three times. The print at this stage is of a bright, brick-red colour. To tone it, the same dish in which it was fixed having been washed, the print is introduced, and a sufficient quantity of sulphide of ammonium diluted with five times its volume of water is poured into the dish and the effect noted. The staring red colour is superseded by one of rich blackish-brown; and, although this change is effected in a few seconds, yet no harm occurs if it be not removed for a minute or more. The print is now rinsed in a few changes of water and dried. No hitch will occur unless the fixing has been imperfectly effected, in which case the lights will be destroyed by becoming browned.

At the meeting to which reference has been made at the commencement of this article, the Chairman said that he had transparencies on glass which had been toned by means of potassium sulphide more than twelve years since, and they were quite as good and brilliant now as when first prepared. This also speaks well in favour of sulphur toning when properly carried out.

But the toning of a transparency in the way indicated must not be confounded with the system of first bleaching by means of bichloride of mercury and *then* subjecting them to treatment with an alkaline sulphide. In the latter case the image is wellnigh certain to fade sooner or later, no matter how well it may be protected by varnish.

BACKGROUNDS.

A comparison between a collection of photographs of the present day and one of a score or even a dozen years ago, would reveal a vast stride in the direction of artistic taste displayed, particularly in the point to which we are now directing especial attention.

In the earlier days of the *carte*, as many of our readers will remember, it was considered almost a necessity for the photographic artist to be provided with a "set of backgrounds," as they were then termed; and very painful, elaborate affairs they were. The first photographers of the period adopted them, and with one or, perhaps, two notable exceptions their use in a photograph entirely did away with any artistic excellence, though, otherwise, the posing, illumination, and general execution left nothing to be desired. The two establishments we allude to, however, produced photographs with pictorial backgrounds which, in many instances, were in correct taste and drawing; and they found many imitators—we might almost say servile copyists—who copied without a knowledge of art, and produced in consequence very ludicrous effects. We are bound to say, also, that the whole of the pictures sent out by those two firms were by no means free from glaring faults in the composition of background and figure. There are at the present time many of "Silvy's" pictures in old albums with which this whilom illustrious foreigner would have blushed to own his connection.

Gradually, however, a better taste has been evinced, in the cultivation of which we are happy to think The British Journal of Photography, by its advice and strictures, has played an important part. Those dreadful arrangements—those discords in pillar and paint—were banished to fifth-rate studios, and a plain background became the commonest form adopted. But to carry off with success a perfectly flat surface, as the background of a portrait requires, the highest skill combined with great taste in posing is essential, while even this is apt to lead to a disagreeable monotony of effect.

This fact has probably been seen and appreciated; but whether it has been so, or other causes have had their share in bringing about a revolution, the fact exists that a few years ago an entirely new class of backgrounds were placed upon the market from an American source, and they at once seized the fancy of photographers. Painted in monochrome with a light touch and with great dexterity, conceived upon an entirely new *motif*, and dealing with subjects never before attempted—trees, foliage, leafy bowers—the new backgrounds were to be seen in almost every first-class studio in the kingdom, though the price was twice or three times as much as had hitherto been obtained. Direct copies and feeble imitations, as a matter of course, soon sprung up; but the New York backgrounds to this day have kept their price, and, we are given to understand, are still sold. The harshest critic would not object to them—so cleverly are they painted, so harmoniously arranged, subdued in the proper place, yet broad and powerful in parts, while obtrusive details are softened and toned down in a most graceful fashion.

Given the best background in the world, thought must be expended in its application, or its beauties are lost and its excellence becomes a stumbling-block. Accessories must be cautiously used, and with due regard to the exigencies of the scene and its relative perspective. A cabinet dexterously painted in the background as though placed against a wall slanting away from the spectator would ill accord with a table placed exactly across the picture as if resting against the cabinet; yet such crudities may frequently be seen. Bad as such arrangements may be made, still worse may be done when the movable scenes (equivalent to the set-scenes of the theatrical property man) are employed. Considerable skill and knowledge is required to make them carry out the appearance of reality, so that no trained eye could at once detect a falsity.

In the present Exhibition we remember a water picture, which we did not pause to closely criticise, with boat and children that made an excellent *tout ensemble*. A boat-piece from the studio had been taken and fitted into a view of a lake with swans taken out of doors, the deception being so complete and the dexterity of design so clever that it would be quite possible to pass by the picture and not notice the trick, though, as we have observed, we have not further examined it to see whether any law of perspective was really broken.

What can be more absurd than a picture such as we lately saw of a flowing stream spanned by a rustic bridge—most prettily built, be it said—with a two-years' old child and a dog carefully posed upon a hair-rug balanced on the middle of the bridge immediately over mid-stream? Perhaps the dog was an afterthought to suggest the safety of the child should it fall into the water. In any case a more preposterous arrangement of what in itself is capable of picturesque treatment could scarcely be imagined; and our chief aim in this article is to point out how necessary it is to use these extremely clever backgrounds and accessories with thought and judgment.

Among those which have been special favourites may be mentioned the sea-pieces; yet of all others they most offend artistic propriety. A good sky—not too conspicuous—a faintly-delineated distance, and rolling, breaking waves in the foreground, form a picture really effective, but which when criticised is found lacking in an essential point—the position of the horizon. In a wooded scene the horizon may be anywhere; in a sea-piece it is only where cloud and sea join, whether seen from the top of a mountain or lying upon one's back on the sands. The horizon in a picture represents the level of the spectator's eye, and hence in a view containing a standing adult figure of average proportions—unless he be poised on a brick or a footstool, or elevated in some manner—cannot be truly represented in any way but on a level with the eyes of that figure, a slight deviation being fairly allowable.

In the painted scenes of which we speak this horizon is usually about two feet only from the base of the picture, and though it will in a photograph appear higher—say about on a level with the hips—no argument will make it correct, and it will always offend the artistic eye.

A little artistic licence may allow of the horizon being (say) as low as the shoulders, but not further; while with children it ought to show high above their heads, and thus nothing but sea form a background.

Let anyone spending a day at the seaside to whom this effect is unfamiliar observe any figure between himself and the sea, and upon the same level as himself. He will notice that the sea horizon is always on a level with the head, whether the figure be seen from a mountain side or the sands, providing only he and the spectator are of average heights. This is so important a point and one so universally departed from that we give full prominence to the error in the hope that future views of the same sort may be more correctly designed. It is easy to imagine a scene painter falling into the error; for his stage, at the back of which a seascape would be placed, is so much higher than the front that the horizon though low on the canvas would be high to the audience, who also are usually supposed to be seated, which naturally lowers the level of the eye and, as a consequence, the horizon.

We will conclude by noticing one more point about the management of a sea background. It is the custom of many photographers to have their backgrounds so mounted that they can turn them at any angle to the light, and thus obtain variety of illumination and consequent difference in depth of shade in the background, which at one time may appear light and at another dark. This slanting cannot be carried out with a sea-piece when the horizon is not absolutely on a level with the eye, as a low horizon placed at a slant would not be at right angles to the figure, so that the consequence would be, if the figure were upright, that the water would appear higher at one side than the other—an effect the ludicrous nature of which would be palpable to the most uncritical eye. We trust that we have made it clear that our sympathies are quite with the occasional use of a "painted background," provided it be a good one and used with thought and discretion.

THE PHOTOGRAPHIC EXHIBITION.

[Fourth Notice.]

Mr. H. J. Godbold shows a number of pictures, many of which give evidence of a more than ordinary degree of skill having been exercised. Undoubtedly the most sensational, even in these days of instantaneous work, are *To the Rescue* and *Rescued* (Nos. 226 and 260), in the former of which a vessel has been driven ashore, and the lifeboat not having arrived a rocket is being fired over the wreck. The flight of the rocket, its trail of smoke as well as the line, are clearly and sharply defined, forming one of the most extraordinary photographs ever exhibited, and a picture withal. In the other the lifeboat is depicted on its return from the wreck with the rescued crew. Surely realism can be carried very little further. *Break, Break, Break on thy Cold Grey Stones, O Sea!* (No. 40), shows thoroughly artistic conception, and *Old Hastings During a South-West Gale* (No. 237) gives an excellent idea of the roughness of the sea on our southern coasts. The exposure has been much shorter than in the case of the medal pictures of the same class, but there is no want of detail in even the darkest portions.

Mr. P. H. Emerson, B.A., M.R.C.S., exhibits several very praiseworthy *genre* studies. His best work is, however, *A Study of a Head* (No. 324), in red carbon, the subject a rugged-featured fisherman in "sou' wester," forming a picturesque object. *Walberswick* (No. 548) is a happy rendering of a quaint fisher village.

Mr. Matthew Whiting has two frames—*Views on the Thames* (No. 112) and *Views in Scotland* (No. 564). In the former the views about Richmond and at Greenwich and Sheerness are specially noticeable. Amongst the Scotch views two pictures of Loch Marec and Ben Slioch should be mentioned first. *Towing Home the Wreck, Leith*, exhibits a good, natural sky.

Mr. F. Hollyer is chiefly represented by his floral decorative studies, so well known in previous exhibitions. *A Lily Dado* of five panels (No. 307) makes a very handsome appearance; but for exquisite artistic delicacy and truth we must select *Dandelions* (No. 136). A series of reproductions from paintings by Burne Jones, representing *The Six Days of Creation* (No. 145), will have attractions for the æsthetically inclined.

Mr. F. W. Broadhead's two pictures, *Watching* (No. 305), and *Contemplation* (No. 311), are clearly executed—the former owing more of its excellence to the subject and the latter to the posing. The artificial backgrounds employed in both cases rather detract from the general effect. *Contemplation* forms the subject of one of our illustrations. Two frames of views in North Wales by the same artist exhibit good points, both in selection and manipulation; but we must deplore the taste which placed two pictures of Conway

No. 311—*Contemplation.* By F. W. BROADHEAD.

Castle, four of Carnarvon Castle, and two of Bettws-y-Coed in the same frame (No. 493), and, by the way, under the misleading title of *Views of Snowdon.* The views of Snowdon in No. 510 are really fine, and must have been taken after much labour in climbing.

Mr. Seymour Conway's interiors of *The Vyne, near Basingstoke,* and *Bramshill, Hants* (No. 107), are very fine examples of their class. The perfect rendering of both sunshine and shadow, without the slightest loss of the elaborate and beautiful details, is most noticeable. Amongst his landscapes the best and brightest is

No. 326—*Llyn Crafnant.* By SEYMOUR CONWAY.

perhaps *Aberglaslyn Pass* (No. 326), but as a composition we prefer *Llyn Crafnant,* which we have chosen for illustration.

Messrs. York and Son exhibit a frame of *Views in London* (No. 124) of large size, which fully sustain their reputation. Their lantern slides are also of high quality.

Mr. J. G. Horsey's landscape studies are, as a rule, over-printed, and present a somewhat heavy appearance—not due to the negatives. The first in the catalogue, *Early Morning* (No. 118), is the best. *The Meeting of the Waters* (No. 121) passes but a poor compliment upon the famous Wicklow scene, representing, as it does, an insignificant stream running into another of scarcely greater importance, and with no particularly striking surroundings to call attention to the spot. His *Farm in Surrey* (No. 182) is a good picture, taken evidently with an extremely brief exposure; and the *Cattle* (No. 184) are also well caught.

Mr. F. Whaley's *Thoughts Far Away* (No. 127) is a pleasing figure study of a young lady seated at the spinning wheel, but whose thoughts have for the moment wandered far away from the work in hand. *Waiting for Nursie* (No. 319), and *This Little Pig Went*

No. 340—*This Little Pig Went to Market.* By F. WHALEY.

to Market (No. 340), are cleverly executed, their titles sufficiently describing them. The latter forms one of our illustrations.

Mr. W. Cobb's two frames of *Street Views* (Nos. 139 and 218) contains work of the same character as that which obtained him a medal last year, namely, instantaneous street scenes photographed from the top of an omnibus. In quality, however, they seem to us far superior to last year's. His other picture (No. 495) is a veritable bit of nature—if nature can be supposed to exist in such classic neighbourhoods as the New Cut.

Mr. Adam Diston's medal picture, *Out of Sorts* (No. 330), is full of quaint humour, and fully sustains his reputation as a master in

No. 330—*Out of Sorts.* By ADAM DISTON.

genre work. It is the clock that happens to be out of sorts, and the careful housewife is ministering to its requirements with a pair of bellows—a primitive but by no means uncommon mode of treatment in country parts. The arrangement of figure and accessories is admirably carried out, and an idea of the composition may be gathered from the accompanying illustration.

Mr. Andrew Pringle exhibits—though not in competition, as he was on the list of judges—a couple of frames of landscapes, some of which were shown last year. His views in the Lake District are, however, new and present some noticeable features. Especially worthy of attention are *Rydal Water and the Rothay*, and *At the Foot of Rydal Water* (No. 200).

Mr. G. Renwick sends three *Winter Scenes*, which, however, are but repetitions of his previously-exhibited work in the same class.

Whatever complaints may be framed against the interiors of Signor A. Tagliaferro on the score of want of correctness in the perpendicular lines, there is no denying the admirable delicacy of their details. *The Interior of St. John's Church, Malta* (No. 234), is without doubt the best, but in view of the defects which have been mentioned the question of the justice of the medal award is an open one.

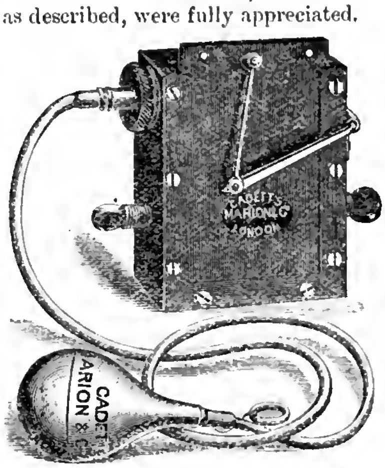
Mr. G. H. M. Whish's frame of *Studies* (No. 358), of which the centre one, which we have chosen for illustration, is a pretty and

No. 358—*Studies*. By G. H. M. Whish.

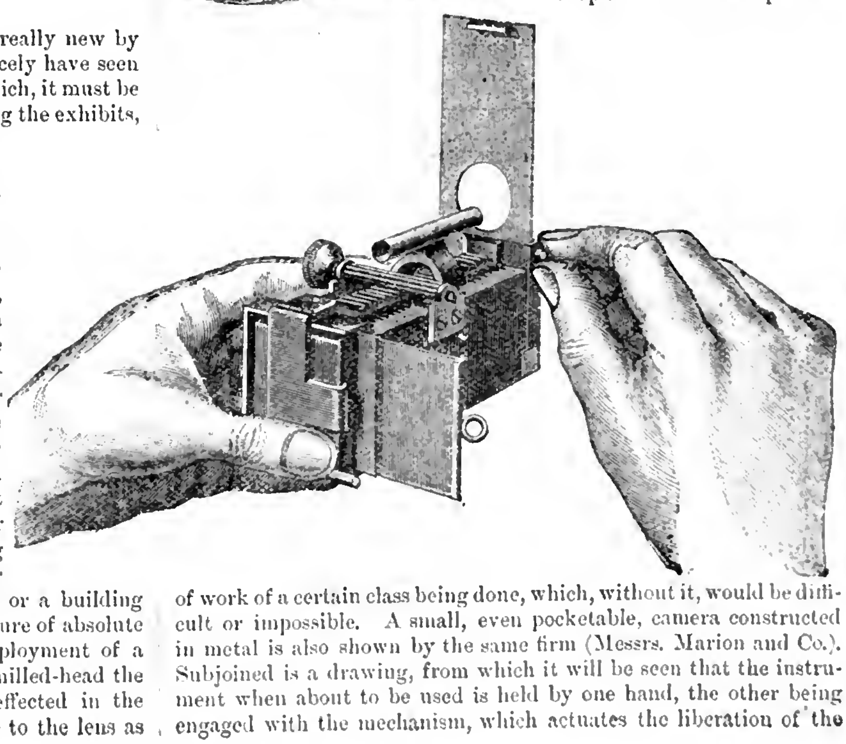
effective grouping of children at play. The small views on the Thames, with steamers in motion, and especially an excellent study of sheep, deserve notice.

APPARATUS.

Those who say, or have said, that there is nothing really new by way of camera production in the Exhibition can scarcely have seen the camera of Mr. S. D. McKellen, of Manchester, which, it must be admitted, was somewhat late in finding its place among the exhibits, owing to a business accident ludicrous enough in itself—an *employé* of the manufacturer having sold to some urgent customer the camera which was laid out to be packed and transmitted to Pall Mall, thus necessitating some delay in having a substitute provided. The features which upon a cursory glance strike us as noticeable in the McKellen camera are, *inter alia*, the following:—When folded up the camera is very thin and light. There is no tripod head, the functions of this hitherto useful and indeed necessary appendage being usurped by a circular plate or ring of brass sunk into the base-board. After the camera has been placed upon the tripod it can be erected by means of two motions of the hand; and we may here say that there are no loose screws about the camera, which is no small boon. The back or front may be swung to any desired extent if tilting of the camera be considered necessary, either for the purpose of getting a foreground in sharp focus or a building presented without converging perpendiculars. A feature of absolute novelty, so far as we are aware, consists in the employment of a double-pinion system for focussing. By means of a milled-head the racking-out of the front which bears the lens is effected in the usual way; but, when this has been brought as near to the lens as the pinion permits, then the traversing action of the centre board may be brought under the operation of a second pinion situated close to the body of the camera, by whose instrumentality the whole length of the sliding portion of the base actuated by the rack is once more brought into operation, and the focus shortened up or down to within an inch or two of the ground glass. Mr. McKellen, in a circular which accompanies the camera by way of explanation, lays down certain principles with which every practical photographer will be inclined to agree readily, namely, that a camera to be perfect must have the following properties:—It must be as light as possible, as a heavy camera only wearies the amateur and detracts from his enjoyment. But it must be not only light; it must also be rigid, as a shaky camera cannot, with certainty, produce the best work. It must be easily erected and folded, and must fold into a minimum of space. It must allow of the use of the shortest-focus lens, and permit the use of a lens with focus at least twice the length of the plate. It must be simple, so that it can be made or repaired at a reasonable cost; and must have swing back and front, so that in using the swing back the front may be adjusted parallel to it. In the camera now under notice these requirements are amply fulfilled. The reception given to Mr. McKellen at the technical meeting of the Photographic Society of Great Britain on Tuesday evening last, at which he exhibited and explained the details of the construction of his camera, was of an enthusiastic character, and showed that its various adjustments, as described, were fully appreciated.



Messrs. Marion and Co.'s exhibits include a camera fitted with one of Cadett's recently-introduced shutters, which have won golden opinions from all who have had occasion to use them. The diagram shows the nature of the shutter. It is fixed upon the lens, and upon pressure of the pneumatic ball the shutter, which slides in grooves in the frame attached to the lens, is raised, and remains so until the pressure is relaxed, when it instantly drops. This shutter permits



of work of a certain class being done, which, without it, would be difficult or impossible. A small, even pocketable, camera constructed in metal is also shown by the same firm (Messrs. Marion and Co.). Subjoined is a drawing, from which it will be seen that the instrument when about to be used is held by one hand, the other being engaged with the mechanism, which actuates the liberation of the drop shutter in front of the lens. There is a small piece of tube erected just over the camera through which the operator views the scene or subject which he desires to photograph, and at the fitting moment the shutter is liberated and the scene secured. The new patent syphon plate-washer of this firm appears to be a highly-effective instrument for the purpose for which it is intended. The water charged with the hyposulphite is rapidly withdrawn in favour of a supply of pure water.

Mr. Leon Warnerke exhibits two cameras invented by Professor Ezutchewsky, of Moscow. These, at first sight, are suggestive of a camera invented and patented by Mr. Cook, of London, several years ago, in which a number of sensitive plates were stored away in one portion of the camera ready to be brought to the front in rotation by the operating of handles, which were drawn up and down. In one of the Moscow cameras that we examined the plates are changed by reversing the apparatus. It is very gratifying to be afforded an opportunity of examining the inventive and mechanical ingenuity of our Russian brethren.

Messrs. Watson and Sons exhibit several cameras, of which one for 15 × 12 plates presents a very imposing appearance. It is well fitted and beautifully finished. It has a double swinging back and long focal range. There are two other cameras of different sizes, but equally effective as regards construction. One of their snap shutters, of which we gave an account (with a drawing) last year, together with a drop shutter, are also to be found among the exhibits of this firm. A small camera possessing certain novel features was shown by Mr. Watson at the technical meeting on Tuesday evening last, but we defer a description of it till next week.

As the Exhibition in Pall Mall draws towards its close we may remind our readers of the immediately-succeeding one at Northampton, the announcement of which appears in our advertising columns. Exhibitors in Pall Mall can, we believe, arrange to have their exhibits forwarded direct if so desired; but all information can be obtained from the Honorary Secretary, Mr. H. Manfield, Northampton.

The meetings of the various sections of the Society of Chemical Industry, London, Liverpool, Manchester, Birmingham, Glasgow, and Newcastle, are about to commence. The president of the Society is Dr. W. H. Perkin, F.R.S., while the chairman and officers of the local committees are well known in the regions of chemical enterprise. In December, Mr. J. M. Thompson will read a paper on *Photography for those Engaged in Commercial Pursuits*, which will doubtless attract much attention in the circles interested. The General Secretary's Office is now at Palace Chambers, 9, Bridge-street, Westminster, S.W.

Under the title of *Photography for Everybody* our contemporary, *La Nature*, describes an apparatus devised by Mr. Bauer of the *XIXe Siècle*—an amateur devoted to photography—who has conceived the idea of offering to the subscribers of the above-named journal a really good set of apparatus at a low price. Judging from the description and the accompanying illustration the price is sufficiently low; though whether it is worthy of the appellation "the very height of cheapness" it is impossible to say—in the face of the wonderfully-cheap and good apparatus manufactured in this country—until we have seen the apparatus itself. The set comprises camera with double dark slide and achromatic lens, tripod, treatise on photography, three bottles of chemicals, funnel, glass stirrer, filter papers, dry plates, sensitised paper, graduated measure, printing-frame, two porcelain dishes, and a packet of dry plates—the whole contained in a wooden case with hinged lid. To the subscribers of the journal the price is twenty-four shillings, and to outsiders thirty-six shillings. M. Davanne considered it efficient and cheap enough to be worthy of being brought before the notice of the Photographic Society of France. In doing so he described it in detail, and explained its parts and the performances of the lens. This, he said, might be larger with advantage for outdoor work, though he had taken a view in less than a second, and a copy of a plaster cast in his studio in two seconds. The lens, he explains, should be blackened in its interior, seeing that as at present made it fogs the image with a bright light outside; and though it gives slightly-curved lines at the margin it is, he truly says, in this respect not any worse than other single lenses.

Photography is to be employed in illustrating *Quaint Old Norwich*—a work now in preparation by Mr. E. P. Willins. It is not, however, photography from nature, but photolithographs from pen-and-ink drawings that are chosen. We cannot perceive why this should be.

Photographers who sometimes fail to see the cause of the great price of lenses of large diameters may gain some idea as to why large lenses should be dear by reading an account of the progress of the great Lick telescope. The order was given for the instrument in 1861, the diameter fixed upon being only thirty-six inches; but this "only" indicates the largest instrument in the world. Messrs. Alvan Clark and Sons have the work in hand, and they had but two firms in the whole world to choose from to cast the rough glass discs from which the lenses were to be fashioned. The flint lens was cast in an unexpectedly short time, but they have never yet received the crown glass. Messrs. Feil and Co. have made nineteen attempts, without being satisfied. At last it is stated that they have made two discs which they believe will be perfect, and which will shortly be on their way to California. Thus the completion of the whole observatory has been delayed by the difficulties in casting one slab of glass; for until it was finished and in the optician's hands, so that its refraction index might be determined, it would not be possible to calculate the focus of the instrument, upon which had to be founded the dimensions of the dome and mounting.

The Russian astronomers made great preparations to observe the recent lunar eclipse; but according to a letter from Professor M. Nyrén, Director of the Pulkowa Observatory, near St. Petersburg, not a vestige of the moon could be seen during the eclipse. At Helsingfors, however, the moon could be discerned through the stars, though at Dorpat, the second great Russian observatory, nothing could be done.

We alluded in our last issue to the importance of bisulphide of carbon as an antiseptic, and its value is continually being recognised. M. Pasteur has been making further investigations into its properties. He anticipates that it will become the most efficacious of all antiseptics, as it is also the cheapest, costing but a fraction of a penny per pound in large quantity. It is also the best insecticide known, and for this purpose may, perhaps, be useful to preserve wood-work in tropical countries. Some idea of the use it is already put to may be gathered from the fact that over eight million pounds of the substance are used annually to check the ravages of phylloxera.

Carbon bisulphide, as first produced, is about as foul-smelling a compound as it is possible to find; but it is capable of purification till all offensive odour is removed, and it is sufficiently pure in smell almost to mix with a perfume.

A very interesting note on the colour of chemical compounds, referring to the properties of its constituent elements, was recently given by a correspondent in a continental journal. Premising that the colour depends on three conditions—the temperature, the quantity of the electro-negative element present, and the atomic weights of the constituent elements—he gives details of the particular changes. Thus he states that in the chromium compounds the application of heat causes a regular sequence of changes in colour following the order of the colours of the spectrum. In many compounds he shows that increase in the electro-negative elements involves a change of colour to the red end of the spectrum. The influence of atomic weight is shown in the fact of the elements, as arranged in Mendeleef's tables, changing from white through violet, indigo, blue, green, yellow, orange, red, brown, and black as the weights increase. A long table is given showing the effect produced upon the colour of a compound by the atomic weight of its constituents. His rule had 426 cases and 14 exceptions. We do not know how he would treat the varying colours of bromide of silver. If an exact determination of the modification the bromide undergoes as its colour changes, a most useful light would be thrown upon the physics of emulsion making.

SODA DEVELOPMENT AND OVER-EXPOSURE.

There is to the careful observer something very puzzling in the opinions expressed by photographers respecting every novelty proposed in the treatment of plates. For example: we have had put before us in the Journal of August 1st, by Mr. A. F. Genlain, a clear description of the mode of developing by carbonate of soda, using one grain of pyro. to each ounce of developer.

The article in question treated the proposed change of development so lucidly that I at once made up a quantity of the alkaline solution—soda one ounce, water ten ounces, bromide of potassium eight grains—and resolved to give it a fair trial. The thermometer at the time was exceedingly high, and as soon as my first plate had developed to greater density with *one grain of pyro. to the ounce* than I had previously been able to get with three grains I dropped it, after washing, into hypo., and beheld a most glorious specimen of frilling. Alum was instantly tried, and the plate saved.

Since then I have used the above formula with "Britannia," Wratten's, and Fry's plates, with instantaneous exposures and exposures of ten seconds, and I must say that with all the plates I have had the most perfect printing negatives I have ever had during three-and-twenty years' experience (as an amateur). I find that with this mode of development I get transparencies on ordinary plates perfectly fit for the lantern, with clear glass, and with some plates of a beautiful black tone.

The puzzle I alluded to above may now be mentioned. I recommended this developer to a friend (of experience), and he instantly replied—"Oh! it is too quick; I cannot do with it." I open the Journal, and the first person who mentions it says it is too slow for him. I find half-a-dozen persons referring to it as producing a nasty yellow colour, which in my case is conspicuous chiefly by its absence, and under the circumstances one can only "give it up" as a conundrum, or one of those things that "no fellah can understand."

I received from a friend, a short time since, two undeveloped negatives (out of a batch taken at the lakes) for development at home, and which had all turned out over-exposed. I thought it was worth while trying an experiment I had been planning; and accordingly, having citric acid at hand in case my idea should fail, I diluted the developer with an equal bulk of water. The picture appeared slowly and developed up to printing density without any need for any restrainer, and the citric acid was not needed. This I thought was very satisfactory, considering that I had no idea what exposure the plates had received.

A couple of nights since I resolved to test the principle of dilution still further. I took a quarter-plate negative—a figure subject, with every gradation of tint from black to clear glass—and, taking an ordinary commercial plate, I exposed it for a transparency four feet from a No. 4 burner for six seconds, and with an ounce and a-half of the above-mentioned developer. I obtained a perfect transparency—quite fit for the lantern. I then exposed a second plate out of the same box *twelve* seconds, poured over it a fresh dose of developer, watched carefully for the first trace of an image, and as soon as it appeared I put the plate under the tap, diluted the developer with an equal bulk of water, and completed the development, retaining *clear* glass to the end. This transparency was not quite as dense as the first, but it was of good colour and "rounder," with more delicate shading and half-tone. I then repeated the experiment with a third plate, exposing this time *thirty* seconds. I first placed the exposed plate in water, then poured on the ounce and a-half of developer, and when the first trace of an image appeared I diluted the developer to four ounces in bulk, obtaining a transparency, to my mind, quite equal to the second.

It seems that this experiment suggests a simple mode of meeting over-exposure. It is easily tried; and, if confirmed by the experience of others, will prove another reason for banishing ammonia from the dark room. I find that the combination of ammonia with this developer produces photographs in colour. Red fog appears of the most vivid kind, and ruins the result. H. N. Atkins.

P.S.—As every variation in formulæ affects the result in some degree, it may be necessary to state that I use the pyro. *in solution* as follows:—Pyro. one ounce (437½ grains), citric acid sixty grains, water forty-three and three-quarter ounces; then giving a strength of ten grains of pyro. to the ounce of solution, and introducing citrate of soda into the developer to a very minute extent.

COATING PLATES WITH GELATINE EMULSION.

About six months ago I promised to publish a description of a little machine (of which I had showed a sketch) for rapidly coating plates with emulsion, suitable for amateurs or others who do not require complicated and expensive machinery. On trying it, though it worked very well, there was still one point which I wanted to improve upon before publishing the details of it in the Journal. Your readers will find that the little piece of apparatus I am now about to describe will coat plates (large or small) quite equal to those supplied by professional makers, and better than those of some of them.

To coat plates perfectly I found the following points were necessary:—

1. That a certain quantity of emulsion should be flowed in one even stream all over the plate, instead of pouring the emulsion in a pool in the centre of the plate and then dispersing it over the whole surface; because in the latter mode of coating large plates the gelatine is apt to commence setting before it is equally distributed, and an unequally-coated plate is the result.

2. The plate ought to be put on the levelling-table before coating, and not be moved before the gelatine is set; because in the dull light of the dark room it is so difficult to prevent the emulsion running off the plate when putting it down on the levelling-table.

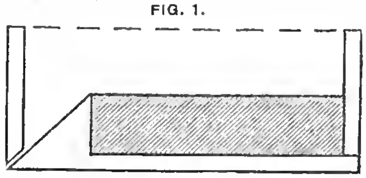
3. I found that if the emulsion be rubbed (so to speak) on to the glass there is much less chance of frilling, &c., than if it were poured on. I think it is because in the former case the gelatine is in firmer contact with the glass. When the gelatine is poured on to the plate the cold glass instantly chills it, and by the time the emulsion has reached the edges of the plate it has so far set as to have partially lost its power of adhesion to the smooth surface of the glass.

Two or three years ago, when it was the practice to warm the plates before coating, I found from a series of experiments I then made that when a plate was warmed before being coated the emulsion commenced setting on the surface of the film, and of course in setting contracted, thereby leaving a partial vacuum between the film and the glass. On development frilling was the consequence. I found, however, that, when pouring the same emulsion on cold glass, on the portion of the plate where it was poured on the film instantly chilled and commenced to contract on to the glass, and it never frilled there; but towards the edges of the plate, as the emulsion had commenced to chill before they were covered, the film was not in such perfect contact with the glass. Any person can try the experiment by first coating a plate in the ordinary way, and on the second plate just pour a small pool of emulsion on the centre; let both dry, and he will then see after exposure which frills the easier on development.

After a series of experiments I found that by brushing a substratum of emulsion on to the cold plate (with a brush made by binding a strip of wash-leather at the end of a strip of glass), and then pouring the full quantity of emulsion on to the substratum (for quarter-plates I used a small silver teaspoon, which held sufficient to cover that size of plate), I found I could coat plates far better and quicker and as easily as when coating with collodion, and I got over the difficulties of having frilling plates.

When only a few small plates are required—such as for experimental purposes—I believe this method is as quick and good as any;

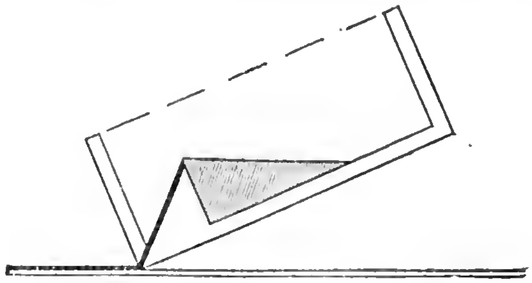
FIG. 1.



Showing melted emulsion in coater ready for coating.

but when several dozen plates are wanted any plan of coating them separately takes a long time. With my plate-coater I can coat a dozen plates in about the time I formerly took to coat one. When coating a number I thought it would be best to lay them in rows on the levelling-shelves and draw the receptacle containing the emulsion over them, rather than keep the latter a fixture

FIG. 2.



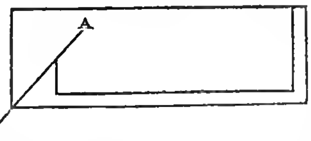
Showing emulsion flowing through the slit on to the glass.

and run the plates under it either on an endless band or sliding shelves; because by the first mode the plates can be fixed close together and the emulsion is less likely to get between them.

The coater is a species of wooden tray (of which the diagrams show the section), having a small slit in one of the bottom edges through which the emulsion passes in one even wave the whole width of the plate. The width of the coater is the same as that of the plate, though one six and a-half inches wide can be used for either half- or whole-plates.

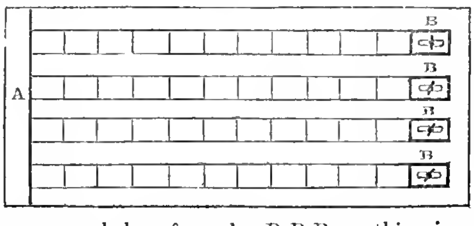
I find the best way of making it, so as to get the slit an equal opening the whole length of it, is to put the back, bottom, and two sides together first, as in *fig.* 3. Then by putting a piece of very thin paper (A B) on the angle piece, when the front piece of wood is put tight down on the paper and fixed in its place, and the paper is drawn out, it will be found that the slit is very even. In one coater I made I had the slit a little too wide an opening, and to reduce it I glued a piece of muslin over it. This I found was a great improvement, as it not only acted as a strainer, but it checked and caused a more even flow of the emulsion over the plate. I varnished the wood and muslin (except over the slit) with black Japan.

FIG. 3.



To coat the plates I put them close together in rows on the levelling-shelf, as shown below :—

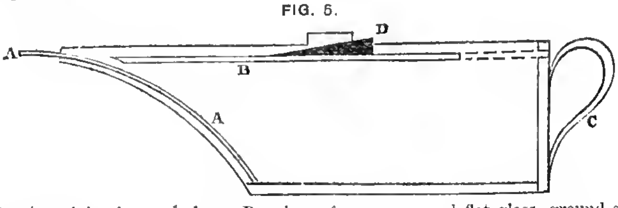
FIG. 4.



A is a thin, narrow ledge of wood. B B B are thin pieces of wood, in the centre of each of which is a small slot and thumb-screw. The plates are pressed against A by the pieces of wood B, and the thumb-screws are then fastened. The plates are thus kept from slipping about. All this, of course, can be done in ordinary white light. The light is then made non-actinic; the melted emulsion is poured into the reservoir of the coater, which is put to the left hand edge of the outer row of plates. It is then lifted up on edge, as in *fig.* 2, and drawn slowly over the row of plates, and so on until the whole of the rows are coated. Of course when not coating plates it is kept in a horizontal position, as in *fig.* 1. The emulsion on the plates is allowed to set without being disturbed ; the shelf is then slipped into the drying-box until the plates are dry, so that they are not touched from the time they are coated until they are dry and ready for packing.

I am at present engaged in making a modification of this coater to hold a much larger quantity of emulsion at one time, when a large number of plates require to be coated. It is something the shape of a flat teapot—

FIG. 5.



A A is a piece of curved glass. B a piece of coarse ground flat glass, ground side uppermost, sliding in two grooves in the wooden sides. C is the handle fixed to the wooden back.

A piece of thin paper is placed on the curved glass, and the ground glass pushed close up and fixed by two small wedges, D. The paper is then slipped out, leaving a narrow, even opening between the two glasses. The width of this opening can be varied by using thicker paper if the plates require to be coated with a thicker film. By using this form the coater can be more easily cleaned, as the ground glass can be slipped right out at the back, and probably in passing from the opening to the plates over the curved glass the wave of the emulsion will be equalised as well as when passing through the muslin. HERBERT S. STARNES.

CANVAS ENLARGEMENTS.

REFERRING to your excellent article in last week's Journal anent the making of enlargements on canvas, I should be obliged if you would insert the following as being my usual practice in making these enlargements.

Presuming, of course, that the reader is acquainted with the ordinary collodion transfer process, I will begin by saying that before the plate (say 15 x 12) has been French chalked, pour a well-diluted solution of sulphuric or hydrochloric acid over it, and then rinse well with water. After wiping well dust with French chalk in the usual way, and prepare for exposing.

When the plate is well washed after fixing (say half-an-hour at least), place some fairly-surfaced white paper (ungelatinised, of course) on the film, and squeegee carefully. Test the corner of the plate to see if the film be likely to come off with the paper ; if so, strip it from the glass, the paper being the support. This being done, the canvas on the stretcher is the next consideration. First wash the whole canvas with soap and hot water until all greasy marks disappear ; rinse well under the tap, and apply a hot solution of gelatine, very thin (say four flakes of French gelatine to twelve ounces of water), and as quickly as possible place the transfer on the canvas in its proper position ; squeegee, and carefully raise the paper, leaving the film adhering to the canvas.

There are one or two things to be attended to in all this, namely, wash the canvas equally all over and see that it is thoroughly soaked, or there is a likelihood of contraction of the canvas after the film is dry.

Presuming a quarter-plate negative is taken of a sitter, and a head and breast enlargement (24 × 20) is required on canvas, my mode of procedure is to throw the image on the canvas exactly to the size and form wanted. I then draw the outline roughly on the canvas, and next take a 15 × 12 collodion transfer in the manner stated above, getting the head and collar, &c., to nearly fill the whole plate. When putting the film on the canvas I have, therefore, a good guide as to its exact position from my outlined sketch, and the artist may easily draw in the coat, &c., from the print off the original negative.

Always use a thin collodion for this class of work, or contraction of the film and canvas will take place, and especially so if the canvas be not well washed as above stated. It is, of course, unnecessary to gelatinise the whole canvas—only such part as accommodates the film ; but in spreading the hot solution on be mindful that it does not get cold, or a lumpy surface will result.

If these hints are of any use to the readers of your excellent Journal I shall be only too glad to have assisted in following up your article. DAVID M. LINLEY.

BOTTLES *VERSUS* GAS BAGS.*

APPARATUS FOR STORING GASES : ITS COST AND DANGERS.

BOTTLES.—The Adams condensed gas bottles, introduced in 1865-6, supplied to me (filled with oxygen or hydrogen) by Mr. Orchard, were made of iron, and though having the disadvantage of being heavy, on the other side, as "per contra," was the great advantage of their occupying little space compared with gas-bags, whether full or empty. These bottles were of two sizes—one for oxygen having seven and a-half feet capacity, the other for pure hydrogen fifteen cubic feet capacity. The dimensions of the smaller bottle were two feet three inches long by four and a-half inches diameter; the other considerably larger, both as to length and diameter—so much so that I soon adopted the plan of using two small bottles "coupled up" for the hydrogen, so that the three bottles *all of one height* could be packed in one case. These bottles were tested before use by hydraulic pressure up to sixty atmospheres, or 700 lbs. pressure on the square inch, thus ensuring safety to the filler and user, as the pumping pressure employed in filling never exceeded thirty atmospheres.

At the present day the smaller bottles are pumped to hold ten cubic feet of gas, and the larger bottles twenty cubic feet, under a pressure of forty atmospheres, and with perfect safety. In America the bottles, or "tubes," as they are there called, are much lighter, being made of copper and steel, and the system of filling is different. These vessels are larger for an equal quantity of gas, and are filled at a lower pressure than in our country. Thus a tube of ten cubic feet capacity measures about two feet six inches long *by seven inches diameter* (in place of four and a-half inches), and is filled at as low a pressure as fifteen atmospheres. Some Americans, however, are advocating the employment of oxygen and hydrogen in bottles of smaller sizes, under higher pressure than thirty atmospheres, as with nitrous-oxide gas—employed extensively in dentistry and surgical operations, both for anæsthetic and local chilling purposes, *with perfect safety.*

Gas bottles present this very important advantage over gas bags—that gas may be kept therein *for any length of time without the slightest deterioration*, and, consequently, be ready for use at any required moment—a matter of grave consideration for those who employ the

* Continued from page 650

lime light in the lecture room, laboratory, or photographic studio at uncertain times. But the most important advantage of the condensed gas system is the increased light to be got thereby. When I look back upon the *light* we students "before the fifties" got out of a pair of Pesy's gas-holders with water pressure, and a "safety jet" with its delivery tubes bunged up with bundles of fine wires and partitions of fine wire gauze, I laugh outright to think we should have considered *that* "powerful light" a thing to boast about as being produced by anyone less than a lecturer or professor of chemistry. It is like calling to remembrance the solemn rushlight of our childhood as compared with the latest manufacture of night-lights, or of the argand oil "Sanumbra" of the old-fashioned drawing-room with one of Deitz's most perfectly-constructed petroleum or of Sugg's patent gas burners. In 1856 I flattered myself that *I had got a light* for my diagram lantern. *That* "Herapath's jet" I should now laugh to scorn and desire it to "be blowed"—a little stronger. The last time I manipulated the lime light in public was at Dr. Carpenter's lecture on the microscope at the Society of Arts. After the lecture a member of the optical trade asked me *how* I got such a light upon the screen. My answer was simply—"By pressure." I had used the gas bottles with the rubber tubes, not "sprung on," but with metal union connections, for the reason that if we take full advantage of the light-giving power condensed gas places at our command we must have strong tubing and metallic connections; for "sprung on" tubes, such as we have used with gas bags loaded with one hundredweight or more, would be blown off with a snap sufficient to alarm an audience. This fact speaks volumes as to the difference of the pressure we are dealing with when we used bottles pumped up to only twenty-five atmospheres on the square inch. Again: with bags it is a comfort—not an absolute necessity—to employ a lime clock to keep your "hard lime" rotating, without having to open your lantern door or bother your head about periodical rotation by hand. But with condensed gas *it becomes a matter of absolute necessity* to employ something to keep the lime always slowly on the move, for the reason that the gases impinge upon it with such force as to pit it into holes so deep that the point of light is soon out of focus.

Again: the fair wear and tear of gas bags—without reckoning upon the rough usage they get from cabmen, railway porters, nails, splintered wood, mischievous youths of an inquisitive turn of mind, and empty-headed folks, such as those who could turn a bag into a pincushion—makes it necessary that travelling lecturers having brisk business should have a new pair of bags every season; but the first outlay on a pair of bottles will be the last for any number of years. The question as to relative cost I will leave till final summing up. I always employed pure hydrogen, as house gas when condensed gave off an unpleasant smell when used; but, through the greater purity of the carburetted hydrogen of the present day, that gas is practically good enough, and so one bottle instead of two will suffice. As the all-sufficient pressure is *self-contained*, pressure boards are not wanted, nor have weights to be hunted for in strange places or carried about, nor is there any fear of their being shifted off on to the toes of those around. Then as to floor space: a pair of bottles packed in a case occupy only one foot by six and a-half inches, as compared with three feet six inches by three feet, with the extra guard-space of at least two feet around them, which must be devoted to gas bags and boards.

There is no deterioration of the inner surface of the receptacle, as with oxygen bags, or where hydrogen has not been freed by washing and neutralising from watery sulphuric vapour, for the first coat of rust formed acts as a protective surface, as far as present experiences go. Then there is no dread in the lecturer's mind of loss of gas from leakage, knife thrusts, nail or splinter punctures, or brooch pins. So far for the economical aspect of bottles. Now, *per contra:* I have already said that *some* arrangement for keeping the lime on the move is necessary. Although I have always manipulated with the lever, working the screw conical valve alone and with the greatest ease, others, not tyros in the use of scientific instruments, have whisked out their seven cubic feet of gas in twenty minutes, or produced a series of "up lights" and "down lights," which would have secured a character for promptitude to any "gas-man" at a theatre; so I have come to the conclusion that an arrangement supplemental to the lever valve, and corresponding to the fine adjustment of a microscope, is really necessary; but the space at my disposal will not allow of my describing the arrangement I have designed. I see that some such arrangement has been "catalogued;" but, as no price is affixed, I take it that, like my own, it is a thing of the future.

On June 4th an advertisement appeared in the daily papers, offering the sale of the English patent for an "Automatic Condensed Gas Regulator" for the sum of £1,000. A few days afterwards Mr. James Bowie, the inventor, favoured me with an inspection of his very ingenious arrangement, but, never having seen it in action, I will not here offer any opinion upon its practical merits. Suffice it that the patent has been taken up, the regulator is being prepared for sale, and it will be shown in action before a public meeting in London during the forthcoming winter session.

Then, though not absolutely necessary, it is a great comfort to have a pressure gauge—first, to know for certain that your bottle, as sent in from the condensed gas engineer or chemist, *does* contain the quantity of gas requisite for an entertainment or lecture; secondly, to know how the gas is going during a lecture, especially towards the end, so as to bring it to a conclusion in a manner the index of the gauge indicates. If the condensed gas system got into full swing the filled bottles would be brought to our doors in the same manner as aërated waters, and the "empties" taken back "in exchange," and this at a price as cheap, if not cheaper, than we could make the gases at home, free from trouble, risk, and cost of the necessary generating and filling apparatus and its wear and tear. This applies to the cost of oxygen and hydrogen where the bag system is followed; for, under either system, at the present day these gases may be obtained ready-made for eight pence per cubic foot, and on a larger scale would be cheaper.

Now for the dangers of the gas bottles: honestly, without bias *to the exhibitor*, I believe *none* exist or can be anticipated. Whatever danger there may be pertains to the filler, and, with all ordinary care, *none* for him. The man who wishes to mount a horse with safety to himself must learn to ride. The boating man, the cyclist, or the gunner must learn the construction of what he is going to use, and from some experienced person how to use it; *then* there is little fear of his coming to grief. So with lime-light apparatus, whether under the bag or bottle system. It is the self-sufficient folks who are entrusted with dangerous tools by the dealers with fear and trembling—not so much lest parties should injure themselves—but trade! When gas bottles are tested under hydrostatic pressure, if there be a weak point in the metal it does not burst with explosive force; but rends at the side, or the bottom may be forced out quietly and pleasantly, water being an inelastic body. Very different would it be if the tubes were tested with elastic gases.

Having been thus tested up to two or three times the pressure that will afterwards be used when filling, danger is hardly to be anticipated. Should there be a burst it will be during filling, and the filler will be the sufferer, if anyone. Should a bottle be filled with a mixture of oxygen and hydrogen, as long as there was a forward pressure—even a lowered pressure—I do not believe there would be any danger of a "run-back" on a light being applied till zero point was reached, and the gases were in equilibrium with the atmosphere. Then I think that the small bore and mass of cold metal in the valve would prevent the lighted explosive mixture from passing inwards. Such faith have I, from what I have seen and tried, that I would unhesitatingly sit upon a bag filled with the mixed gases, if placed between pressure-boards and properly weighted, as long as I had control of the jet. At first this may look like foolhardy braggadocio; but let old lanternists call to mind how long Dr. Woodward employed both gases mixed in one bag and comparatively under low pressure, as described and figured in his book on *Polarised Light*, published by Van Voorst. I should like to learn the exact circumstances under which Dr. Procter's assistant in America managed to kill himself. Probably in a drunken state he mixed the gases, lighted up, and when the pressure sunk to zero point there was a fatal explosion.

I know of a case where a workman who was not drunk had to repair a bottle, and, without emptying it of its contents or opening the valve, placed it on the forge fire. Of course the heated gas expanded to bursting point, and the operator was blown over to "the majority." Who could have anticipated that a skilled workman, used to the work, would have been capable of such reckless carelessness? The only danger that could befal the bottle manipulator at a lecture, &c., is the possibility of the thick glass of the pressure-gauge being blown out in bits on the gas from the bottle being turned full on to see what the contents registered. But all fear of injury from this cause can readily be anticipated by a very simple arrangement of the apparatus without diminishing its full utility.

And, now, as to cost:—

A 7 to 10 feet bottle with lever, value	£2	2	0
A 15 to 20 ,, ,, ,, ,,	3	3	0
A lime clock of recent construction	2	15	0
A pressure-gauge	2	2	0
Rubber tubing with metal connections	0	15	0
Travelling case	0	14	0
Total	£11	11	0

Samuel Highley, F.C.S., &c.

NOTES FROM THE NORTH.

Summer holidays, well planned and properly managed, are always very pleasant and sometimes very profitable, but are generally attended with some drawbacks. Not the least important of these is the fact that the holiday maker is apt to fall behind in his attention to current literature: and if he be a photographer in the habit of giving diligent attention to the literature of his favourite hobby, he is likely, during those happy holiday times, to miss many items that are worth more than a passing thought. This, at least, is the case with myself at present, as, having been a good deal from home during the past few months, I was unable to give the usual exhaustive attention to The British Journal of Photography, and it is only now, when the ordinary routine of home life has been resumed, that I notice several items that seem to require special attention.

First in order, perhaps, comes the amusing theory, expounded at page 501 of the number for August 8th, by Mr. Herbert S. Starnes, as to the formation or nature of the invisible image. Several writers, with some pretension to chemical knowledge, and something like method in their system of experimenting, have, pretty nearly at least, shown that the sub-bromide theory is correct; but Mr. Starnes has, on the ground of the alleged fact that lapse of time—"putting the (exposed) plate away in the dark for a time," he calls it—destroys the impressed image and renders it ready for another exposure, developed a new theory, which teaches that silver bromide is not affected by light at all, but that each atom or particle is enveloped in a little gelatine bladder, which, by getting a good shake from the light becomes ruptured, and so allows the developing solution to reduce the salt.

I need not follow him in his curious experiments—as he somewhat naïvely confesses that, just as he might have expected, the plates were fogged—but will simply say that the bogie he has set up, and invented a theory to account for, is merely "a man of straw." In other words, lapse of time, or putting an exposed plate away in the dark, under such conditions as would preserve an unexposed plate, does not destroy the invisible image. Anyone conversant with photographic literature knows that this has been a long-established fact, and one corroborated in a recent number of the Journal (Oct. 17th), where an "admirable print" is stated to have been sent to the Editors from a negative developed four years after exposure.

Some of my readers may remember that more than a year ago I recorded the fact that by adding fresh gelatine to an emulsion which by decomposition had become as thin as treacle, and acquired a very disagreeable smell, it gave plates, not only in every sense first-rate, but very much more rapid than those prepared with it when fresh. Several of the plates exposed at that time were simply wrapped in coloured paper and laid at the bottom of one of the drawers of my writing table, where they lay till a few days ago, when one of them, on development, yielded a clear, crisp, good negative without speck or flaw. While I would be the last to dissuade any one from publishing his experiences in photographic matters, I feel strongly inclined, in the interests of those who feel that they must read all that is said on the subject, to recommend close attention to Montaigne's advice, viz., "I would have every one write what he knows, and as much as he knows, but no more."

There has recently been a good deal of discussion on the ever-interesting question of development, and several of our friends have amused themselves by reducing the directions given by the various plate-makers to a uniform system of "grains to the ounce," with a view to saving those who use plates of various brands from the necessity of keeping a lot of unnecessary bottles in the dark rooms. At the risk of being "sat upon," I wish to ask *cui bono?* No doubt some of the makers believe the formula that accompanies the plates they send out is the best for that brand, while others are simply anxious to recommend something different from their neighbours; but good plate-makers are not necessarily good photographers, and a good photographer who "developes with brains" is more likely to make better work by the exercise of his knowledge and experience than by anything like a slavish adoption of the maker's recommendations.

In my temporary home in town I have no convenience for the preparation of plates, and therefore during the whole of the present season have been drawing my supplies from commercial sources, including almost every maker of repute. Some of each batch were developed strictly according to the method recommended by the makers, and the rest by what I call my own, simply because I have employed it for several years, and never saw any reason to change it; and while in most cases fairly good results were obtained by the makers' formula, in every case equally good, and in many very much better, work was produced by my own system.

I never quite understood why "ten-per-cent. solutions" are not universally employed. They are handy, keep well, and the only calculation required is to add mentally a nought to the number of grains to be used per ounce. Thus, the plates I generally employ require three ounces to cover them properly. Into a measure graduated to drachms I put one drachm each of the ten-per-cent. solutions of bromide, ammonia, and pyro., fill up to three ounces, and pour over the plate. If the exposure has been about right the image begins to appear in from thirty seconds to a minute, and goes on slowly but surely till a fine negative is obtained, while in cases of under- or over-exposure a few drops of bromide or ammonia respectively readily bring about the desired effect.

I notice, in a recent number, a correspondent recommends a method of preventing the loss of the screw of the tripod head that I had thought was already in general use, viz., tapping the tripod head so as to fit the screw, and filing away a portion of the threads of the screw at its neck, the thickness of the head. All the old Edinburgh-made stands by Bryson, Davidson, Lennie, &c., were so made, and I have used one for twenty-five years without losing a screw.

In reply to my observations in last *Notes* on canary medium, I have to thank Mr. G. D. Scorah, of Bradford, for sending me several sheets very much evener than those I had previously seen; but I am sorry to learn from him that there is not much chance of the manufacturer turning his attention to the wants of the photographer. It is used to the extent of some tons per week for wrapping foreign piece goods, and is made from manilla; hence its strength and also its clouded appearance. I may add that the longer I use it the better I like it, and the more I regret that prejudice and foolish faith in the dismal dark ruby kept me so long from making its acquaintance. JOHN NICOL, Ph.D.

ON TONING.

[A communication to the London and Provincial Photographic Association.]

UPON the previous occasion, when I had the honour of appearing before you in January last, it will be remembered that the subject of *Silver Printing on Albumenised Paper* engrossed our attention through the various stages which led up to a printed result; and here it was decided to stop, partly because sufficient had been said to occupy a longer time than was originally set down as convenient for the delivery of these lecturettes, and partly because it appeared to me presumptuous on my part to attempt other processes connected with the system of finishing, when so many practical photographers of long experience and members of this Association were far more capable of dealing with such subjects as toning, fixing, washing, and finishing, either together or separately, than the information I could gather or my meagre ability would justify.

I must apologise to you for the imperfect manner in which my previous lecture was brought before you, and I trust you will pardon me when I say that I cannot help thinking its very incompleteness has proved beneficial. Whether I am right in my conjecture or not remains to be admitted. One thing must be evident: the older societies laid hold of the subject again soon afterwards with renewed vigour, and, in very able papers from Mr. John Spiller, F.C.S., and Mr. E. Dunmore, thoroughly thrashed out the most important details, so that we have cause to congratulate our Curator on the wisdom he has displayed in selecting suitable subjects at the proper time—operating, as it did, in a manner calculated to set the older machinery in motion, providing, as he has, much useful discussion and practical information in this country, besides reopening the field for further research upon all the subjects on which the lecturers treated, as evidenced by the foreign journals.

As one of the many professionals who regularly practise the perfected researches of others—namely, those photochemical scientists, whose names have become as familiar to all students of the art as that of Galvani, Volta, or Faraday to the students of electrical science—it will be readily understood that I cannot say anything which is new; and if I understood our Curator's intentions correctly it was his object, when establishing these periodical discourses, to make them of such an elementary nature as would enable the younger, and particularly the amateur, members to gain enough knowledge of the details and antecedents of each process as might become interesting to them, and benefit the Association at the same time by a general improvement in the character of the discussions, rather than the establishment of a higher technical style, suited only to advanced students. Premising this to be the case, I shall endeavour to show the *raison d'être* of the various processes to be hereinafter described, and to whom we are indebted for their discovery. Should it turn out that the sources from which the information has been gathered are unreliable, then I shall be glad of the necessary corrections when discussion takes place.

I have already in the previous communication dealt with the means employed in preparing a suitable paper to receive a photographic image, including the methods of albumenising, sensitising, and fuming. Preserved papers were also spoken of, and many useful hints were gathered in the discussion which followed. As it will be necessary to refer to these papers in the remarks which are to follow, it will be found more convenient if we distinguish the preserved paper from freshly-prepared by the cognomen of "preserved" and "ordinary."

Beginning with ordinary paper, printed under a negative somewhat deeper than it is desired to have the prints when finished, we should have a print which, although beautiful to look upon, possesses a charm of only a transient nature—due to the gradual decomposition that takes place when organic substances such as albumen are long in contact with free nitrate of silver; hence the necessity of the processes I have to describe.

In the case of alkaline toning with borax or acetate of soda: the first consideration is to free the paper as much as possible from the excess of silver nitrate remaining therein over and above the quantity used in the production of the print; this is termed washing away the free silver. That operation is satisfactorily performed by soaking the prints in a few changes of clean soft water—usually four, or until the water is no longer opalescent when tested with a few grains of salt. The washing water so obtained is collected in the manner described to you by Mr. F. W. Hart, and precipitated with dilute hydrochloric acid. The vessel employed should be scrupulously clean, either earthenware, porcelain, or wood answering the purpose.

Experiment 1.—The treatment of the prints is sometimes followed by passing them into a dilute solution of sodium acetate or ordinary common salt—about one per cent., such as here shown—and stirring them about for five minutes, when it will be seen they have assumed a brick-red colour, the object of which is threefold:—Firstly, the fibres become charged with a substance which acts as a chlorine absorbent—a necessary property to be mentioned further on. Secondly, a definite colour is ensured to start with, thus obviating the possibility of mistaking fresh prints in the toning bath for those which have become purple by reason of the deposited gold—an important consideration when dealing with fumed paper. Thirdly, the last trace of free nitrate of silver is removed, thereby preventing a too rapid decomposition of the toning bath.

Theoretically considered, it is proper that the last trace of silver nitrate should be removed; but those who are engaged in the daily practice of commercial work do not insist upon the strict observance of such a rule in all cases. An especial exception is permitted and advocated when dealing with prints from weak or under-exposed negatives, this class being found to yield richer tones by not washing any of the free silver out.

The plan of soaking prints in a solution of sodium acetate was originally recommended, in lieu of washing, by a member of this Association, Mr. A. L. Henderson, as long ago as 1861, the following being an outline of the method suggested by him:—Slightly over-printed proofs were soaked in a bath composed of—

Sodium acetate	210 grains.
Water	10 ounces.

The unwashed proofs were moved about in this solution at least ten minutes, in order to convert all the free silver nitrate into acetate of silver. After slight rinsing in clean water the proofs were toned with—

Gold terchloride	4 grains.
Sodium acetate	240 ,,
Water	10 ounces.

Among the advantages claimed was an entire absence from mealiness—a defect, you will remember, we now avoid by the adoption of ammoniacal fuming.

Guide-books to the practice of printing usually recommended three rapid washings; the decomposing action thus set up by the quantity of free silver remaining in the paper materially quickens the speed of toning. To prevent a too rapid deposition of gold some printers prefer adding a small quantity of common salt to the toning bath, which turns the prints sufficiently red and acts in some respects equal to an intermediary bath.

Preserved papers—containing, as they generally do, a certain proportion of free acid—are liable to give some trouble in toning, owing to the retarding action of the acid present. When this occurs it is in a great measure overcome by the use of an intermediate bath of an alkaline character and sufficient strength to neutralise the acid. Either the carbonates of ammonia or soda are found useful for this purpose, and I cannot do better than quote the one mentioned by Mr. Frederick York, which, it will be remembered, is composed of—

Washing soda	1 ounce.
Water	1 gallon.

Prints treated in the manner described are ready for toning by the alkaline method to be dealt with later on.

This brings us to the consideration of toning baths generally. The properties of toning baths vary somewhat according to the mode of preparation. The term "toning," as we understand it, implies a certain change of colour brought about by chemical means, such as the deposition of a stable metal upon one that is easily affected by the atmosphere—electrolysis, in fact.

Evidently Mr. W. H. Fox Talbot was the first to use the toning bath in connection with paper photography, although he does not seem to have made much headway with his process at first; for it is recorded that from January, 1839—the date when Mr. Talbot communicated his discovery to the Royal Society—until 1845 very little improvement took place. These early paper pictures, be it remembered, were designated "photogenic drawings." Talbotype was not patented for some time afterwards.

In the year 1845, however, it was found that steeping the paper in terchloride of gold vastly improved the results. It was not until 1853 that albumen took any part in the production of prints, the honour of its introduction being ascribed to Mr. Henry Pollock, although it seems that M. Le Gray, of Paris, about that time was producing stereoscopic pictures on albumenised paper. To M. Le Gray is due the credit of introducing gold toning in lieu of sulphur. The first toning then was performed by the decomposition of hypo. and known as "sulphur toning," by which fine black tones were obtained upon the addition of an acid, such as acetic, sulphuric, or other suitable oxidising substance to the hypo., gold taking no part in this process. Unfortunately, prints so treated are said to be the least permanent of any; but of that I can bring no actual proof, never having employed the process.

Experiment 2.—Toning by Sulphur.—We have an unwashed silver print here in a twenty-per-cent. solution of hypo., and to that we now add a few drops of slightly-dilute sulphuric acid. It will be seen that a straw-coloured substance is immediately liberated, which is sulphur in an exceedingly fine state of division, and this becomes attached to the print. Toning action goes on, through the silver image being tarnished, or, more correctly, converted into sulphide of silver. This liberation of sulphur may be expressed by the following equation:—

Hypo. + Sulphuric Acid = Glauber Salts + Water + Sulphur Di-oxide + Sulphur

$$Na_2S_2O_3 + H_2SO_4 = Na_2SO_4 + H_2O + SO_2 + S.$$

With respect to the reaction which takes place when toning a silver image with sulphur, I will quote a few lines from the parent work of reference for nearly all recent writers, namely, Hardwich's *Photographic Chemistry*, wherein we find the following paragraph:—

"It is well known that articles of silver plate become darkened by exposure to the fumes of sulphur, or to those of sulphuretted hydrogen, of which minute traces are always present in the atmosphere. If the stopper of a bottle of sulphuretted hydrogen water be removed, and a simply-fixed photographic positive suspended over it, the picture will lose its characteristic red tone, and become nearly black. The black colour is even more intense than an experienced chemist would have anticipated, because analysis teaches us that the actual quantity of silver present in a photographic picture on paper is infinitesimally small; and it is well known that sulphide of silver, although of a deep brown colour, approaching to black when in mass, exhibits a pale yellow tint in thin layers, so that a mere film of silver converted into sulphide possesses very little depth of colour. To explain the difficulty it has been suggested that the toning action of sulphur on a red print is probably due to the production of a sub-sulphide possessing an intense colorific power, like the sub-oxide and sub-chloride of silver. When the toned picture is subjected to the further action of sulphur it is converted into the ordinary protosulphide of silver, and becomes yellow and faded."

The toning baths following the sulphur method were principally mixtures of gold terchloride and hypo. This latter substance was found to be a solvent of certain silver compounds by the Rev. J. B. Reade, in 1839, Mr. Talbot having previously fixed his prints with common salt. Prints, too, were fixed first in some cases, and toned afterwards, washing away the free silver being more or less practised in the mixed hypo. and gold and the sulphur toning processes. When fixing was employed before toning, it was usual to soak washed prints in a twenty-per-cent. solution of hypo. for a period of ten minutes, or until the soluble silver salts were removed, the resulting colour being a disagreeable yellowish-brown. To improve the result so obtained the prints were passed into a solution of—

Gold terchloride	10 grains,
Water	20 ounces,

when toning action quickly followed, the yellow colour giving place to that of a dark sepia tint. From this stage to that of mixing these two substances together was only a natural sequence, and effected a diminution of gold to the extent of one-fourth, as will be seen by the following recognised formula:—

Hypo.	7 ounces.
Water	20 ,,

When dissolved, add—

Gold terchloride	5 grains.
Dissolved in water	20 ounces.

After mixing, a clear solution should result.

The *sel d'or* process followed, and was expected to give still better results. It was found, however, that the solutions would not keep, and as a considerable quantity of the gold salt was needed it caused experimenters to search for a less expensive method. One decided point in its favour was the circumstance that prints suffered no loss of intensity during the operation, as they do in the case of all other toning methods. Briefly: the prints were well washed to extract free silver, and, after soaking five minutes in salt and water, they were passed into an alkaline solution composed of—

Liquid ammonia	60 minims.
Water	20 ounces.

Here they became very red. After washing in clean water the surface was flooded with a toning solution composed of—

Double hyposulphite of gold and sodium *(sel d'or)*	½ grain.
Hypo.	1 ,,
Water	1 ounce.

Upon the print assuming a purple-grey colour it was withdrawn and fixed in a sixteen-per-cent. solution of hypo. to dissolve the unacted-upon silver chloride. Gold, when in a fine state of subdivision, is of a rich purple colour. The layer obtained by deposition upon a silver image is very finely divided; hence the colour. The only object in continuing the toning action beyond the stage at which a good surface colour has been reached is to obtain a deposit of sufficient density to completely neutralise the red colour of the organic silver image beneath; therefore, it is preferable, in forming a judgment of toning action, to examine proofs by transmitted light rather than by reflected only.

Before dealing with the various formulæ for alkaline toning I should like to step out of the golden track to say a few words on platinum tetrachloride, $Pt.\ Cl_4$.

Experiment 3.—Platinum Toning.—The value of a platinum salt as a toning agent for silver images has been thoroughly demonstrated before you by Mr. Henderson, when he initiated us into the secrets of ceramic photography. My trials with this salt as a toning agent for paper proofs have only been partially successful. By that I mean that toning does take place when a dilute solution is employed, but the action is too tardy for demonstration here tonight, since anything like a black tone could not be obtained under half-an-hour. You will observe that the surface becomes covered with chloride, showing the necessity for copious washing. Yellow or discoloured prints are bleached when toned in this bath, the whites becoming very pure. The formula here given is capable of producing a very good shade of brown in less time and should be permanent, since platinum is a metal practically unaffected by the atmosphere; and I think there is good reason to suppose that if a thin coating of platinum could be deposited on the silver image the protection offered would be more economical as well as stable. Something has already been done in this direction, but not in recent years.

The following is the composition we are now using:—

Platinum tetrachloride, syrupy solution, colour of old East India sherry	5 minims.
Hydrochloric acid	150 ,,
Water	20 ounces.

Wash away the free silver thoroughly, warm the toning solution to 70° Fahr., and fix in a twenty-per-cent. hypo. bath.

Mr. A. Watt, in the second volume of the *News*, gives a formula which runs as follows:—

Solution of platinum	30 minims.
Hypo	3 grains.
Hydrochloric acid	5 minims.
Water	5 ounces.

This bath is said to act instantly, but I have not had an opportunity to test it. The strength of the platinum solution here given is indefinite, but any of our experimental members can soon ascertain the amount of dilution necessary to obtain the most favourable results.

Alkaline Toning.—Owing to the bleaching action which occurs in toning silver prints with gold, which is slightly acid, certain experiments were made, and it was found that bleaching increased in proportion to the quantity of hydrochloric acid added. Now, in the action of toning chlorine is disengaged, and in order to render this powerful bleaching agent inert it has been proposed to introduce a substance capable of combining with it, and thus, in absorbing it, prevent undue loss of vigour. To obtain this a slightly alkaline toning bath became a necessity, and to Mr. Waterhouse we are indebted for the introduction of the alkaline salts (Hardwich).

Here is an example:—

Experiment 4.

Sodium carbonate ($Na_2\ H.\ Co_3$)	5 grains.
Auric terchloride ($Au\ Cl_3$)	1 grain.
Water	10 ounces.

Instead of the dry bicarbonate we will use a saturated solution. In this as well as the following experiments we shall tone three prints of the same subject, namely, ordinary, fumed, and preserved.

Mr. Maxwell Lyte has written on and investigated the properties of toning solutions a great deal more than most men, and we find the following emanating from Mr. Lyte:—

Sesquichloride of gold	15 grains.
Phosphate of soda	300 ,,
Distilled water	1¾ pint.

And in the same communication it is mentioned that 180 grains of borax may be substituted for the phosphate with a like result. Therefore it will be seen that a borax toning bath is not of recent discovery, although it does not appear to have been quoted in many formulæ for at least a dozen years after its publication.

After the publication of Mr. Lyte's formulæ it was found that other salts behaved similarly; and among the first suggested we found sodium acetate, the qualities of which, extolled by the introducer, Mr. Hannaford, have since been verified by the whole photographic world. Here is one of the ordinary formulæ:—

Experiment 5.

Gold terchloride	1 grain.
Sodium acetate	10 grains.
,, chloride	10 ,,
Hot water	20 ounces.

Mix twenty-four hours before use. Neutralise with chalk or whitening (carbonate of lime).

The name of M. Le Gray must be mentioned as the originator of the lime and gold toning bath; although the original formulæ differ somewhat from the one now used the results are identical. The original formulæ consisted firstly in washing away a portion of the free silver by soaking the proofs for a few minutes in two changes of water, then submitting them to the action of an auriferous bath, composed of—

Terchloride of gold one-per-cent. solution	1 part.
Hypochloride of lime (white powder)	3 parts.
Distilled water	1,000 ,,

The action was complete in ten to fifteen minutes, when the prints required washing in two changes of water to free them from the chloride of lime remaining in the fibres previous to fixing in one to six of hypo. If the tone were satisfactory at the expiration of fifteen minutes the ordinary washing could be proceeded with; if not the proofs were submitted to a final bath composed of—

Gold terchloride	2 parts.
Hypo.	200 ,,
Distilled water	1,200 ,,

M. Le Gray says:—"The proof ought not to be left in this bath less than fifteen minutes, as that is the minimum time necessary to ensure the permanency of the picture; but it may be allowed to remain in it for as much longer as is requisite for obtaining the desired tone." Efficient washing in warm and cold waters completed the operation. Should any of our provincial members experience a difficulty in obtaining calcium chloride for their experiments, it can be easily made by causing dilute 7 : 3 hydrochloric acid to react on common whitening, and when neutral filter and set aside for the crystals to separate out.

Experiment 6.—The uranium and gold toning bath has many friends. The tones are said to be richer and to economise gold, whilst it is very easy to work. I am unable to give the author's name, but I can present a formula which has worked well in my hands. After washing away the free silver tone in the following mixture:—

No. I.

One-grain acid solution of gold terchloride	1 ounce.
Water	7 ounces.

Neutralise with sufficient of a twenty-per-cent. solution of sodium carb. (Na_2HCo_3).

No. II.

Three-grain solution of uranium nitrate	1 ounce.
Water	7 ounces.

Neutralise as in No. 1. Warm each to 70° Fahr., and mix. The bath is then ready for use. It can be used repeatedly if desired by acidifying with citric acid and neutralising before use; but nothing is gained by using it a second time.

There are methods of toning which resemble more or less those which have occupied our attention tonight; among them may be mentioned the tungstate bath, likewise citrate of soda. The vermilion bath, too, might afford sufficient matter alone for a lecturette. If some one experienced with it could be induced to bring it before us I am sure it would prove interesting.

My experience with toning is so limited that I find I have become exhausted, so (*nem. dis.*) must conclude; but before doing so allow me to express a desire that one of our able members will, when opportunity occurs, gather up my disjointed remarks and shape them into a paper, which may also include the processes I have omitted. W. M. Ashman.

Our Editorial Table.

Blanchard's Durable Sensitised Paper.

We have had an opportunity of trying the new durable sensitised paper prepared by Mr. Valentine Blanchard, whose name has been for many years intimately connected with the subject of the preservation of albumenised paper after sensitising. In richness of tone and brilliancy of surface it is unsurpassed by any in the market, while the toning operation is entirely free from those difficulties so frequently found in connection with ready-sensitised papers. But the feature which will specially recommend it more particularly at this time of the year is its wonderful rapidity in printing. We have tested it against some of the leading papers in the market and find it decidedly the quickest of all—an important quality in winter.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

At the technical meeting of this Society, held on Tuesday, the 28th inst., the proceedings consisted of the display and explanation by the several exhibitors of the apparatus upon the tables in the Exhibition now being held at the Society's rooms in Pall Mall,—the chair being occupied by Mr. Payne Jennings.

The first exhibitor called upon was Mr. Watson, who explained at some length the characteristics of the work shown by his firm.

Mr. C. Sands showed a camera, in which there was an intermediate frame or "cradle" between the base and the upright parts. He also exhibited a shutter in which the moving plate worked up and down, so as to give longer exposure to the foreground than to the sky.

Mr. Samuels showed the camera exhibited last year with some alterations, particularly in the front. The back had been found to work well continuously, and would, he thought, be advantageously employed in studio work, where it was frequently desirable to expose another plate, or several fresh plates, rapidly after the first one. The swing front with which it was now fitted did away with the necessity for a swing back.

A Member inquired whether a swing front would answer the same purpose as a swing back.

Mr. Samuels replied that Mr. Debenham had some time since demonstrated that the effect was identical.

The Chairman observed that, no doubt, the most valuable feature of this camera was the means supplied of rapidly changing the plate.

Mr. Herbert S. Starnes showed a combined camera and changing-box. There was no dark slide, but the ground glass was laid against a frame about the middle of the camera box. The back of the box and a sort of sleeve behind it served to darken the ground glass, and enabled the operator to dispense with a head cloth. When the focussing was accomplished the hand was inserted by the sleeve before mentioned, and the ground glass removed. Its place was then taken by a plate lifted from one of two receptacles or "wells" found in the bottom of the box. After exposure the plate was removed to the second well. Both of these receptacles were kept covered by lids, except during the time of actually changing the plate. As the plate was pressed against the same frame as the ground glass, perfection of registry was ensured.

The Chairman considered the latter point an important one. Of the cameras sold he believed that one half would be found imperfect in respect of registry, and this was very important when using quick-acting lenses.

Mr. A. Cowan inquired whether there was any protection for the films as the plates lay upon one another in the wells.

Mr. Starnes replied that paper could be laid between if desired, but he found that by cleaning the backs of the plates they did not injure one another. The lens was adjusted to focus by being set in a tube carrying a screw thread. On turning the tube round the lens was little advanced or retired, and no light could pass between the tube and jacket.

The Chairman said there was no doubt it was very important to prevent stray light from entering the camera by any means. He never trusted to any camera without having a black cloth over everything.

Mr. S. W. Rouch next showed a very portable camera and shutter.

Mr. G. Shew exhibited a camera similar to that shown the previous year, but in the present model instead of a long rack there was an arrangement for clamping the back at different parts of the tail-board, when a short rack-and-pinion would give the more precise focussing. The tail-board was long, but part of it could be turned down out of the way when length was not required. He also showed an adapter for use with a small camera, rendering it capable of taking slides of a larger size.

The Chairman considered this exhibit to be very useful. Many people, after having settled upon the size for their camera, found an occasional requirement for a larger-sized plate, and regretted the inability to produce it.

Messrs. Marion and Co.'s representative then showed a spring shutter and a washing trough for negatives. The last-named appliance was furnished with a syphon of large bore, so that the trough was rapidly emptied as soon as filled.

A MEMBER inquired whether this style would not be liable to cause the upper part of the plates to be weakened by exposure to the air whilst containing a weak solution of hypo. He thought that the plates should be entirely covered for some appreciable time.

Mr. S. D. MCKELLEN said that his experience of a trough of this kind was not favourable. He preferred a box having grooving along the bottom and up one side. It would then suffice for plates of a given or any smaller dimension.

Messrs. Marion and Co.'s print-washing machine was next shown. The prints being contained in an inner frame of perforated zinc, there was no tendency to their running towards and choking the run-off pipe. Streams of water kept the prints revolving whilst the machine was in use.

Mr. W. ENGLAND considered that zinc was an improper material to use, and that the inner vessel might advantageously be made of gutta-percha.

Mr. J. WERGE said that zinc had an injurious effect upon a silver print.

Messrs. Marion and Co. also exhibited a miniature camera for use by those who would not be burdened with a larger size.

Mr. J. CADETT showed a shutter which was an improvement upon those he had previously exhibited, inasmuch that there were means of adjustment by which it could be used with a slow exposure of any length desired, or with a very rapid adjustable exposure up to one hundredth of a second or less.

Mr. MCKELLEN exhibited a camera which combined several points of novelty and utility. The camera was for 15×12 plates, and opened to about thirty inches, but when closed was only about three inches thick. The stand was fixed to a large mahogany flap—a base which permitted of the camera being rotated or fixed in any position. The back and front were easily and rapidly raised into place, and the front was fitted with a rotating inner front in which the flange was placed excentrically. This arrangement permitted of using the lens on one or other side of the field and of acting as a high rising front.

Mr. L. WARNERKE showed a combined camera and changing-box constructed by Professor Ezurtchewsky, of Moscow. The camera was of stereoscopic size, and when closed contained the lenses and was complete. The plates were kept in a receptacle below the camera proper, and were brought by a rackwork one by one under the groove in which they were to be exposed, and, by another rack-and-pinion, were raised into the groove ready for exposure.

Mr. W. E. DEBENHAM was pleased to see any indication of a return to favour of the stereoscopic form of photograph.

The CHAIRMAN concurred in this feeling.

Mr. WARNERKE also showed tablets covered with phosphorescent material for giving definite exposures to transparencies upon gelatino-bromide plates.

A shutter, by Mr. THOMAS FURNELL, was then shown, and this was followed by a dark slide with changing frames, by Mr. A. G. HOPKINS. In this arrangement a thin dark slide is brought over an opening in the camera back, and the plate contained in an inner frame is pushed by a pin down into its place. After exposure the pin is drawn up, bringing the plate and inner frame back again into the slide.

Mr. HART showed a shutter of Belgian construction. This will be found described in the report of the London and Provincial Photographic Association, before which it was exhibited some months back.

A vote of thanks to the exhibitors closed the meeting.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Association, held on Thursday, the 23rd instant, the chair was occupied by Mr. J. Traill Taylor.

The lecturette *On Toning*, which had been postponed from the second Tuesday in the month on account of Mr. W. M. Ashman's indisposition, was on this occasion delivered by that gentleman [see page 698], and illustrated by demonstrations of the processes described.

At the conclusion of the lecture, in answer to a question,

Mr. ASHMAN said that he had toned many thousands of prints in the bath of gold and uranium, and that he considered it a very nice bath.

Mr. A. L. HENDERSON said that the lecturer had stated that they were indebted to Mr. Waterhouse for the introduction of the alkaline method of good toning, but he (Mr. Henderson) considered that that introduction was a misfortune to photography, and that ordinary sulphur-toned prints were more permanent than those produced by the alkaline gold toning method. Sulphide of silver was a very stable substance. With reference to the use of nitrate of uranium: he had found it advantageous to employ it in the silver sensitising bath. Prints that were made upon paper thus prepared would appear somewhat yellow in the lights before fixing, but in the hypo. this yellowness entirely disappeared.

Mr. W. E. DEBENHAM said he believed that the view generally held that sulphur-toned prints were very unstable was perfectly sound. In confirmation of this he mentioned that many years previously he had some d'oyleys which were made of fine white jean, and had drawings upon them made with marking ink. This marking ink was a silver compound from which the silver was reduced in a black or dark brown condition by the application of heat. In some cases, where the drawings had appeared too brown in colour, he had subjected them for a short time to the fumes from sulphide of ammonium. This changed the colour to a good black, but in a short time the fine lines in the drawings thus treated faded to a dirty-yellow colour—much like that of a faded photograph. With regard to what had been said and illustrated of platinum toning, he observed that the print toned before them by that method was exceedingly weak and poor, and this was not to be wondered at, as the toning solution was acid with hydrochloric acid. He thought he remembered having seen it recommended to neutralise the hydrochloric acid in the platinum solution and then faintly acidify with nitric acid, but there might be a better method. The borax and gold bath, which had been referred to, he had found very satisfactory, and was what he was in the habit of using.

The CHAIRMAN remarked that he had some transparencies toned with sulphur that had not faded.

Mr. DEBENHAM inquired whether they were protected by varnish.

The CHAIRMAN replied that they were.

Mr. HENDERSON said that if a so-called faded print were immersed in a solution of platinum and iodine the faint parts would be strengthened. At first sight the print looked useless, as the iodine combined with the starch in the paper to make a dark compound all over the picture, but after a time this was got rid of.

Mr. W. K. BURTON stated that, as he had always understood the alkaline gold toning process, there was formed a compound which was the toning agent: but in a work on silver printing, recently published by Captain Abney and Mr. H. P. Robinson, it was stated that the chloride of gold was the toning agent, and would act more quickly without the addition of an alkali, but that the alkali acted as a restrainer. He would like to hear the views of members on the point.

Mr. DEBENHAM believed that the function of the alkali was not that of a mere restrainer, but that a compound was formed by it and the gold which was a better and more active toning agent than the chloride of gold itself. He had recently found that a bath which had gold added to it without additional alkali (borax) did not work so well, and, he thought, not so quickly, as after the addition of more borax.

Mr. BURTON'S experience had been similar to that of Mr. Debenham, and he held the same view as to the function of the alkali. With regard to platinum toning he did not know whether it was generally known that in one of the commercial lists of chemicals there was a platinum salt, which he believed was sodic-chloride of platinum. It was sold to be used either by itself in lieu of gold in an alkaline toning bath, in which case strong black tones were given, or it might be mixed with gold and intermediate colours obtained.

Mr. HENDERSON did not think that toning was a substituting but a gilding process.

Mr. W. H. PRESTWICH used only gold and water for toning with, and no alkali at all. He made a very weak solution and used it next day.

Mr. DEBENHAM observed that London water contained an appreciable quantity of carbonate of lime. If chloride of gold in a very small quantity were added to it there might be sufficient lime to form a proper toning compound. That there was an action of this kind in Mr. Prestwich's case was indicated by the fact that he mixed for use the day before. Mere dilution did not require time, but chemical action did.

Mr. A. COWAN suggested that Mr. Prestwich should make up a bath with distilled water and see how that would act.

In answer to a question as to the preparation of ready-sensitised paper,

Mr. L. WARNERKE said that he had employed successfully a formula published by Captain Abney. After floating on the silver bath the paper was transferred to pure water to remove the free nitrate, and then floated upon a ten-per-cent. solution of nitrite of potassium.

Mr. BURTON had found that this method did not yield such rich prints as those produced in the ordinary way.

Mr. WARNERKE agreed that with ordinary albumen paper it did not give such rich prints. He used double albumenised paper with this method.

Mr. HENDERSON said that upon the occasion of the last meeting, when Mr. Ball spoke of the difference that existed between different sensitometers, he had been asked to send them to the meeting for inspection. He had done so, and a great difference was perceptible to the eye. On plates of the same make one registered 20 and the other 15.

The further discussion of Mr. Ashman's paper was adjourned until the next meeting.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

THIS Association met on the 3rd October,—Professor H. W. Vogel in the chair. Several new members having been admitted,

The CHAIRMAN showed a pamphlet, issued from the Royal Lithographic Institute, at Stockholm, containing some reproductions of copperplates and drawings and some views from nature, in which the half-tones were broken up by a network of lines; also some reproductions of drawings on granulated paper. The Chairman also presented the Society with a copy of an illustrated publication issued to celebrate the opening of the new Technical High School at Charlottenburg, Berlin.

Herr GAILLARD called attention to certain coloured lichtdrucks to be seen in many art shops, and stated that the method by which they were produced was generally something as follows:—A black photolithograph is first prepared, and as many prints made from it upon toned paper as there are plates required for the coloured print. Each of these prints is then retouched so as to remove all the parts except those required for a single colour, so that each print may be considered to represent a single colour. Each of these retouched prints is again photographed, and from the negative so obtained the lichtdruck printing plates for the respective colours are prepared. When circumstances permit all the photolithographs are fixed side by side upon a board, and all photographed together.

Herr QUIDDE remarked that Herr Gaillard's own coloured lichtdrucks were considered very good, and, in his own opinion, there did not exist a better process than Herr Gaillard's.

Herr GAILLARD replied that he had given up working his process, as he could not make it pay. The public did not seem to care for coloured pictures, nor to be able to distinguish between good and bad ones, and, consequently, would not pay for the good ones.

The CHAIRMAN showed a number of black heliotypes and of coloured pictures, produced by Herren Angerer and Göschl, Vienna, by their own process. These were examined by Herr Gaillard, who pronounced them excellent.

Herr SACHS exhibited a collection of instantaneous views, principally street scenes, which he had taken in Spain.

Herr VEIT showed a pasteboard dark slide, which was so far an improvement upon Herr Martini's that it was light-tight.

Herr HALWAS exhibited a photograph of a *danseuse* swinging in the air. She was suspended by a single wire, while the tip of the toe of one foot only rested upon a horizontal wire.

The CHAIRMAN showed the second number of Herr Czermack's work on *Meteorites*, which is illustrated by some splendid microphotographs by Herr Grimm, of Offenbach.

Herr CHRISTMANN presented a number of *Harper's Weekly*, containing a humorous illustration entitled "A day in the life of a photographic amateur."

Herren ANGERER and GÖSCHL spoke very favourably of the results of their experiments with azaline-stained plates.

Herr HABERLAND, referring to the blue intensification, said that if the plate were washed long enough with water the blue colour would disappear, and with it all intensification.

The CHAIRMAN explained by saying that apparently this intensification was produced by the formation of soluble Berlin blue, a substance which has long been known to chemists.

Herr QUIDDE called attention to a cement or mountant called "alligin." He thought it particularly suitable for household use on account of the ease with which it could be used. It did not, like glue or gelatine, require to be warmed, and it had a much greater adhesive power than gum arabic starch, and kept very much longer than the latter.

The CHAIRMAN found that a coating of mould was apt to form on the top of the alligin. It was, however, very easily removed and did no further harm, but it would be very apt to make people mistrust it.

Herr QUIDDE had a sample in his possession which he had opened in the beginning of July, and which he had, therefore, possessed for three months; but as yet it had shown no tendency to become mouldy—perhaps because he kept it in a well-closed bottle.

Herr HABERLAND remarked that both the hyposulphite of soda bath and the alum bath he used for gelatine plates became brown after being a short time in use, and he inquired the reason.

The general opinion was that it was caused by the developer being imperfectly washed off.

Herr HALWAS had remarked that when he laid a plate immediately after development, without being washed, into the alum bath and let it lie there the plate was rendered useless by flame-shaped spots; but if the alum bath were kept in motion this phenomenon did not occur.

Herr KUNZE sought the cause of this phenomenon, which he also had observed, in an unequal further development of the plate, produced by some developer still adhering to the plate and being acted upon by the alum bath. If the bath be left at rest this developer does not distribute itself equally in the alum; consequently the subsequent development only takes place in patches, while these are prevented from forming by keeping the bath in motion.

Herr ROLOFF did not use alum at all in the case of plates which showed no direct tendency to crapiness or frilling or to dissolving off.

Herr SACHS recommended that all plates should be laid for ten minutes or so in an alum bath; that contributed to the permanency of the plate by destroying the last remaining trace of hyposulphite and removing any yellow fog, while at the same time imparting a brown tone to the plate, in consequence of which it would furnish more brilliant copies. In the case of plates which were readily dissolved off, such as those intended to be stripped off, he advised their being placed in an alcoholic solution of alum.

Correspondence.

PHOTOGRAPHS ON CANVAS.

To the EDITORS.

GENTLEMEN,—There can be no doubt that, by the method described in last week's Journal, photographs can be transferred to canvas, and probably the process would give results which, so far as *appearance* goes, would perhaps be better than any other. But the picture on the canvas is required for artistic purposes—to be covered with oil colours. The substratum being of gelatine, "moderately strong," no worse method could be proposed.

If artists would give their experience I think we should hear that all prints on canvas having gelatine as a basis are not to be relied on—that, sooner or later, the picture will crack, and, not improbably, may leave the canvas in parts.—I am, yours, &c., A. BROTHERS.

Manchester, October 28, 1884.

DEVELOPING FORMULÆ.

To the EDITORS.

GENTLEMEN,—A continuation of my experiments with the hydrokinone developer has induced me to substitute one drop of pure strong nitric acid for the citric acid; then only twenty minims of liquid potassium are necessary, with the most satisfactory results. The hydrokinone appears to keep well in solution. I think one grain to the drachm of soft or distilled water will be found a convenient solution. It ought to be filtered then with ten drops of nitric acid made up to 100 minims with water. You have all your solutions convenient, and no weighing every time. I think anyone trying this developer now will be perfectly satisfied with it.

I find many of my negatives that were strengthened some year and more since are going, and I hope and believe that with this developer "strengthening" is a thing of the past. I am trying a modification of the old fixer, viz.:—

Cyanide of potassium	300 grains.
Citric acid	100 ,,
Water	20 ounces.
Methylated spirit	5 ,,

I have not tried it sufficiently yet. I think it promises a more brilliant picture, but will not bear washing after fixing and before drying.

I think it would be worth while to try the result of substituting pyro. for hydrokinone, although I do not anticipate so good a result. As I said in my former letter, hydrokinone appears to me to give any amount of density without sacrificing the high lights.

I also tried a mixture of 240 grains of cyanide of potassium and twenty ounces of saturated solution of alum; but the result, after leaving it for the night, was a straw-coloured liquid with a colloid deposit, which filtered out beautifully. Although, however, smelling strongly of cyanide, the filtrate was utterly powerless as a solvent of the chloride. The other fixer gave a brown tone to the negative.—I am, yours, &c., W. T. F. M. INGALL.

Greenhithe, Kent, October 27, 1884.

THE TRICYCLE AND PHOTOGRAPHY.

To the EDITORS.

GENTLEMEN,—Having seen some correspondence going on in the Journal respecting tricycles for photographers, will you allow me to introduce to your notice a photograph of a tricycle which has been specially designed for touring photographers by a local maker in Exeter, and which I find very convenient?

The tricycle is named "The Photographer." It is narrow and light, will pass through an ordinary door without any alteration, or can be wheeled up a flight of steps. It will go through a very narrow gate and allow me to ride it into a field, where I can get the best view, instead of leaving it in the road.

The front bone is extra long, and quite straight for the convenience of strapping on the tripod. The camera is fixed underneath the rider on a neat bracket, padded with rubber. The camera I carry is a 12×10 with two double dark slides. The weight of the camera and slides balances the rider, thus causing ease and comfort in riding.

The extra length of the straight front bone, and the weight of the camera and slides balancing the rider, causes the machine to run with less vibration than usual. The tricycle is the design of Mr. E. Monkhouse, of Exeter, assisted by practical photographers.—I am, yours, &c.,

October 27, 1884. BROMIDE.

MISUSE OF THE ROYAL ARMS.

To the EDITORS.

GENTLEMEN,—In regard to my proceedings against Messrs. A. and G. Taylor respecting the above, permit me to remark that when the Patent and Designs' Act, 1883, came into operation I felt confident that this firm were never entitled to use the name of Her Majesty in connection with their trade, or had any authority whatever for displaying the royal arms, either in front of their premises or on stationery which they issued to their numerous canvassers. Upon application to the Lord Chamberlain's Office, and otherwise, I found such to be the case, and hence the proceedings which I found necessary for me to prosecute.

In all cases where an Act of Parliament imposes a penalty for its infringement it has been the rule that no officer of the Crown should prosecute, but the vindication of the Act has been left to one of the public, his reward being one-half the fine inflicted, and I believe also the costs of his proceedings being paid by the offender, except in cases where it is called a test case or first proceedings under the Act. Now, in the case of A. and G. Taylor it has been a very aggravated one, as their boast has been that they are the largest photographers in the world, and in a recent pamphlet issued by them they assert that they employ upwards of 800 artists, operators, &c.

Therefore, if that be the fact by their own showing, it stands to reason that this position has been mainly gained by their assumption of being photographers to Her Majesty, the Prince and Princess of Wales, &c. &c., which has been proved to be untrue, though at the same time it has had a great effect with the public, and has enabled them to monopolise a large portion of the photographic business of the country to the detriment of other photographers, their process of obtaining trade being so peculiarly exhaustive as to stop nearly every avenue of business against others, not only in London and its suburbs, but in all provincial towns throughout the country, where you find their satellites actively at work in every railway station, market place, post-office, police station, and all descriptions of workshops. Not only that, but they also pursue a house-to-house canvass in every neighbourhood where it is likely to pay, and with their representations above mentioned manage to intercept business in all directions that would otherwise be legitimately shared by other photographers.

For further information I have to refer to proceedings already reported, in which there have been four adjournments, and in which they had engaged the services of the most popular counsel of the day, who only succeeded in reducing the penalty and obtaining a nominal amount of costs by representing that they were totally innocent of transgressing the law, and had made every reparation in their power by removing the royal arms, &c., from all their premises.

In conclusion: I beg to say that I shall watch this firm very zealously, and if I find them breaking their parole they shall be again called to book by—Yours, &c., WM. TURNER.

140, *Upper Kennington-lane, London, E.C., October* 22, 1884.

To the EDITORS.

GENTLEMEN,—The decision given in the above case is evidently conclusive that the prosecution was a righteous one, There is no denying the fact that work has been obtained by virtue of the statements erroneously made by the defendants. It is also beyond contradiction that a *very serious injury* has been done and trade diverted from its legitimate channel by the defendants' mode of procedure. In fact, I thoroughly believe that the profession has been entirely revolutionised, and that the "club" system introduced by Messrs. Taylor has given a mortifying wound to the trade.

I hold that this case is a case for the profession generally, and it is they who, to my mind, should now come forward and bear the expenses incurred. To say that the prosecution was instituted for the sake of the moiety of the fine (*at most* £10) is out of the question. Who would undertake the anxiety of a lawsuit of this character for such a trifle? I propose, Messrs. Editors, that you start a subscription list; I am prepared with my 5s. I suggest that out of the fund thus raised you pay the law costs and other expenses incurred in this suit, and any surplus to be handed over to the "Photographers' Benevolent Fund"—I am, yours, &c.,

12, *Clapham-road, October* 23, 1884. GEORGE J. TEAR.

MEDAL AWARDS AT THE PHOTOGRAPHIC EXHIBITION.

To the EDITORS.

GENTLEMEN,—In the name of art and photography I am most desirous of knowing the merits of the three medal pictures—*Knuckle Down Tight*, *Small Studies*, and *Interior of St. John's Church, Malta*.

The first is an example of the lowest type of *genre* picture, in which two of the figures have moved, and indifferent technical work is exemplified. The *Small Studies* are indifferent in choice of subject, pose of figures, and technical execution. The *Interior*, with its halation and total disregard of perspective, is surely not equal to Mr. R. H. Lord's *Interior of New Archæological Museum, Cambridge*, with its perfect lines and even lighting of the sculpture—a most difficult task considering the newness and whiteness of the casts. I should feel much obliged if some one would point out how any of these even approach such artistic and perfect work as that of Messrs. Gale, Gibson, Horsey, Forsyth, and others.

Again: may I humbly ask where the science is in the three pictures for which scientific medals have been awarded—one purely a photomechanical process and the other two triumphs over technical difficulties? I fail to see that it is any more "scientific" (oh! misused word,) to photograph a streak of lightning than a breaking wave.

These are the things which send men away sadly from such places, cynically wondering when this rotten something in the state of Denmark will be righted.—I am, yours, &c., P. H. EMERSON, B.A.

October 25, 1884.

To the EDITORS.

GENTLEMEN,—The Rev. H. Victor Macdona, M.A., by the tone of his letter in your last issue, appears to have gone back to his parish in Cheshire after his special visit to the photographic exhibition with a great deal of "the dog in the manger" about him. He appears to envy several of the successful exhibitors their awards, and would lead one to suppose that the gentlemen who acted as judges knew nothing about photography; and the hanging committee——well, they ought to be executed, and, doubtless, the reverend gentleman would be pleased to act as executioner. It seems a great pity that there should be so many gentlemen to act in the capacity of judges, hanging committee, &c., when there appears to be one who is competent to undertake the whole of it. I would suggest that the Rev. Mr. Macdona be appointed next year to hang the exhibits and act solely as judge.

My *Sea Studies* seem to have specially called forth a most unwarrantable attack from the reverend gentleman, who says that "they bear all the distinct traces of very indifferent retouching." He will, perhaps, be astonished when I say there is *no retouching* either on the negatives or prints, the negatives scarcely requiring even ordinary spotting. I should say that the well-known gentlemen who acted as judges were quite capable of judging whether the work they were examining was either *elaborately* or *indifferently* retouched. If not, they certainly ought to have had the reverend amateur at their elbows to advise them.

I may mention that the Royal Cornwall Polytechnic Society awarded me their medal in August last for the same case of *Studies* that have received such attention from Mr. Macdona.—I am, yours, &c.,

Waterloo-square, Bognor, October 29, 1884. W. P. MARSH.

To the EDITORS.

GENTLEMEN,—In reference to the Rev. Mr. Macdona's remarks respecting Mr. W. P. Marsh's *Sea Study* negatives being elaborately retouched, I feel it but just to say that in consequence of having made transparencies from most of the plates exhibited by that gentleman I am in a position to state that they are not retouched.—I am, yours, &c., JOHN HARMER.

Wick, Littlehampton, October 29, 1884.

Notes and Queries.

GEORGE ADCOCK writes:—"Is there any objection to my counting seconds by means of a string suspended to the camera, a small weight being attached to its lower end to cause it to act as a pendulum? If you think well of the idea please inform me what length of string will be the most useful. Ought not a quick vibration to be preferred to one that is slow?" ——In reply: We have often adopted the method of counting seconds suggested by our correspondent. This was, however, in the times of slow plates and long exposures. A bit of string ten inches in length, with a pistol bullet attached to the end as a "bob," will vibrate in half-seconds with practical accuracy.

"OUGHT the eggs which are to be employed in the albumenising of paper to be fresh or stale?—ALPHA."—Well, this is a query to which we cannot give a "square" reply, because we know that some albumenisers—men of probity and experience—say one thing, while others—equally good and experienced men—say the other. Albumen which is *quite* fresh is not employed as a rule by the majority of albumenisers, who prefer keeping it for a period ranging from two to four or five days before using it for coating paper.

W. JOHNSTON inquires:—"1. Does it matter which side of the focussing-glass (matt or smooth) is outside the camera nearest the eye?—2. In using the photometer (direct to source of light) does this mean the instrument to be pointed to the sun or brightest part of the sky, or held pointing towards the view to be taken, as I find there is a considerable difference in effect from the two positions?"——In reply: 1. Cameras are invariably constructed so as to necessitate the ground surface being placed next to the lens.—2. Let the photometer be directed towards the light by which the view is illuminated.

THE REV. E. P. RIVERS writes:—"Some time ago you gave a description of the newly-invented balance thermometer of Messrs. Watson and Sons, of High Holborn. Can you say from actual knowledge whether it does all that was originally claimed on its behalf?"——In reply: The thermometer in question, having been improved since the date at which our article appeared, does rather more than we anticipated on its behalf; for it is so sensitive that the mere lighting of a candle, within a foot of the instrument, will cause it to register the change of temperature produced thereby by means of its indicating end, while as yet such change can only be imperfectly discerned on the register engraved on the tube itself. It is a most convenient instrument in a dark room or any other room.

"OBSERVING that you have published Mr. W. Ackland's process of collodio-albumen for transparency work, will you permit me to inquire in what respect, essential or non-essential, it differs from that which a few years ago was sold as a secret process by Mr. B. J. Edwards? And will you permit me further to inquire, in the event of the two being found to be practically similar, to which of these well-known gentlemen are we to consider ourselves indebted for the inception of this special development of the collodio-albumen process?—I am, yours, &c., THE GHOST OF TAUPENOT." ——To these queries we are somewhat unable to reply; but we were made aware of the Edwards method at a date long prior to that which the Ackland system was brought under our notice. Concerning the identity, or even similarity, of the two systems, it is not necessary that we should here speak, especially as Mr. Edwards has not *published* his, so we leave the matter for those interested.

PRINT-WASHING TROUGHS.—A correspondent writes to inquire if we can furnish him with the name of any London maker where the print-washing troughs recently described by us have been made, and, also, whether one eighteen inches in diameter would be suitable for washing three hundred *cartes*. We have communicated with the gentleman whose apparatus we saw in work, and he writes us that the apparatus was made fourteen years ago by a plumber and zinc-plate worker in London (Clerkenwell direction) to designs supplied, but that he cannot at present furnish any address. If, however, he be able to find the name he promises to send it, and in that case it shall be forwarded to our correspondent. We should advise that a trough twenty-four inches in diameter be used for so large a number as three hundred *carte-de-visite* prints. When prints are packed very closely in a limited quantity of water there is less chance of the rotating current passing over the surface of every individual print, and in print-washing the desideratum is that every print should be equally and well washed.

PERSIAN asks—"Can a glass positive be fitted into a locket, or even a finger ring?"——We reply: There is no reason why any difficulty should be experienced in doing so. Let us suppose that we have got an unvarnished (to take the worst case) positive on glass which has to be fitted into a small locket, and that the edge must be so perfectly cut as to show no chips or fractures. Having placed the "besil," or ring in which the glass is contained, upon the picture, draw with a needle point a line round it, scratching the photograph. Next cut the picture by means of a diamond, and with several cuts as near to the mark as possible. Then, by means of a pair of sharp and, by preference, new cutting-pliers, chip off the glass until the mark has been reached, and gradually encroach upon this until after repeated trials the portrait is found to enter inside of the frame. Seeing that the glass is usually finished with a squarely-ground bevel it is not possible to see the extreme edge of the portrait, and, as a consequence, minute defects in the margin will not be observed. A brush charged with black varnish should then be applied to the edge of the glass, the back having, of course, been also well coated with black. This method affords the perfection of mounting and fitting glass positives.

Exchange Column.

No charge is made for inserting these announcements; but in no case do we insert any article merely OFFERED FOR SALE, *that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a* NOM DE PLUME *be thought desirable), otherwise the notice will not appear.*

I will exchange a two-gallon still for a scenic background.—Address, J. GRIMSHAW, Dale-street, Haslingden.

I will give a good exchange or cash for a copy of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1880.—Address, B., 53, Cowgate, Dundee.

I will exchange a Ross's meniscus, three and a-half inches diameter, for Dallmeyer's wide-angle view lens or whole-plate.—Address, J. HILL, Malvern.

I will exchange Seavey's boat and background, cabinet lens, also a splendid *carte* lens, for large photographs or anything useful.—Address, J. W. D., Sand Pits Parade Studio, Birmingham.

I will exchange a Lerebours' half-plate portrait lens, with stops, in good condition, for violin and case, or anything useful.—Address, R. S. BONNALTO, The Factory, Kimberley, Notts.

I will exchange a Lancaster's enlarging lantern, also Marion's cabinet burnisher, for a Cadett's shutter and a good posing-chair.—Address, WILLIAM HALL, 34, Lansdowne-place, Lewes.

I will exchange *Picture-Frame Making*, by James Lukin, cloth binding, clean and perfect, for *Pictorial Effect in Photography*, by H. P. Robinson.—Address, OPAL, 31, New-street, Ashford, Kent.

I will exchange a *carte* lens, by Lerebours, with stops, in case, equal to new, for a posing-chair, backgrounds, or anything useful in photography.—Address, J. BARKER, 106, Chestergate, Macclesfield.

I will exchange a drying cupboard, made according to England's drawings, also a large sheet of plate glass—size 36 × 24 inches—for anything useful in photography.—Address, W. H. SEDGWICK, South View, Sedbergh, Yorkshire.

I will exchange a good *carte* lens, by Hermagis, which will take a small cabinet head, eight inches back focus, for a good artist's outfit, both oils and water-colours; if not both, oils preferred of good quality.—Address, C A., 21, St. Sidwell-street, Exeter.

Wanted, an $8\frac{1}{2} \times 6\frac{1}{2}$ or 10 × 8 portable camera with three double slides (must be light and in good condition), in exchange for pictures in frames (large variety to choose from), albums, frames, fancy goods, tobacconists' goods, &c.—Address, C. F. HEWITT, St. Mary's-street, Wallingford, Berks.

I will exchange a Voigtlander's *carte* lens, an oak studio camera-stand, an iron head-rest (both nearly new), a half-plate water-tight bath in polished pine case, and a 10 × 8 ditto in mahogany case. Wanted a 10 × 8 burnisher in good condition, four Victoria lenses, nine gems, or Ross's 10 × 8 wide-angle lens; difference adjusted.—Address, J. A. BELLINGER, photographer, Sidmouth, Devon.

An artist requiring photographic apparatus, which must be in good condition, is willing to paint a few oil-paintings (landscape), work-up enlargements, finish opals, &c., in oil or water-colour, in exchange for anything useful in photography, particularly a good rolling-machine, 10 × 8 dry-plate bellows-body camera, complete with lens and slides, also a half-plate and quarter-plate ditto, and studio and alpenstock stands; references exchanged.—Address, X. Y. Z., 19, Whitefriars-road, Hastings.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

NOTICE.—*Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a* NOM DE PLUME *as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.*

PHOTOGRAPH REGISTERED.—

W. L. Shrubsole, Davey-place, Norfolk.—*Photograph of Their Royal Highnesses the Prince and Princess of Wales and Shooting Party at Thornage, Norfolk.*

AJAX and A. B.—Write to the Secretary.

W. C.—There is no work published on the subject. Articles upon it will be found distributed through this and previous volumes.

BATH.—Write the titles neatly with black varnish on the negatives. You must write them backwards, as a matter of course.

GEO. SMITH.—Many thanks for a copy of the reply. We shall be very pleased to see the result of your trials if you will kindly forward them.

EDWARD NEVILLE.—By a six-per-cent. solution is meant a solution containing six per cent. of the salt—the bichromate of potash in your case.

T. P.—Your previous letter was not preserved. Kindly, therefore, repeat your query, and, if possible, send a plan of your proposed studio, and we will help you if possible.

H. ARNOLD BEMROSE.—In speaking of the novelty we did not infer that the thing had never been done before. There is an old adage—"There is nothing new under the sun."

W. W.—Try Messrs. Langton and Bicknells, 89, Newington Butts, S.E. They will perhaps supply you with a small quantity, as we surmise you do not require much. They, as a rule, only supply large quantities.

X. X. X.—See an article on *Photographing Interiors*, by Mr. H. Y. E. Coteswortlh, in the issue for May 16th of the current year. The same remarks apply equally well to the work you have in hand. We know of no such formula. Cold tones will be better than warm.

J. R. T.—It is not advisable to wash the prints in such very hot water as you suggest. You say that the hot water will not be used until "the prints have been well cleansed from the hypo." If the prints are well cleansed from the hypo., why the necessity of the hot water?

O. O. O.—Pure paraffine wax is far preferable to pitch for coating the insides of wooden dishes which are to contain silver solutions. If you cannot procure it in your village, Messrs. Hopkin and Williams will supply it. It is not nearly so expensive as you appear to imagine.

ROWLAND.—The results are very promising, and certainly should encourage you to continue your experiments. Try the effect of using the ink thinner than you are now doing, and do not be in a hurry with the different operations. Remember: "Rome was not built in a day."

W.—*Eau de javelle* is a very useful hyposulphite eliminator. The cause of the spots of which you complain is that you have printed from the negative before the whole of the hyposulphite of soda was removed from the film; hence the silver paper has acted upon it and produced the spottiness.

WM. NASH.—It is illegal for you to make a photographic copy of a Bank of England note, though it is often done. If you only make a reduced copy for use as a microscopic object, no doubt you will not be interfered with. Such copies are—or at one time were—to be purchased at most opticians'.

COUNTRYMAN.—The Exhibition of the Photographic Society of Great Britain is open daily from ten till dusk, and on Monday, Wednesday, and Saturday evenings from seven till ten. The charge for admission in the daytime is one shilling and in the evenings sixpence, members being admitted free.

ALF. B. HOWARD.—Blue glass was at one time employed for glazing photographic studios, though it was never really in much favour. White glass is now used almost universally. If you use white glass you can, of course, paint or stipple over with any tint desired, and clean it off at any time if not approved.

I. LIGONIER.—The "halo" is what is known as a flare spot from the lens. As yours is a single lens, the cure will be to alter the stop slightly from its present position. If you slide it gently backwards and forwards, while watching the effect upon the image on the ground glass, you will soon discover the best position so as to avoid it in future.

NOVICE A.—It is clear that one fault in your prints is that the silver bath is much too weak—probably not more than half the strength it should be. This is quite sufficient to account for the majority of your difficulties. The prints, we may mention, bear unmistakable evidence of slovenly manipulation, as shown by the finger marks on the backs and, in some instances, on the front. These are caused by the paper being touched with fingers contaminated with the hyposulphite of soda.

PHOTOGRAPHIC CLUB.—The forthcoming meeting on Wednesday next, November 5th, will be the annual general meeting of the Club.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—At the next meeting of this Society, to be held on Thursday, the 6th November, in the Hall of the Society of Arts, John-street, Adelphi, Mr. J. Traill Taylor will deliver a lecture *On Florida and its Orange Groves*, illustrated by numerous photographs shown as dissolving views by the lantern.

A PROPOSED AMENDMENT IN PHOTOGRAPHIC TERMINOLOGY.—Professor Vogel suggests that, instead of using so many different names for the photo-chemically-produced negatives for the typographic press or relief printing-press (such as phototypes, autotypes, and heliotypes), they should all be called *licht-hoch-druck* (which may be translated *photo-relief prints*), and that the processes intended for the copperplate press, such as heliography, heliogravure, and photogravure, should be called collectively *licht-tief-druck* (equal to light-deep prints or *photo-intaglio prints*). Henceforth he intends to use these terms, which are certainly more intelligible than those he wishes to supersede, as they convey a definite idea of the thing spoken of; but this effort in the right direction will, we fear—so strong is the force of habit and of vested rights in the various names—be as unsuccessful as a previous effort to introduce the word "photogram" for the photographic print, as "telegram" is for the message sent.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician,

For the Week ending October 29, 1884.

THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

Oct.	Barometer.	Wind.	WetBulb.	Dry Bulb.	Max. Solar Rad.	Max. Shade Tem.	Min. Tem.	Remarks.
23	30·01	SE	45	45	—	56	42	Foggy.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1279. Vol. XXXI.—NOVEMBER 7, 1884.

SULPHITE OF SODA IN THE DEVELOPER.

We have purposely refrained from replying to Mr. W. Hanson's remarks a fortnight ago until we should be in a position to speak from actual experiment on certain points mentioned by him. We are now in that position, and propose as briefly as possible to show in what manner we differ.

Mr. Hanson, it will be remembered, holds that sulphite of soda retards the development—a view which we ourselves attempted to controvert on the ground that sulphite of soda being itself capable of development can at anyrate not be a retarder, even though it be not an accelerator. However, Mr. Hanson says:—"But does it necessarily follow because an image can *slowly* be brought out by the aid of sulphite of soda that, therefore, it accelerates development when used in conjunction with one or other of the alkalies?" Then, again, he says:—"When things of an opposite character are joined together a medium product is generally the outcome of the union. Now, let sulphite of soda be allowed to represent extreme slowness in the operation of development, and ammonia (of the right strength) extreme quickness; then a combination of the two according to the above general rule ought to yield a mean ratio of speed, depending on the proportions on which they are mixed."

Now the suggestion contained in this quotation is, we venture to think, based upon an utter and grievous fallacy. In the first place, even accepting Mr. Hanson's own view of the respective functions of sulphite and of ammonia as representing *slowness* and *quickness* relatively, they are *not* "things of an opposite character," but rather represent different degrees of the *same* character. Again: It is to be borne in mind that sodium sulphite is not *substituted for* ammonia, but is *added to* it, and that, therefore, whatever developing energy the latter may possess, it must be augmented by whatever slight developing action the sulphite may exercise. On the other hand, to introduce an *ad absurdum* argument, we will suppose the developing energy of ammonia to be 10, while that of sulphite is 1 and its retarding action 6. Now, with the combined ammonia and sulphite developer the sum of the developing action would be represented by the equation $10 + 1 - 6 = 5$. If the ammonia be eliminated the developing action would be represented by $1 - 6 = -5$—a negative or retarding action. And yet, as we have shown, such an alleged *retarding* solution is really a *developer*, which is utterly absurd.

We are quite prepared to agree with Mr. Hanson that sulphite of soda is a less energetic developer than ammonia or other alkali, and that if it were substituted for an equivalent proportion of the ammonia solution of developing strength then the result would be, as he suggests, a mean between the two. But such is not the case; for, whether sulphite be used or not, the same quantity of alkali is (or should be) present in each ounce of developing solution, *plus* in the one case the sulphite.

Speaking of the theoretical result to be anticipated under his view of the question, Mr. Hanson further says:—"And in practice I find this to be so, for the more sulphite there is present in the developer the slower it works." Now, again, with one important modification, we should be willing to agree with Mr. Hanson, but that modification traverses the whole question. If for the word *sulphite* in the last quotation the word *sulphate* be substituted perfect accord would exist between us, and it is with the view of showing it is really sulphate which produces the result complained of by Mr. Hanson that our experiments were instituted.

We have always called attention to the importance of using pure, freshly-prepared sulphite, pointing out how in consequence of its rapid oxidation it is not to be trusted after having been long in stock. Let anyone interested in this question take the trouble to test a sample of sodium sulphite obtained through the ordinary commercial channels, and it will invariably be found to contain a considerable proportion of sulphate, the retarding action of which is so well known. Different samples will, of course, vary very considerably according to age and other conditions of storage; but it is practically impossible to find a sample that will not give the sulphate reaction.

In order to try the matter thoroughly sulphite of soda was specially prepared and used at once. A solution of pure carbonate of soda was divided into two parts. One half having been saturated with sulphurous acid, the two were mixed and very carefully neutralised, and evaporated until crystals began to form. In ten ounces of the saturated solution fifteen grains of pyro. were dissolved; a second solution was made by dissolving fifteen grains of pyro. in ten ounces of filtered rain water; and a third by using a solution of commercial sulphite to dissolve the fifteen grains of pyro. The same solutions of ammonia and bromide and of carbonate of soda were used throughout, and the developers employed were strictly identical, except in the presence or absence of sulphite and the substitution in some cases of soda for ammonia.

As the result of several experiments, we may say briefly that in no case, either with ammonia or soda, was there the slightest difference in the rapidity of action of the first two pyro. solutions; the third, made from commercial sulphite, developed a little more slowly, but produced an equal result if a slightly longer application were allowed. This was a fairly good sample of sulphite, giving bu little reaction of sulphate.

In conclusion: We are more than ever convinced that where the slowing action of sulphite is complained of it is the result, as we have before alleged, of the presence of sulphate in the sulphite of soda.

AN INCANDESCENT PLATINUM LIGHT.

That there is room for new and powerful modes of illumination in connection with the various departments of photographic practice will be admitted without hesitation by every photographer.

To those interested in this development of physical science we have some pleasure in directing attention to a gas lamp which was introduced to the notice of the London and Provincial Photographic Association at their meeting last week. It consists in the rendering of a thimble of platinum gauze incandescent by the heat emitted from the combustion of a mixture of a large proportion of atmospheric air, with a small proportion of carburetted hydrogen or common house gas.

Ever since the period when Bunsen made his investigations in this direction the heating properties of this admixture of gas and air have been well known, and their special value recognised and applied in various and wide-spread departments of social and manufacturing economics. Indeed, the "Bunsen burner," in one or other form modified to suit special requirements, is now to be met with in every workshop and almost every dwelling-house, its services ranging from the melting of metal down to boiling the domestic kettle.

When a flame of this mixed gas is made to impinge forcibly upon metal it invariably melts, unless it be one of the more refractory class, of which platinum forms a good example. This metal, when subjected to the intense heat of the mixed gases (relegating for the nonce the *rôle* of a gas to atmospheric air), becomes incandescent, and emits a powerful light. Difficulties of an apparently insuperable nature seemed to have hitherto attended the utilisation of this principle of lighting; but from the exhibition that was made at the society mentioned they would appear to have been at length quite overcome. During several years a lighting engineer, Mr. Lewis, has been engaged in the solution of the problem of an easy and satisfactory method of utilising the incandescent platinum principle, and he has now attained such progress as to have elicited the encomiums of *savants* like Professor Tyndall, who has eulogised it highly. At two of the principal railway stations in London it now competes with the electric and other systems of lighting; while at the meeting of the photographic society referred to attention has been directed to its possibilities in connection with photography.

The light, as adapted for either enlarging by the lantern or for the exhibition of transparencies upon a screen, is produced by a small conical thimble formed of platinum gauze about the diameter, at the base, of a lime cylinder, but tapering upward to a point. This forms a species of cap to a circular orifice, through which passes the mixture of gas and air. When this is ignited a poor, dull red colour is imparted to the platinum cap, proving the insufficiency of the flame to warm it up to even a respectable red heat. A glass chimney, when placed over the flame, does not sensibly increase the power of the light. But no sooner is the lower end of a tall chimney, made of thin and light metal, brought to rest upon the glass than in an instant, and as if by magic, a pale, lurid flame which was seen to play around the platinum thimble then disappears, and in about two seconds the gauze becomes incandescent, emitting a light so powerful as to dazzle the eye.

What the chimney does is to increase the draught of air, by which the heat becomes intensified almost instantaneously. The quantity of gas consumed by the small burner that was exhibited at the meeting in question is only three feet per hour, and we are unaware in what other way a light possessing an equal degree of intensity could be obtained by so small an expenditure of gas. Air is the chief factor in the production of this intense illumination, and *it* costs nothing.

In the course of a brief description of the Lewis light, the gentleman by whom it was introduced spoke of an ingenious method by which the necessary increase of air was obtained without the use of either a blower or a tall chimney. Mr. Lewis, it appears, found that if the gas could be placed under an increased degree of pressure, several strong air currents could be induced by the agency of certain short pieces of brass tube, which acted the part of conduits, and by which sufficient air could be supplied to the flame to impart all the heating power necessary. This is one method by which the intensity of the heat can be augmented. But as it involves the employment of either a bag or some other analogous means for increasing the emissive force of the gas, it may not eventually prove so popular in the case of lantern illumination as other and simpler methods.

The best substitute for the long chimney—in itself neither cumbrous to carry nor difficult to manipulate—would seem to consist of a small blower or fan driven by a light piece of clockwork, and by which a gentle current of air could be made to ascend through the bottom of the burner; but whatever system, eventually, be found to possess the balance of advantages in regard to purposes involving extreme portability (such as the application of the light to the lantern), it is satisfactory to know that, by peculiarities in the construction of the burner itself not hitherto introduced, the problem of applying common gas to the production of a powerful and intense light is undoubtedly solved. Owing to its small volume the Lewis incandescent light will prove useful for producing sharp enlargements, this being in accordance with optical laws which we need not here explain, contenting ourselves with reiterating the adage—"A small flame gives a sharp image." We shall watch with interest the further development of this light.

REVERSED NEGATIVES.

Now that the different processes in which reversed negatives are essential—such as in the various photomechanical processes, the carbon process by single transfer, and numerous other processes based upon bichromated gelatine—are being worked still more extensively than ever, it becomes an important question to determine which is the best method for their production.

The Photographic Club have considered the subject of sufficient importance to devote an evening to its discussion, and this took place last week. Various plans were advocated by different members and duly discussed, and the weak as well as the strong points of each were brought prominently forward. It would be quite impossible in the space of a single article to give even a brief outline of all the different methods there are for producing reversed negatives. It is almost superfluous to explain that by the term "reversed negative" one is meant which, if it be printed in the usual manner, will yield an impression that is reversed as regards the left and the right.

The methods of making reversed negatives may be classed under four heads:—First, the plan of producing a negative direct from a negative without the intervention of a transparency; second, by removing the film from the glass so that it may be printed from the reverse side; third, the reproduction of the negative in the camera from a transparency; fourth, taking the negative reversed in the first instance.

Under the first head comes the "nitric acid" process, in which the positive image—resulting from printing from a negative on a collodio-bromide plate and developing by the alkaline method—is dissolved out with nitric acid. Then, after washing and subsequent exposure to light, it is again treated with the alkaline developer, when a negative results. Again: there is the "dusting on" process. This, as most of our readers are aware, consists of coating a glass plate with bichromated gum, dextrine, or analogous substances, and, after exposure under a negative, dusting over with plumbago or other powder in a fine state of division, which then adheres to certain parts of the film in proportion as they have been protected from the action of the light.

Some few years back Mr. W. Brooks worked out a process of producing reversed negatives. His method is somewhat similar to the nitric acid one, except that in place of the nitric acid a solution of iodine is employed to convert the image into iodide of silver, which is unacted upon in the second development. The advantage of Mr. Brooks's process over the nitric acid one is that it is applicable to gelatine plates as well as collodion. About the time that Mr. Brooks introduced his process Mr. Thomas Bolas, F.C.S., devised one for attaining the same end. This consisted of treating an ordinary gelatine plate with the bichromate of potash, which, after drying, is exposed under a negative. When developed in the usual way with the alkaline developer a negative image is brought out instead of a positive.

None of these methods, however, are employed to any extent in practice. The nitric acid plan is objectionable principally on account of the fumes evolved, and also because considerable experience is necessary to obtain success under all conditions. The dusting-on method, especially for large sizes, is somewhat difficult to work, inasmuch as it is dependent upon the hygroscopic conditions of the film, and these are not easy to control in our variable climate. Although we have obtained excellent results, both by the process of Mr. Brooks and that of Mr. Bolas, we believe neither of them have really been fairly tried on a commercial scale.

We will now consider the second system—that of removing the film from the glass. After the negative has been taken in the ordinary manner, a sheet of gelatine—such as that employed for *bon-bons*, or for glazing prints—is softened in water, then gently squeegeed down upon the film, and now allowed to dry. When dry it is easily detached from the glass, which, by the way, should previously have been treated with French chalk. In place of employing sheet gelatine, some operators prefer to place the negative on a levelling-stand and pour on a solution of that material. This is then allowed to set and dry, when the film can be removed, as in the previous case. Instead of using gelatine at all, the plate may be coated alternately with india-rubber solution and collodion until a film of sufficient thickness is obtained, when it is stripped from the glass.

Both these methods are extensively employed in practice, but there is no disguising the fact that they are attended with some inconveniences, namely, that the gelatine films are liable to be influenced by moisture—a serious evil when the subject happens to be copied to scale. Although the compound film of india-rubber and collodion is free from this defect, unfortunately it is sometimes found to become exceedingly brittle after keeping for a few years. Moreover, negatives which have been varnished are not so easily stripped. It is true the varnish may be dissolved off, and then, by treating the film with dilute acetic or other acid before the gelatine or india-rubber is applied, the stripping may be accomplished, but only at considerable risk to the negative, except it be done by a very skilful hand.

We now come to the method of reproducing the negative in the camera from a transparency. This plan, like the previous one, is extensively utilised, especially when varnished or stock negatives have to be dealt with. The weak part of this plan is that, unless considerable skill be exercised in the production of the transparency, there may be a great loss of delicacy in the reproduction. Furthermore: if the optical appliances are not of the most perfect description there must be a sacrifice of definition. But, as a set-off to this, there is the great advantage that the original negative is preserved intact for other purposes, when perhaps a reversed one would prove worthless.

We have now the last of the four systems enumerated above to consider, namely, that in which the negative is taken reversed in the first instance. There are two methods of accomplishing this. The first is that of making the exposure through the glass supporting the film; that is, placing the plate in the dark slide reversed, so that the glass side is next the lens instead of the film. If this plan were to be adopted it is manifest that any imperfections in, or scratches upon, the glass itself must be reproduced upon the image. But this is not all, for it is found in practice, even if the glass be perfect, that the image is never so sharp and crisp as when it is impressed upon that side of the film to which the developer is applied. The second method of taking the reversed negative direct is that of placing a prism, or a mirror at an angle of 45°, in front of the lens—not necessarily in front, be it understood, for it will answer equally as well if placed behind; indeed, there are some advantages to be gained by its occupying this position.

During the discussion at the Club it was suggested that the mirror or prism would absorb a considerable amount of light, and, consequently, entail a greatly prolonged exposure. But it was pointed out by those who had considerable experience in working with the mirror that such was not the case, provided the mirror was kept bright. It was also elicited that a mirror, with care and an occasional polish with rouge, would continue in good condition for a year or two without requiring to be re-silvered.

As the result of the discussion the general impression appeared to be that the best methods of obtaining reversed negatives are those now almost universally employed commercially, namely, that of removing the film from the glass as a pellicular negative, and that of taking the negative direct with the aid of a prism or mirror. For the larger sizes it was thought that the latter method is to be preferred to the former.

THE TREATMENT OF FRAMED PICTURES.

The unfortunate fact that photographs were once very fugitive has been a perpetual stumbling-block and a continual source of trouble, annoyance, and anxiety to the conscientious photographer who, desirous that nothing deserving the epithet of ephemeral shall issue from his studio, puts himself to considerable trouble in overlooking the carrying out of all desirable precautions in his silver printing, and, wherever possible, puts that entirely aside and works in carbon or platinotype. Let him be ever so careful, and his assistants ever so trustworthy in following his instructions, he is liable at any moment, whenever some particular piece of outside carelessness happens to his pictures, to have them brought to him and their fading away pointed out. True it is that a certain portion of the public are now actually aware that photography is as capable as line engraving of turning out permanent work; yet it is not more than three or four years since the *Athenæum* itself, in one of its critiques, deplored the necessary fugitiveness attaching to all photography, and utterly declined to notice a communication which one of our contributors forwarded to it, pointing out that there were many mechanical printing processes in which the pictures were formed in printing ink alone.

One gentleman informed us that he intended to place upon the back of every framed picture he sent out a notification to the effect that it would be undesirable to boil, bake, or roast the enclosed photograph, as he would not then be answerable for the consequences; for he assured us that pictures often received treatment equivalent to this.

There came within our own notice, some little time since, an instance of something very similar. The lady of a house, which was in the throes of the usual "spring fever," passed over some of her less valuable pictures to one of her domestic "helps" to dust and clean. The said "help," being vigorous and thorough, placed one end of the frame in her bucket of soap and water and conscientiously laved the whole frame and glass with her washleather; and then, turning the frame upside down, repeated the operation. Fortunately, for the photographer's reputation, the whole transaction was noted at once, as, otherwise, we feel no doubt the changed appearance presented would have been put down to "those fady photographs." When, again, the gilt frame of a photograph can be subjected, as we have seen, to the tender mercies of a nail-brush and soft-soap to remove fly-spots, what possible indignity can be imagined to which the photograph itself would not be subjected?

These are examples of crass ignorance; but what shall be said of the client—familiar, we scarcely doubt, to every photographer—who brings a faded, yellow, surface-abraded thing with the unfortunate artist's name on the back of it, and demands another print to be done in its place as it "has not stood," when the real truth of the matter is it has been subjected to careless treatment and has "stood" a great deal too much? Put first of all in a cheap frame, the glass of the latter having soon been broken, and the owner either too indolent or too indifferent to get another, it has been knocked about—now given to the baby to play with, then placed on the drawing-room table, and finally banished, perhaps, to the mantelshelf which adorns an ever-smoking chimney—how can it be anything but pale-brown, faded-looking, and ugly?

We may here say what in this regard we think is not generally insisted upon. We consider that a mantelshelf and the wall above it are about as unsuitable places as it is possible to devise for placing a valued or valuable photograph. The dust, smoke, and dirt perpetually circulating around when the fire is alight cannot but influence the photograph, causing it almost inevitably to give way if it be a silver print, and begriming, staining, and spoiling other pictures, whether permanent photographs, engravings, or water-colour drawings.

Still another impeachment must be laid against many members of the general public—the careless disregard of all necessary precautions against damp and moisture, which, though a continual characteristic of certain walls in some houses, is yet quite capable of being evaded. When no precautions are taken, and it is possible at times to see the walls actually glistening with moisture, condensed or percolated, how improper it is for the owner of a picture hung against such a wall to bring it to the photographer and complain that it faded, streaked, or mildewed, when the only wonder is that it had not succumbed far sooner. A wall covered with thin lead specially made for the purpose, or even with pitched paper, would keep out all moisture and render a room far more healthy to live in at the same time.

Further: a room which is not actually damp may yet, if exposed to violent fluctuations of temperature and conditions of atmosphere, be most unsuitable for either photographic or other work, if only by reason of the occasional internal condensation of moisture produced when a long-continued moisture-laden atmosphere has quickly given place to a spell of sharp, cold weather.

We have yet one other point to which attention should be drawn. The old stereoscopic view and the *carte* view have gradually been entirely displaced in favour of those of larger size. In every print-seller's shop in the kingdom may be purchased scrap photographs, views of local interest, &c., &c., nearly all of which are sold in the unmounted state. Bearing in mind our remarks upon the subject of bookbinder's paste, &c., last week, it may easily be seen how large a proportion of these very pictures may be quickly put upon the road for extinction because of the use of some one or other of these vile compounds.

Having exhausted the list of indictments against the members of the public, it is fit that we should call attention to lapses on the part of photographers themselves. We think it would be a most desirable thing that all scrap unmounted photographs should bear, carefully printed upon their plain side, a lightly-printed announcement giving full details of the precautions desirable to take in the mounting and storing of photographs.

Further: though no words of ours will move the man who works always in one groove and produces pictures bound to fade because of the processes he employs, there are many to whom a hint is always acceptable, and to them we would point out the necessity of eschewing, in even the cheapest frame, every possible source of evil. Every glass should be scrupulously and carefully pasted into the frame, leaving not the least corner where air could penetrate; otherwise a streak of dust would inevitably follow in its train and quite ruin the appearance of the picture, this fine dust stain being sometimes almost ineradicable. The same precaution should be taken at the back, for no frame ought to be sent out with the back boards merely held in their place by a nail or two. It should, on the contrary, be most carefully pasted on, and, if in several pieces, each portion carefully pasted over with slips of paper. If this be desirable for appearance only in the case of a permanent picture, far more so is it in the instance of a silver print, which fades most rapidly when not preserved from the action of air—an action almost entirely prevented by the pasting of the back and front of the frame. We can, from our own experience, state that there are many photographers who send out large quantities of framed work, yet who never paste a single glass to the frame—a course that we cannot too strongly deprecate.

The practical conclusion to be drawn from our observations is that, though the public does not yet appreciate the possibilities of permanency in photographs, the fact may be impressed upon them that pictures by photographic processes can be so produced that they shall not fade, and that in all instances it is necessary for photographs to be treated with care and consideration. Finally: that, to ensure this being done, we consider it would be a most desirable thing if all photographers would have stamped upon their works a few brief hints as to the best mode of pasting in books, &c., or upon the most suitable mode of hanging to provide against all contingencies.

THE PHOTOGRAPHIC EXHIBITION.

[Fifth Notice.]

Mr. John Lewis exhibits a few frames of landscapes that are noticeable rather from a technical point of view than from any special claim to the picturesque. Good photography and mediocre subjects do not, as a rule, conduce to the finest results.

Mr. W. Muller exhibits three small collections of pictures representing respectively *Views in Cornwall, South Devon*, and *Scotland*. In No. 110 the Cornish coast scenes are splendid renderings of rock and water, the next frame of Devonshire views being scarcely inferior.

Mr. Henry Stevens sends a couple of frames of his well-known flower subjects—perfect in manipulation, but not differing greatly from his exhibits of the past two years. His figure *Studies* (No. 231) are equally good in technical quality; but the "untouched" work of the cleverest amateur cannot, nowadays, aspire to compete with professional productions in figure and portrait subjects.

Mr. George Hadley's exhibits are of a very varied character. First in the catalogue is *At the Wheel* (No. 24), which shows us, as its name suggests, "the man at the wheel," rough and grimy, clad in greasy canvas, top boots, and sou'-wester—just such a figure as may be seen every day on board our coasting vessels, from one of which, no doubt, the subject was taken. Amongst the same artist's *Small Studies* (No. 362) are remarkably good ones, especially the former subjects. Of the two centre ones we have chosen one for illustration.

No. 362—*Small Studies*. By G. Hadley.

Mr. Richard Keene's *Book Illustrations*, printed in platinotype (No. 466), some of which we have previously seen, will show to the most casual spectator what can be done in the way of artistic embellishment of books by photographic means. Practically permanent—as permanent, at least, as the paper on which they are printed—these pictures possess much, if not all, of the qualities of fine mezzotint engravings. The portrait and enlargement of *Viscount Ingestre* (Nos. 384 and 469), taken in a private room, show what may be done in this direction by a skilful artist.

The annexed illustration is one of Mr. Donkin's Swiss views—*The Way to the Matterhorn* (No. 374)—one of the most picturesque little "bits" amongst the whole collection, reminding us very much of Mr. Andrew Pringle's *Great Dome* picture from the Yosemite Valley, which we gave last year.

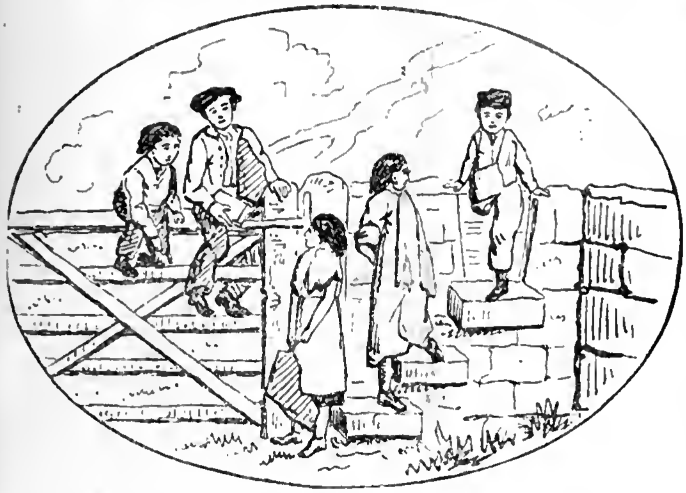
No. 374—*The Way to the Matterhorn*. By W. F. Donkin.

Major Verney's different exhibits remind us, this year, more of the old wet collodion days than any other works in the Exhibition. The strong contrasts in some of the pictures savour more of iodised collodion and pyro. development than of modern dry plates. As a rule, the subjects are well chosen; but we cannot help denouncing the taste (or, rather, the want of that quality) exhibited in one of the pictures in No. 405. We should blame the catalogue probably for some vagueness in the description of others of the pictures.

Captain Abney exhibits in two sizes, his larger pictures being, we fancy, superior to their smaller companions—$7\frac{1}{2} \times 5$. Of the former, two views, *On the Cherwell* (Nos. 261 and 262), are specially noticeable for the delicacy of the rendering of the reflections in the river; but the brightest and best of the series is *Greenwich Hospital* (No. 265). Of the larger ones, two views of *Glaslyn* (Nos. 270 and 271) are worth attention.

Messrs. West and Sons, of Gosport, have a single frame of very fine yachting views, in much the same style as their last year's exhibit. Though the collection contains no individual picture to equal the famous *Chittywee*, the general average is far better than last year; indeed, it may be said that there is not a single "weak" picture in the frame.

Mr. Edwin Smithells devotes his attention principally to *genre* subjects, several of which are well worth a little study. *Shadows* (No. 149) is hung so high that we can scarcely recognise its right to that title. The next two in the catalogue (Nos. 238 and 239) are merely animal portraits, presenting little of interest. Better are *The Mowers* and *A Summer Day* (Nos. 332 and 333); but the most taking picture of the collection is *Just Let Loose from School* (No. 400)—a happy arrangement of figures, but rather marred by



No. 400—*Just Let Loose from School.* By EDWIN SMITHELLS.

extreme fuzziness of the background. This we have selected for illustration, and another picture by the same artist, *A Reverie* (No. 550), we shall probably give next week.

Another of our illustrations is by Mr. J. R. Dunlop, who shows a frame of *Village Scenes* (No. 444), best of which is the group of

No. 444—*Village Scenes: New River Side.* By J. R. DUNLOP.

girls at a well, a rough sketch of which is appended.

Mrs. S. G. Payne's solitary picture, *Knuckle Down Tight* (No. 528), which has been awarded a medal, suffices to remind us that

No. 528—*Knuckle Down Tight.* By MRS. S. G. PAYNE.

we might enjoy the Exhibition better if it contained more of this lady's work. It is a few years since we passed our "marble" days, but we can fully enter into the spirit of Mrs. Payne's picture.

In our next notice we shall close our review of this year's Exhibition. We are glad to learn that, financially and in other respects, the present year has been one of the—if not *the*—best the Society has known.

APPARATUS.

WE now give a description of the new style of camera exhibited by Messrs. Watson and Sons. The front is fitted in a horseshoe, going in a very compact space and giving movement both of rising, falling, and sliding, together with the power of being swung in any direction, horizontal or vertical. By an ingenious arrangement of a double flange, one of which rotates inside the other, a reversing front is secured equivalent to the reversing back of the ordinary camera, which allows the pictures to be taken either horizontal or upright. The dark slides are fitted in a light frame at the back of the camera, instead of sliding in grooves like the ordinary pattern. The grooves being thus dispensed with, the sides of the dark slides are perfectly smooth. This permits all the slides to be made to a gauge, so as to render those belonging to cameras of one sort interchangeable. These slides are thinner than usual, their shutters being composed of lightproof and waterproof cardboard, which, while strong and durable, is lighter than wooden slides can be made. Again: the slides are not cut open, but the two plates are inserted from the side of the dark slide and held in position by a spring which shuts over this from the outside.

It is of such recent date that we described the simplex slides and reversible camera backs of Mr. A. G. Hopkins, it is here only necessary to state that these are on exhibition.

Upon looking for a new form of shutter exhibited Mr. J. Cadett—one differing in certain respects from any hitherto described by us—we quite failed to discover it among the articles exhibited, although entered in the catalogue.

Mr. Thomas Samuels exhibits certain improvements upon his camera, changing-back, and packing-cases as placed in the Exhibition last year. The ingenuity displayed in their construction is undeniable, and we doubt not that in practical work in the field the camera will acquit itself well.

A drop shutter and a spring shutter exhibited by Mr. T. J. Smith are good and efficient instruments, their construction not calling for any special description.

Making here a slight deviation from the order of our remarks on the apparatus displayed upon the tables in the Exhibition, we have to allude to the transparencies prepared for the lantern.

A collection of exceedingly-choice productions of this class, exhibited by Mr. George Smith, challenges admiration. Only a limited number of subjects are shown, but of each of these there are several examples in *facsimile*, the object presumably being to show how absolutely alike these pictures may be produced by the process of printing of which Mr. Smith is such an acknowledged master. The tone of pigment selected is a peculiar shade of brown not easily described, but so transparent as to permit the light to penetrate through even the deepest shadows. It would be very gratifying if Mr. Smith were to impart to the public a knowledge of the mysteries which enshroud his method of printing; for we are aware of some who have tried the production of transparencies by the Woodbury system, but have quite failed in producing results at all comparable with those of Mr. Smith.

The lantern slides of Messrs. York and Son, which find a place on the tables in the Exhibition, comprise excellent selections from some of the numerous series of story or lecture subjects issued by this enterprising firm. They are understood to be produced by wet collodion, the fine neutral tones by which they are characterised being obtained by chloride of platinum.

Discarding all adventitious toning agents, Mr. William Brooks—whose exhibits are produced by the collodio-bromide process, in which he has had great experience—is known to obtain his special tones (usually a warm purple) by modifying the developer. If it were necessary to cite examples of the work of this gentleman we might direct attention to his scenes taken in or near Bettws-y-Coed, which possess a charm peculiar to themselves.

THE following gentlemen will act as jurors at the Northampton Museum Photographic Exhibition: — Messrs. Andrew Pringle,

W. Bedford, and V. Blanchard, photographers; Mr. Joseph Clark, Member of the Institute of Painters in Oil-Colours; and Mr. G. W. H. Brogden, the representative of the local society. We learn that the Exhibition will be opened on Tuesday, December 16th, and *not* December 15th, as previously announced.

Our contemporary, *La Nature*, though generally giving details of the very latest scientific news, renders itself liable at other times to have the stale joke "old news" directed at it. Thus, last week, amid a variety of interesting topics, we find two columns of letter-press devoted to an account of the manner of producing the well-known "magic" photographs—the toy of nearly a score of years ago. The photograph is made, as our readers are aware, by rendering a silver picture invisible by means of bichloride of mercury, and then causing it to start into existence at any future time by placing it in contact with a damped sheet of filter-paper previously saturated with "hypo." The process is amusing enough, but utterly useless. Indeed, when first introduced to public notice it savoured more of the nature of a trick than a scientific amusement, many purchasers being (foolishly enough) under the impression that their shilling's worth of magic photographs would enable them to produce at will a picture of any subject they chose.

Apropos of the subject of the glass used for optical instruments—the great cost of which and the difficulty in obtaining it were alluded to in our last issue—we may give an extract from Mr. Norman Lockyer's recently-delivered Cantor lecture, in which reference is made to the same subject. He says:—"If I am rightly informed, no optical glass of the size now required (for which almost fabulous prices are given) is being made in England. If I am again rightly informed, the only source of supply in the world now available for us will shortly run dry."

It really does seem marvellous that England—which exports large quantities of optical glass to the continent for making instruments which it purchases back again—should not be able to make it in sufficiently large pieces to satisfy the makers of big instruments. Possibly the demand is too limited in extent to render it really worth while going to the expense of the necessary plant and the sacrifice of valuable time. It is not every day that a lens one yard across is required.

The use of a silvered mirror is often recommended for the purpose of taking reversed negatives, and it is certainly a far cheaper instrument than a prism; but a mirror perfectly flat is by no means readily purchased or quickly made. Mr. Lockyer, in the lecture referred to, puts down the cost of one a little over a yard and a-half wide as forty thousand francs—say sixteen hundred pounds!

It used to be the case that, although no optical glass equal to that of English make could be purchased on the continent, yet such instruments as opera-glasses and soforth, for which this glass was needed, were not made at all in this country. It is not the case, however, now, as these instruments have been made for some time in London—not perhaps of the very best class, but still made *bonâ fide* by workmen in our own country.

It is tolerably certain that the use of the tricycle will spread among photographers even more than among the general public. It is advantageous for either amateur or professional use, forming, too, as it so conveniently does, a complete substitute for a tripod. One of the drawbacks to its use is the churlishness with which drivers on the road frequently treat riders on the iron horse; but a lesson recently taught these obstructives will no doubt have a very salutary effect. The Rev. J. T. Dove, who is a county magistrate, was lately riding his tricycle along the road when he came up with two coal-carts, the drivers of which refused to leave the crown of the road when requested by Mr. Dove to do so that he might pass. He had, in consequence, to pass them by riding on the path. They, however, did not know their man, and he summoned them for an offence under the Highways Act. He did not press for penalties, but only for a decision to show the rule of the road, and, in consequence, the drivers were let off with a reprimand and payment of costs.

Professor Hartley, in the Cantor lectures, treating of *Fermentation and Distillation*, puts photography to a new use, namely, the testing the purity of spirit of wine—a substance which ordinarily he considers to be one of the purest commercial products. His method "consists in causing the rays emitted by an electric spark passed between two points of metal to traverse a vessel, with sides of rock crystal, containing the liquid, and afterwards to pass through a slit and a prism and a lens of quartz, and receiving the rays on a photographic plate."

In a list of antiseptics compiled by Herr Miquell we find two photographic substances, one at the head and the other at the tail of the list. Mercurous and argentic iodides were required in quantities of only ·0025 and ·003 per cent. of the liquid experimented upon, while hypo. needed 27·5 per cent. to prevent decomposition taking place.

A very interesting note by Mr. Philip S. Brito, M.B., upon reactions for discovering the presence of iodine in the presence of large quantities of bromine is to be found in the last number of the *Chemical News*. He says it transpires that the process is not really new; yet he thinks the instructions he gives may be of use in the furtherance of chemical knowledge. It would from its simple character seem to be of considerable value, for example, in readily ascertaining the presence of iodide in a dry plate whose composition was unknown. He says:—"In the ordinary process of analysis, from a solution supposed to contain bromine or iodine we liberate the halogen by the aid of small quantities of chlorine, and carry it down with chloroform. The violet-coloured iodine, or the dark sherry-brown colour of bromine, picks out the element; but in a mixture containing both the colour of the less abundant halogen is masked. When iodine preponderates it is got rid of by the addition of sulphate of copper and sulphuric acid. When, however, the bromine is in very great quantity, I find that the addition of a crystal or two of sulphate of iron completely decolorises the brown colour and renders visible the minutest traces of iodine dissolved by the chloroform. The value of this test may be gathered from the fact that in the bromide of potassium supplied as a reagent in the laboratory, and which is supposed to be pure, the application of the sulphate of copper demonstrates the existence of iodine as an impurity. Further: when the colour alone is not decisive, and any doubts exist, its application will settle the point. * * * How far this decolorisation can be taken advantage of to determine volumetrically the amount of bromine in a given exercise can be settled by actual experiment."

We have heard much of late about the injurious effects produced by the inhalation of ammonia since dry-plate development has been the standard work of the dark room. We think that if the method suggested by us some time since, and often referred to, were to be adopted we should hear little about the catarrhal effect of ammonia. Our suggestion was to keep the ammonia in stock in a diluted form, and so preserve it from rapid deterioration of its strength. When such is done and the ammonia in a dilute form is measured, instead of being "dropped" in a concentrated state there will be little opportunity for the escape of ammonia into the atmosphere. We scarcely think that anyone would suggest there could be ill effects from the evaporation of ammonia from the open dish of developer.

YET ANOTHER MODIFICATION OF THE CAMERA.

In spite of the thousand-and-one suggestions for the improvement of the camera, the main features of the instrument in common use at the present time remain about the same as they were years ago. For general outdoor and studio work it answers its purpose fairly well; but for baby portraiture and animal photography it is undoubtedly too primitive, and requires modification in respect of making it capable of allowing the operations of focussing and exposing to follow each other and be performed in as nearly as possible the same second of time. To this end have been applied the double camera and lenses of like focus, the camera with finder, the divided camera with sliding front, the reflecting mirror at right angles, mirrors and shutters combined, and soforth. All, however, appear to have some disadvantage (if it be only that of never having been put on the market) which has prevented their adoption.

That some means for ensuring the exposing of the plate immediately after focussing the living subject is desirable, no one who has had any experience with fidgetty specimens of life will deny. Its necessity is felt when the animal (of whatever genus) is placed or driven before the instrument for the purpose of being photographed, without taking into account its powerlessness of dealing with free and natural attitudes which, probably, would not last through the time required in the preparations to photograph them. It is, therefore, a wonder to me that the camera in its present form has been tolerated as long as it has. It is most certainly a long way behind the times in respect of the loss of time and trouble occasioned between the two operations of focussing and exposing. If photographers would only wake up, our clever and ingenious manufacturers would soon supply their demands; but the former can scarcely expect the latter to take the initiative while they have more business than they can manage in supplying the old forms.

The convenience and rapidity of the present dry plate has put quite another face on the matter. Under the old system, when a man had to haul his hundredweight or so of paraphernalia about, and prepare his plates on the spot as he required them, he did not dream of securing a transient effect except by the merest accident; and, if he saw anything he would care to photograph, the question had to be put—"Will it last for half-an-hour or so?" If this were likely he might commence preparations, and feel in these circumstances that a few seconds more or less between any two operations were not of vital importance; yet, even then, the delay between focussing and exposing his plate was frequently most annoying. It has, at anyrate, proved a nuisance to me, and has given rise to more than one experiment and suggestion in the effort to abate it.

The modification I have now in view, and which I will endeavour to make clear, consists broadly in having the back of the camera fitted with a sliding board, either rectangular in shape or in the form of a segment of a large circle, with two apertures side by side—one to be fitted with the focussing-screen and the other with grooves for the dark slide. In front of the lens is a similar one of suitable size likewise having two apertures, one of which is open and the other fitted with an exposer. These two sliding boards are actuated together from one pivot passing along the base of the camera in such a manner that when the open aperture of the front board admits light through the lens the screen is in position at the back, to pass by a simple turn of the handle to the closing of the lens with the shuttered aperture, and to the bringing of the dark slide with its shutter drawn into position at the back at the same instant.

Such is the naked idea. I will now try to explain the addition in detail, and will take for the purpose a rigid base studio camera, which racks out from the front. To the back of this fit a board something like the back of a repeating camera—that is, sufficiently wide to contain focussing-screen and dark slide (the parts for the latter projecting to the right), and upon which are grooved pieces, into which another board slides having apertures fitted to hold screen and dark slide side by side. In a back thus prepared the slide may be placed, and its shutter drawn at the outset ready for exposure. The only act required with the camera in this state is to push it into position when the lens has been covered.

On the front of the camera, and racking out with it, is placed another board to just clear the hood of the lens, before which an aperture is cut to admit light. The lens is connected light-tight up to this board by having another piece fitted to its hood and sliding in upright grooves upon the back of the front piece. This provides for the raising or lowering of the lens as required to suit the subject in hand. Upon the front of the board at the top and bottom are grooved pieces to admit the sliding of another board having an aperture fitted with an exposer. A pivot or spindle, with lever or winch to turn it by, is secured to the base of the camera in the direction of its length, and is connected up to the sliding board on the front carrying the exposer and that on the back bearing the screen and slide, to both of which it imparts motion by means of slotted arms working upon studs affixed to these boards respectively. That arm on the front has a sleeve to fit the squared end of the front, so as to allow it to slide backwards and forwards during the operation of focussing.

When the whole is adjusted the action is as follows:—The lever being turned to the right, the focussing-screen is brought into position and the lens is uncovered. A simple turn to the left suffices to cover the lens with the exposer already set for action, and to bring the slide into position at the back of the camera, likewise ready, the whole only requiring an instant of time to effect the change.

It does not strike me, in bringing this suggestion forward, that it would be advisable to fit large cameras in this way, but to confine it to half-plates and smaller sizes. This, however, would depend on workmanship to a great extent, and could be decided in practice. Respecting the adoption of some such modification, it would give me much pleasure to see the matter discussed with a view to its improvement or alteration, during which I would be glad to give any further details or explanations as they occurred to me. Perhaps some of our friends will open up. Will Mr. G. Smith, Mr. A. Pringle, Mr. W. H. Harrison, or Mr. G. W. Webster do something towards settling the matter? JOHN HARMER.

MODERN "DARK ROOM" IMPROVEMENTS.

No. I.

THE superseding of collodion by gelatine plates has necessitated an overhauling, not only of the operator's manipulative modes but of his various appliances. The "plant" that sufficed for developing and washing a collodion plate is no longer adequate. The room, often a mere cupboard, has had to be expanded into a more spacious apartment. New arrangements, in fact, all along the line have had to be introduced if comfortable and easy work is to be done in any quantity. Each operator has, doubtless, had to work through a series of tentative conditions, and sometimes through blunders, till such means are found as fairly meet his needs; and then he settles down to their use—the "rule of thumb" often, perhaps, working fairly well in practice. The *ideal* dark room is, doubtless, a variable quantity. What suits a business where small portrait work, pure and simple, is practised will be very different to that suited to a really mixed practice where enlarging, carbon developing, transparency printing, chemical operations of various sorts, and, perhaps, a little emulsion making is occasionally carried on. It is the object of this article to collate a few of the "notions" that have been found useful in a varied business, premising that nothing is set down from theory, but that everything named is, or has been, in actual testing. Only such things are set down as have been proved to save time, labour, or expense, or to produce improvement in the result.

A Comfortable Window is one of the first desiderata in a well-appointed room, and it is not quite so easily attainable as it appears at the first blush. The light should be *perfectly safe, easily changed*, and *thrown on the work*. To take the last point first: the light, in perhaps ninety-nine out of every hundred cases, is thrown principally into the eyes instead of down on the plate or dish, or other work in hand. This must be the case with a window vertically let into the side wall, unless a screen be placed to protect the eyes, and that is but a partial remedy. The window is usually placed as low as possible, and the work near it. The result is an uncomfortable sense of glare, simply through the eye being taxed with the quantity of light it has to look through, instead of that light being on the work and the eye in comparative darkness.

The plan I have found effective is as follows:—Inside the ordinary permanent window of the room is fitted a wooden glazed framework, sloping at an angle of something like 45°. Imagine a second window placed just at the back of the permanent one. Then, keeping the lower part of the two close together, the top of the inside one is sloped inwards so far, and at such a height over the sink, as just to clear the operator's head, and throw the light, not in his eyes, but directly down on the work. The ends of the framework are also glazed, throwing the light along the sides of the room. The upper part is a sort of wooden lid, part or all of which opens to admit extra ventilation. A part of the sloping sash frame is devoted to a framed pane running in grooves, and with a handle placed conveniently for instantly drawing back and admitting a flood of white light. The whole arrangement can be constructed by a mechanical amateur at very slight cost, whilst the pleasant sense of comfortable lighting is recognised by every operator who enters the room.

Next, as to a Safe Light.—The vexed controversy of ruby *versus* yellow and other lights I do not care to enter on. Theory, spectroscopic analysis, and fine-drawn experiments have been applied almost *ad nauseam* to the subject, and are very well in their way. The practical photographer constantly at work more or less in his "den" should value more his practical experience of what he finds safe. My own experience has been rather painful—probably like that of most who adopted ruby in all its depth and power. Some of the glass used was preached up as of special trustworthiness, and it certainly wanted nothing in price. This and other brands were piled on till they made a case of "darkness visible"—in the early dry-plate days, not *very* visible either, though uncomfortable enough. The bottles knocked over and the general awkwardness need not be described; are they not written too well in the memories of most of us?

Worst of all, the eyes were suffering severely; pain on suddenly changing rooms and growing weakness of sight constituted evidence that hardly needed the word of warning raised by Mr. Ackland and others. This was the state of things when Mr. W. E. Debenham's heresy from the orthodox ruby was announced. Many will thank that gentleman for daring to try if ruby light was such a *sine quâ non* as it was supposed to be. I hailed it as a very great relief if only it were true. Mr. Debenham very courteously favoured me with samples of his materials, and experiments were made which proved quite satisfactory. I replaced the ruby with one thickness of the rolled or "cathedral" green and two thicknesses of paper. A second screen of similar light-obstructive power was placed in reserve in ease of need when the sun was shining directly on the window; but this reserve was not put up, it never having been required.

This alteration was effected one evening after the day's sittings were over. Next morning I had to leave home for two or three days, and on returning the operator had a tale to tell—how the new light looked so scaringly like daylight after the previous ruby darkness. He could not fancy it safe. The plates at first were developed with all caution of huddling them up from it. How gradually his courage rose as he found no ill results appear! and now, behold! as with pride he passed in review negative after negative with the clearest possible shadows, and manipulated in a light that by comparison might almost be called daylight. The negatives with the yellow light have proved a *far better average* as regards brilliancy than under the previous ruby *régime*. The window has a south aspect, and during the past fine summer has had the sun shining on it a great part of the day. It is also subject to strong reflections from a wide expanse of sand often wet; but there has been no instance of fog that could be traced to the lighting, although an amount of light is admitted that enables the smallest print to be read with ease in the furthest corners.

It is rather interesting to note if any effect has been produced on the eyes by these altered conditions. It will perhaps seem almost like romancing to the incredulous when it is stated that not only did the pain in the eyes common with the ruby *cease* with its removal, but that now the *sight is very much improved*, and there is a commencement to do without glasses. Before this the tendency was to supplement them with extra power.

I do not want to say that this yellow paper with green glass is, *par excellence*, the photographer's light. Probably there are other media just as good. The "golden fabric" seems to transmit light of a similar character. But I do say this—that the use of deep ruby with its disadvantages is nothing less than an anachronism and absurdity as regards the everyday work of the photographer.

I now come to the actual working appliances—the sink and its adjuncts, means of washing and drying, enlarging apparatus, &c.; but these must be dealt with in a succeeding chapter.

BENJAMIN WYLES.

ON THE NATURE OF THE INVISIBLE IMAGE.

I HAVE just seen an article by John Nicol, Ph.D., in the last issue of THE BRITISH JOURNAL OF PHOTOGRAPHY, containing some remarks on a communication of mine (page 501) on the above subject. It will be remembered that I gave several facts, and I asked if they did not create grave doubts as to whether the action of light on a sensitive plate is really to reduce the bromide of silver to a sub-bromide when the invisible action takes place requiring development.

One of the facts I mentioned was a discovery, by one of the Editors, that collodion emulsion might be left for hours in bright sunlight without being injured. The second was that bichromate of potassium will eliminate the effect of light. Dr. Kenyon demonstrated this years ago, when he showed how an emulsion could be prepared in daylight. The third fact I mentioned was one I discovered myself, namely, that a plate can be exposed to bright gaslight for two minutes, and by simply remelting the emulsion the effect of that exposure can be eliminated. True, after exposing and developing a plate covered with the remelted emulsion behind a negative there was a slight fog; but how does Dr. Nicol explain why there was any picture at all—perfect in its tones from light to dark—after the whole of the film had been previously exposed to white light for two minutes?

Now, Dr. Nicol neither says that these facts are wrong or attempts to explain them by the theory of a reduction to a sub-bromide, and, after making such an attack upon me, he must see that he ought to do one or the other. If he can do neither he must acknowledge that what I stated was correct, namely, that these facts create grave doubts as to whether the sub-bromide theory is correct.

It is most amusing that the only one of my statements which Dr. Nicol attempts to contradict was one I quoted from the opening address to the Leeds Photographic Society by their President, some months ago, in which he stated that an exposed plate that had been put by for a time and again exposed on development showed no trace of the first exposure. Dr. Nicol says this is wrong. Because one of his plates had been exposed one year, and another, which he mentions, four years before development, and both turned out well, does that prove that the statement of the Chairman of the Leeds Photographic Society is wrong? Possibly his plates were kept under different conditions of damp or heat. One of the members of the Parent Society told me that he had plates which acted in the same way. Dr. Nicol recommended my close attention to Montaigne's advice. Would not slight attention on his own part be advisable?

I regret to have to call attention to the unfairness of what are apparently wilful misquotations of my statements. For instance: he says my "new theory teaches that silver bromide is not affected by light at all." I never said anything of the kind. What I said was "that when salts of silver are held in suspension in collodion or gelatine the action of light on the particles at first causes a rapid vibration or expansion of them"—that is, there is a mechanical action. With silver bromide or chloride, if the action of light be allowed to continue, a chemical action or reduction to a sub-bromide takes place, as on a daguerreotype plate or in the ordinary printing processes.

A few days ago Mr. A. L. Henderson told me Mr. W. E. Debenham and himself had discovered that there appears to be a phosphorescent action on a sensitive plate which can be produced by light and other means. What is phosphorescence but the *rapid vibrations* set up in the molecules of a substance by the ether waves? If there is proved to be such an action I calculate it will be rather awkward for the "reduction-to-a-sub-bromide" theory, and it will be another proof in favour of my theory.

If we prepare pure bromide of silver *in the dark*, and pour over it the ordinary developer (pyro. and ammonia), the particles will be reduced to a metallic state. *In this case there is no previous reduction to a sub-bromide by light;* but if we form an emulsion by adding gelatine to the silver bromide, pour it on a plate, and let it set and dry, on pouring on the developer the gelatine will be found to protect the particles from being reduced to a metallic state. Were it not so, photography by development *would be impossible.* If we wash off the developer and expose the plate to actinic light, and afterwards develope, we find that this protecting power of the gelatine has been destroyed (through the breaking of the gelatine cells by the vibration of the particles), and the silver bromide is then reduced to a metallic state. The first experiment proves that it is not necessary to reduce the silver bromide to a sub-salt before it can be reduced to a metallic state, and we know that friction by destroying the protecting power of the gelatine has the same action as light, and there can be no reduction to a sub-bromide in that case. The second experiment shows that the gelatine acts as a protector to the particles, as well as to hold those particles in a fine state of subdivision.

Dr. Nicol says "several writers, with some pretension to chemical knowledge, and something like method in their system of experimenting, have, pretty nearly at least, shown that the sub-bromide theory is correct;" and yet we find Mr. G. D. Macdougald, in his paper on *Chemistry and Photography*, read at a meeting of the Dundee and East of Scotland Photographic Association on the 2nd ult., advising the members of that Society to go into these very questions.

On the one hand we have gentlemen elected as officers to our photographic societies calling attention to the necessity of further investigations into these subjects, which shows that *they* do not consider them settled. On the other hand we meet men who simply pooh-pooh everything but what they have been taught as being incorrect, without inquiry or experiment, and who consider that that only is correct which they have themselves been using or thinking for the past twenty-five years.

I do not wish to enter into any controversy. I have simply called attention to certain facts, and stated what I consider those facts prove. Whether my ideas are only worthy of Dr. Nicol's opinions of them time will show. Meanwhile I look to that gentleman to prove that his remarks are justified by explaining the above facts by the sub-bromide theory.

HERBERT S. STARNES.

SOME PHOTOGRAPHIC USES OF FLUORESCINE.

RECENTLY I pointed out that for practical purposes a solution of carmine in albumen and ammonia gives the operator the power of making his own lantern screens, possessing the same optical properties as the ordinary ruby glass coloured with sub-oxide of copper.

Absorption of light takes place in the interior and not at the surfaces of bodies, so a sufficient quantity of the substance must be used to bring out its chief optical properties. Pure distilled water, for instance, is of a bright green colour; but when this is proved sometimes, as at the Royal Institution, a tube about fifteen feet long by eight or ten inches in diameter is used. Its ends are closed with glass plates, and a parallel beam of white light from the electric lamp is sent through its whole length. The circular disc at the farther end then appears of a bright green, from the colour of the water. The same principles apply to glass coloured with sub-oxide of copper, or albumen films coloured with carmine. When feebly coloured they are more or less pink, letting plenty of blue through, and are at that intensity useless for developing-room illumination; but let the colour be increased in intensity, they become exceedingly safe. Nevertheless, from their chief optical properties, they have always a tendency to permit the passage of a small amount of blue when their powers are overstrained by the use of a strong initial light.

On hypothetical grounds I pointed out in these pages several months ago that the best way to overcome this tendency was not by the use of two thicknesses of ruby glass, but by the use of a second sheet of glass faintly coloured by any other substance which has special powers of absorbing the blue, and yet permits red to pass without obstruction. The special merits of a "stained red" glass as opposed to ruby began to occupy attention about that time, and it was published more recently that that glass is coloured with sub-oxide of copper on the one side and oxide of silver on the other. The latter has the requisite power of specially absorbing the lower blue rays, and the practically useful results of the combination prove that the original hypothesis was a sound one.

Of late I have tried a long series of experiments with fluorescine, and find it to be of such use in relation to developing-room illumination that I am likely to keep it always at hand for the future to aid in effecting that purpose. A sufficiently-strong solution of it in albumen, to which one-fourth the volume of the latter of the strongest liquid ammonia has been added, has the power of giving films which cut the spectrum in half. When the solution contains just enough fluorescine to give a bright yellow film all the rays above the yellow-green are cut off when the initial light is not stronger than that of diffused daylight. Statements as to what rays a particular glass or other coloured film cuts off have little meaning unless the intensity of the initial light used be also specified to some extent.

Fluorescine has another useful property. Being fluorescent to the blue and violet rays it lowers their refrangibility to green, and then transmits the yellow-green so produced for use in the developing room. Thus it actually utilises some of the actinic rays themselves, changing them so as to be of value in developing operations. At the same time, it cuts off none of the rays below the yellow-green when the film is of the depth stated; consequently no better medium can be imagined for transmitting a very large amount of light, free from the blue-green rays upwards. After five months' experience and experiments with it, it has given me satisfaction in every respect.

By means of a strong single or double film of carminised albumen and a single film of fluorescine, a screen is made resembling in its optical properties the now celebrated "stained red" glass. The only difference is that the compound albumenised screen is the better of the two; it gives the clearer and brighter red, with no orange. Stained red, when tested by a strong light, such as the direct light of the sun, passes a trace of orange.

Albumenised solutions of carmine and fluorescine mix without apparent decomposition, so probably their combined optical advantages may be obtained in a single film; but being now away from home I have not tested the optical properties of the mixture.

A strongish solution of fluorescine, having a good orange rather than a bright yellow colour, cuts off almost all the green rays. A weak solution of fluorescine has a greenish and fluorescent appearance; it then transmits some of the blue rays unchanged, and lowers the refrangibility of the remainder. Is it possible to lower the refrangibility of some of the extreme violet rays by means of a fluorescent film, transforming them into rays of the wave-lengths which act most powerfully on photographic plates, and thereby to increase rapidity? To avoid loss by additional reflections, the almost colourless film might be formed on a surface of the lens, in optical contact therewith. A substance is wanted which is fluorescent to the extreme violet, and transparent to other rays.

Weak and alkaline solutions of fluorescine have magnificent fluorescent properties far in advance of sulphate of quinine and uranium glass. As the organic dyes vary so much with different manufacturers, and are for the most part not sold as definite chemical substances, it may be well to mention that my sample was purchased from Messrs. Hopkin and Williams, at four shillings an ounce. A very small weight of the crystallised dyes will usually go a very long way in preparing photographic lantern screens, and make the user independent of the manufacturers of coloured glass.

Although the means have herein been pointed out of obtaining the optical powers either of ruby or stained red glass, it must not be supposed that I approve the use of lights produced by their aid in the developing room. Mr. Debenham has rung the death-knell of pure red light in the developing room for ever, and has at last made a convert of the well-known expert, Mr. J. Traill Taylor. The chief light of the future will be principally yellow when examined with the spectroscope—although to the eye it may not be always such, as in Mr. Debenham's light modified with glass of a feeble green tint. His green glass is of little use in promoting safety; it cuts off some of the red of the spectrum, and thereby so modifies the rest of the light that the observer hardly knows what colour to call the available illumination, so constantly is the human eye the victim of optical illusions and delusions.

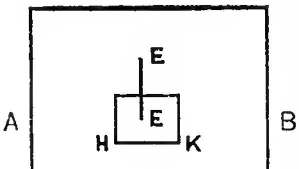
From its practical properties fluorescine is usually catalogued with the aniline dyes; but in chemical composition such may not be altogether its proper place. It may also be used to form films when it is dissolved either in collodion or varnish rendered strongly alkaline, by adding some ammoniacal gas dissolved in strong alcohol; but the solution in albumen is the best for present purposes. In collodion, after a certain strength in fluorescine is passed, the film becomes opalescent. When too much ammonia in alcohol is added to varnish some of the resin is precipitated and not redissolved. Unless there be a strong proportion of ammonia in the liquid, the colour imparted to the film by the fluorescine is less intense, so more dye has to be added to produce an equal effect. Another way of increasing the intensity of a film thrown down from a liquid weak in ammonia is to subject the dried film for some hours to the action of ammoniacal gas. The best plan, however, is to dissolve the fluorescine at the outset in albumen and ammonia, as already stated; in this liquid it dissolves freely and immediately to apparently almost any extent. As to the keeping qualities of the solution: mine is two months' old, and as good as at first. Two or three weeks after mixing it exhibited symptoms of gelatinising, so it was diluted with a little ammonia and water, which restored it to its original condition.

What is known as "true canary medium" owes its safety to its thickness—to its translucency and not to its colour, for it transmits blue of low intensity. Herein the use of separating the safety of colour from the safety of translucency is seen, because if the same make of white paper as used in canary medium be purchased, and then stained with fluorescine to the same depth of yellow as the canary medium in the market, a paper apparently the same can be produced, yet which will allow the passage of safer and stronger transmitted light.

I have only recently commenced experiments on the values of different increments of translucency. The first step taken was to deal with the colour element to get it under control, and to become independent of the meagre and variable supply of coloured glasses in the market. Fluorescine at one blow cuts off the most mischievous of the rays which fog photographic plates, yet is fortunately perfectly transparent to all the rest, in which it gives no trace of an absorption band. The yellow-green can next be cut off when desired by a stronger solution of fluorescine aided by a little carmine, a safe and bright apparent orange being the result; in it, however, the red rays are present. When it is desired to specially absorb the yellow and orange rays alkaline solution of litmus will do; but as yet I have not tried to make transparent litmus films. With any pure colour of the lower end of the spectrum obtainable at will the colour element will be under complete control for experimental purposes, and the hues brighter than those of stained glass.

The optical properties of a sheet of glass coated with fluorescine and albumen are interesting when the sheet is used as a screen through which to observe a landscape. As it completely cuts off all the rays which are blue, or nearly blue, but permits the rest to pass freely, the general colours of the landscape and all but blue flowers are much the same as before, but the whole scene is greatly heightened in warmth and brilliancy. The leaves have the bright, green hues of early spring; the dull leaden clouds covering the whole sky appear as though the sunshine were about to break through them. Yellow glass has the same effect in a degree, but those specimens of yellow glass in my possession exhibit it inferiorly, because their colours are not so pure and bright as that of the albumenised fluorescine. Light yellow rays are said to have a cheering effect on lunatics; those sane photographers who look at a broad landscape on a dull day through one of the films just mentioned will find that it has a cheering effect on everyone. The sight also reveals what a large amount of blue is reflected by the leaves of trees, their apparent darkness at this season being changed to the brightness of youth by cutting off the cold blue element. The electric light is commonly said to have a ghastly effect; this is due to its containing more blue in proportion than does daylight. We do not call daylight ghastly, because we are accustomed to it and its normal proportion of blue; but, after gazing at a landscape for a few minutes through a film of albumen and fluorescine, the same landscape appears ghastly when viewed by ordinary daylight, especially when there is no direct sunshine. If a window were formed wholly of such films, the illusion would be strong enough to make unwary observers believe on a rainy day that the weather is fast clearing up, whereas in reality it is as bad as ever.

A photographer who cannot spectroscopically test the light of his developing room, or of any new screen he purchases for its window or lantern, is in a very helpless position in the matter of getting the best light for working. A spectroscope is not, however, necessary for the purpose, Dr. van Monckhoven once pointed out a simple way of testing coloured glasses and screens. He took a large sheet of cardboard, A B, thick enough to be opaque to light. In this he cut the narrow slit E E, then laid upon the cardboard a piece of the glass H K to be tested. It will be noticed that the glass but half covers the open slit E E, so that when a white light, such as that of a paraffine lamp, is placed on the other side of the cardboard it shines through the upper part of the slit freely. The illuminated slit is then viewed through a prism, at a distance of a yard or more. A common prism will do from a chimney-piece ornament. A prism of optical glass is not necessary; one worth a penny or twopence is all that is required. Through the prism the operator will see the upper part of the slit giving the spectrum of white light, and the lower part of the slit giving the spectrum of the light after its passage through the glass under examination. He will thus, by comparison, see at once whether all the blue and violet are cut off by the glass. It is more comfortable to make observations of this kind with the room in total darkness, with the exception of the light coming through the slit. This is easily managed by using the above arrangement as one of the windows of a dark lantern. A way to test a coloured window is to temporarily fix a sheet of tinfoil on it with glycerine. The tinfoil should have a slit cut in it. The operator then places a paraffine flame close behind the slit, and after dark examines with a prism from outside the window, the light passing through the slit.



As the film of albumen on glass is excessively thin the solution of fluoresceine must be strong enough to look nearly as dark as ink. It is useless to attempt to get a thicker film of albumen by horizontal drying, for directly the film has any appreciable thickness it cracks as the water evaporates. These films should be varnished with a benzol varnish; alcohol dissolves the colour. W. H. HARRISON.

RECENT RESEARCHES IN STELLAR PHOTOGRAPHY WITH THE EQUATORIAL STELLAR CAMERA AT THE LIVERPOOL ASTRONOMICAL SOCIETY'S OBSERVATORY.

[A communication to the Liverpool Amateur Photographic Association.]

THE application of photography to astronomy during the last few years has been very extensive. Until last year, however, it has been used chiefly for photographing isolated objects, such as the moon, the great nebula in Orion, or the comets. Professor E. C. Pickering, the Director of the Harvard College Observatory, United States, during his European tour showed some negatives of large fields of stars. The instrument used by him was an equatorial stellar camera with an aperture of three inches, and with this he succeeded in photographing stars down to the eighth magnitude. During his visit here to address the Astronomical Society of Liverpool he showed me these negatives. The line of research seemed to me so interesting that I at once set to work to attempt the photographing of certain constellations. A camera with a lens of two and a-half inches aperture was borrowed, and an altimuth stand was converted into an equatorial. The exposures of an hour were done entirely by hand. The first negatives were shown at the second meeting of the Astronomical Society's session, and the Council at once determined to ask for subscriptions for providing a suitable instrument. We quickly discovered that the purchase of any such instrument was entirely beyond our means; but at this state of affairs came a generous offer from Mr. Howard Grubb, F.R.S., to lend us what we required. The instrument arrived in March, and was very soon in position and at work. I must now give a brief description of it.

The lens is a compound lens of four and a-half inches aperture, and focal length of 15·8 inches. It is fitted into an ordinary wooden camera. Upon the camera is fixed a finder of short focus. The only form of mounting admissible was that known as the "equatorial." The principle of the equatorial, as you doubtless are aware, is an axis parallel with the earth's axis of rotation. To this is affixed another axis at right angles to the first. The first axis is called the "right ascension axis;" the second the "declination axis." The convenience of this form of mounting lies in the fact that the star can be followed with one motion only. The equatorial is of massive iron. The wooden camera is attached to this by screws, while a suitable counterpoise is affixed on the other end of the declination axis, so that the camera will remain in any position. The declination and right ascension axes are fitted with circles suitably divided. The iron mounting is attached by screws to a strong wooden stand. As the exposures have often to be of considerable length a clock motion is added, so that the camera is kept fixed on a star during the required exposure. Additional slow motions are provided in the declination and the right ascension; the right ascension one is so contrived that the camera can be moved without stopping the clock.

The work which I was especially desirous of undertaking was the determination of the actinic magnitudes of the stars. The brightness of a star to the eye is the combined effect of all the rays of the spectrum that are emitted by the star; but the impression on the photographic plate is due solely to an isolated part of the spectrum. The action of light on the plate is greatest at the violet end, and decreases as the spectrum approaches to the red. You will at once perceive we shall have on the plate a totally different scale of star brightness. The more a star abounds in rays of great refrangibility the brighter it will appear on the plate. A star of an orange or red hue will, therefore, be diminished on the plate, while a star of blue colour will be proportionately increased. Taking, then, the eye magnitude as mean magnitude, the photographs will show a certain number of stars superior and a certain number inferior to the mean magnitude. Now, a star is white to the eye, because the rays of all refrangibilities are in their proper proportion to produce the absence of colour. In about two-thirds of the stars this proportion is maintained. Taking these as our standards for the reduction of the plates, we shall find that in the case of two-thirds of the stars the eye magnitudes and the photographic magnitudes will agree; but in one-third they will differ from the mean magnitude by a quantity depending upon the refrangibility of the rays they emit. In other words, the photographic magnitude gives us one of the factors necessary for the determination of the colour of the stars.

The question, then, to be solved is how to obtain photographs of large fields of stars, and how to reduce the photographic magnitudes from them. Now, with the rapid plates at present in use daylight photographs may be taken in an exceedingly-minute fraction of a second with a lens of very small aperture; but for photographing the stars long exposures are needed, because the starlight is so faint. An object photographed in the daytime is photographed by the light it reflects, but the stars have to be photographed directly. The most sensitive plates now made ought to have their sensitiveness increased many times for stellar photography.

The quantity of light we have to deal with is, except in the case of a few bright stars, so small that long exposures are necessary. Now, length of exposure means increase of probable error. The errors fall under—(1), the instrumental errors; (2), temporary cloudiness of one part of the field photographed; (3), unequal absorption—the last a very difficult and complex matter. In the first place, it is never a constant quantity—not even from hour to hour; hence it is impossible to reduce one plate by comparison with another, supposing them both of equal sensitiveness. Each plate must be reduced separately. The first two sources of error have been eliminated by allowing the stars to drive. In this way the stars, instead of coming out as dots, come out as lines. Supposing a cloud to intervene in any part of the field: its presence is shown on the photograph by a break in the line. Supposing the stars were photographed so as to come out as dots: it is obvious that the cloud or mists present might pass undetected, and a serious error be introduced in the resulting magnitudes. The exposures for the ordinary zone work are generally between minutes and half-an-hour. On these plates stars down to eight and a-half magnitude are photographed, and on nights when the absorption is at a minimum stars of even smaller magnitude.

The number of stars that can be reduced on any plate is limited by a curious fact, which came out in the reductions for the catalogue of the photographic magnitudes of five hundred stars lately published. This is over-exposure in an insidious form. If α be the quantity of starlight necessary to penetrate the silver film completely in half-an-hour, it is obvious that all stars whose light is greater than α will penetrate it before half-an-hour, and the action perpendicular to the plate will immediately cease. At first sight it would seem easy enough to tell where this has happened, for all stars whose light is greater than α would come out the same. If the rays of light passed through a medium whose refractive power was constant during the exposure this would be so; but in the case of the air the quantity is never constant nor similar in any two directions for a moment, and hence the light is spread out all round the star's image. The action on the plate thus resolves itself into a vertical and horizontal action—the vertical being due to the star's light falling directly on the plate, and the horizontal due to disturbance of the star's image by atmospherical inequality.

You will see at once, then, that if we attempt to determine the magnitudes of stars greater than α we really use a different method to that in the case of stars less than α. In the former, we use the horizontal impression, which is purely due to spurious discs caused by the lens and by atmospherical inequality of refraction; and, in the latter, we make use of the vertical impressions on the plate due solely to the star's action. The value of α is affected by three things:—(1) Length of exposure; (2), aperture of lens; and (3), the sensitiveness of the plate. From the photographs already taken I have been able to get a provisional formula for the equatorial stellar camera from Wratten and Wainwright's "drop-shutter" plates. Having the aperture constant, and the sensitiveness of the plates supposed to be constant, the following formula is approximately true for exposures under one hour:—

$$\alpha = \sqrt{T}$$

When T is the length of exposure in minutes, and α the value of total penetration in magnitudes.

I may be allowed to point out that increased sensitiveness of the plates is more important than either size of aperture or lengthened exposure. If T equal the time of exposure, A the aperture of the lens employed, and S the sensitiveness of the plates, the joint results will be expressed by some relations of

$$T, S, (A)^2$$

Supposing this to be—

$$\text{Minimum magnitude} = \frac{(\sqrt{T} + \sqrt{S}) \times (A)^2}{30}$$

—a provisional formula which fairly represents observations up to the present date—it is obvious that the increase of aperture is of more consequence than either increase of exposure or sensitiveness. But increase of aperture means increase of focal length and decrease of the field of vision; hence we are very quickly limited in this direction. Increase of T means increase of all sorts of errors, both instrumental and atmospherical. The only thing we can infinitely increase without error is S, the sensitiveness of the plates.

In conclusion: I must apologise for the incompleteness of this paper. There are several points to which I should have liked to draw the attention of the Society, namely, atmospherical actinic absorption, and to the importance of the new line of research in other respects. In the stars we have the past and future of our sun written in no uncertain hand. Intense energy is shown by the star being white, decline of energy by the yellow star, and the approach of extinction by the red star. The actinic light disappears first. Our sun has reached the second stage; each thousand years the actinic light will grow more feeble, till life will at last disappear. But the camera tells us that the universe is comparatively new, not above a third of its myriads having reached the second stage yet; but it tells also of universal slow decline. What powers of recuperation space contains we cannot say. Remove the actinic light and we blot out life; increase it and we have a luxuriant vegetation and contemporary prolific animal world. If it be true that our sun has reached the second stage, then it was in the first stage that animal and vegetable life appeared on the earth. With the decline of chemical light the sun's forcing power diminished, and life—vegetable and animal—adapted itself to the change by natural development. We should find, then, that in the first stage life was more prolific, but in the second more developed. An interesting path of speculation is open, but I must refrain. This age should be the age of exact observation; to the future belongs the teaching of these observations. But whatever the future discovers it will owe it in a great measure to your noble science—the science of photography.

T. E. Espin, B.A., F.R.A.S.,
Special Observer to the Liverpool Astrom. Society.

HOLIDAY TRIP TO WEST CORNWALL.

I have frequently been asked—"Where is a good place to get some studies of shipping, boats, &c., suitable for the camera?" There is not a better place known to me than the town of Falmouth. It is reached by the Great Western Railway from London, and by tourist ticket the journey is by no means expensive for the distance. The fare from London (all tourist tickets being available for two months) is—first class, eighty shillings; second class, fifty-five shillings; and third class, forty-two shillings and sixpence. Passengers are allowed to break the journey at many of the stations either going or returning. Not only from London can tourist tickets be obtained, but from most of the great centres, such as Manchester, Liverpool, &c.

The town of Falmouth in itself is not very prepossessing, the main street, which is the old part of the town, being long and narrow, but the Corporation are widening this street as much as possible. On the outskirts modern residences are fast springing up, and plenty of apartments can be obtained. Of studies of boats, shipping, &c., any number can be obtained. In the harbour, and all along the shore, will be found boats building, boats new, boats old, and boats all to pieces in every conceivable variety.

Falmouth has a natural harbour, said to be one of the finest in the world, and a hundred ships can anchor within it. All round the coast is very picturesque, with rocks and woodland scenery of very great beauty. A most magnificent panorama can be obtained from the high ground, which is well suited for the camera. The entrance of the harbour is guarded by Pendennis Castle and fort on one side, and St. Mawes Castle and fort on the other, whose guns sweep the whole entrance. They are said to have been built in the time of Henry VIII. Both these castles make very good pictures.

Pendennis Castle is not very far from the railway station. It is situated on the headland, and a very charming walk can be had round the castle drive. There is one thing not to be overlooked, and that is the number of seats for the weary placed about by the Corporation—a good example for other towns to take pattern by—and these little comforts are fully appreciated by visitors. The view from Pendennis is very grand indeed, and a capital panoramic picture can be obtained showing the harbour on the one side and the bathing beaches on the other. St. Mawes Castle is reached by steamer, which starts from the market strand pier. The fare for return tickets is sixpence halfpenny, the distance each way being about three miles. On the steamer a good sight of the harbour is obtained. The castle can also be reached by sailing or rowing boat.

One of the prettiest trips by boat is up the river Fal. This is one of the most delightful river trips that I have ever had. The steamer is "The New Resolute," Captain Benney, who is only too pleased to give all the information possible to visitors. I think the distance is about ten miles each way—that is, from Falmouth to Truro. The return fare, first-class, is one shilling. The fore part of the vessel is, I believe, somewhat cheaper. The time on the passage each way is about one hour and a-half. The river at times seems perfectly land-locked, owing to the windings. On its banks is situated the charming seat of Lord Falmouth—Tregothnan. There is only one stoppage on the way at Malpas—pronounced by the natives "Mopus." Here, also, are to be had plenty of boat studies. The steamer runs according to the tides, which serves twice daily, and gives several hours' stay in Truro, the newly-created city. Truro in itself is one of the most dead-and-alive places a person can possibly imagine, and what formed the inducement to make it a city I am at a loss to conceive.

I am going on too fast, however. I should have mentioned a little about St. Mawes. This town has a small harbour, and at times here are to be had some capital studies—fishing boats, &c., and also of fisher folk. The inhabitants are very hospitable and obliging. The castle can also be visited. On my last visit to St. Mawes an old fisherman nearly ninety years of age was pointed out to me, who, it is said, has never been more than ten miles into the country, and never has been in a railway train. I should think he must have had a very contented mind. I also saw some very quaint cottages, with porches. Pendennis can well be seen from here, and so can the town of Falmouth. Any amount of little "bits" can be got along the coast in every direction, the fishing gear, crab pots, &c., in these little villages making charming foregrounds.

From Falmouth again the little town of Flushing must not be overlooked. It is best reached by walking on to Green Bank and crossing by the ferry boat; or any of the watermen will row parties from Falmouth. The town of Flushing is very quaint in parts and very interesting, and plenty of boat studies can also be obtained from here.

Opposite to Falmouth is Trefusis Point, which is very picturesque. One of the best shore views of Falmouth can be obtained from hence. Again: all along the coast charming studies can be obtained in every direction, and there is a large number of little creeks and coves with boats hauled up in all positions suitable for the artist. On the Falmouth bathing beaches plenty of rock studies are to be had. The name of the bathing beach is Gyllyngvase, and following this beach round from Pendennis to the right brings us to what is called the Swanpool Beach. The Swanpool is a kind of lake, very picturesque, with tall rushes and flags on its banks; it is separated from the sea by a roadway or sand-bar. The further headland is crowned by a tall chimney stack, which belongs to some old disused smelting works. This headland is called "Pennance Point." From this point, near the Stack, capital views can be obtained; and it is a very delightful walk from Falmouth. Near this point is a little cove called Maenporth, and other very picturesque coves follow the coast line round in which the artist may revel.

Following the beach we come to the entrance to the Helford river and harbour. Here, again, some very pretty little river studies can be had by proceeding up the river. Those who care for breaking seas as studies can have any number during the end of the autumn and winter months on the bathing beach, as it is very rough at times, the seas breaking heavily on the beach.

To those who care to visit Falmouth in the summer time a few hints may be acceptable. In the hot weather it is by far the best to seek apartments on the upper terraces. If the lower ones are chosen it will be found warm and relaxing; but by getting on the top it is much more cool and bracing, and the breeze is felt. It is rather a stiff climb up, but it is well worth the fatigue. The present observatory is on these top terraces, and can be seen for miles; it is, besides, a good landmark for all the country round.

If any days prove unfavourable the time need not be lost, as several views may be found of interest in the town. There is one place to which I must call special attention, and that is the "old curiosity shop" kept by Mr. John Burton. It is true to its name in every sense of the word. No one need be afraid to enter; although everything is for sale no one is ever asked to buy. China vases can be bought from a few pence per pair up to one hundred pounds. The proprietor is a most genial man, and is very happy to give all information either about his goods or the neighbourhood. Almost everything will be found in the collection, from a needle to a sheet anchor. The last time I was there I saw many things that would be far more suitable as studio accessories than half the rubbish which is intended to mean everything and means nothing. No one ever enters Falmouth without paying this place a visit; all the aristocracy who enter the town go to see it. I have often wished that it was possible to get a photograph of it.

In the month of September is generally held the Polytechnic Exhibition at the Polytechnic Hall. The last was its fifty-second annual exhibition. A prominent feature in the exhibition was the photographic department. The institution was founded by Miss Anne Maria Fox, who is still living and takes as great an interest in it as ever. There are some very excellent shops in Falmouth, and some very quaint old ones. In Killgrew-street—a short cut into the next, or, as it is called, Wellington-terrace—is a flight of stone steps called by the inhabitants Jacob's ladder, which consists of 109 steps, but I need not say that some prefer going round to mounting the so-called ladder. Coming down is all very well provided one can do it the same way as the boys do, viz., sliding all the way down the iron handrail. I have frequently seen a dozen coming down in this fashion. I myself (not being one of the lean kind) prefer going round. It is a straight flight from top to bottom without any turning, and is, as the Cornish say, "going up orver steers." But, instead of "going up orver steers," we keep straight along Killgrew-street, which will bring us to Kimberley Park—a small enclosure beautifully laid out and kept. It is a nice place for a rest in the heat of the day.

There is one thing I must not omit to mention, and that is the cheap means of getting about. I mean by vehicles (not rail) and also by boat, as will be seen in the former part of this article. During the summer months a brake and four runs nearly every day to the Lizard and back, a distance of nearly fifty miles, for four shillings; but all through the year it can be reached by the daily 'bus *viâ* Helston. There is another thing to which I must refer. The visitors to Cornwall, as a rule, are very select, for there is an entire absence of the rough element, which constitutes such a nuisance at what are termed the fashionable seaside places. There is also another inducement for visiting this district, namely, the cheapness of living compared with many other similar resorts; for although, in the first place, the railway fare seems more than from London to the so-called cockney watering-places, when all expenses are put together for a month it will not be found more expensive, if so much, and one gets a thorough change into the bargain.

Wm. Brooks.

THE CARBON PROCESS FOR AMATEURS.

[A communication to the North Staffordshire Photographic Association.]

The carbon or autotype process is one of the most beautiful of all printing processes, and, having as one of its principal attributes the advantage of permanency, is especially recommended to the amateur photographer, who, as a rule, only requires one or two prints from each of his negatives, and who, whilst admiring the beautiful range of tone obtainable in silver printing, prefers to use a more permanent and satisfactory method of making a picture.

Several of the difficulties inherent in the carbon process have been the means of deterring many people from working it. I propose to deal with those difficulties *seriatim;* and, without touching upon the history of the discovery of the fact that a film of bichromated gelatine is rendered insoluble by exposure to light, give you a practical demonstration of the method of developing a carbon print, with a few such hints upon the requisite exposure necessary for various kinds of negatives as my own personal experience will allow.

Here is a piece of unsensitised carbon tissue. The colour happens to be "portrait purple." To sensitise it it is immersed in a bath composed of bichromate of potash one ounce, water twenty ounces, with the addition of about twenty grains of carbonate of ammonia. This last neutralises the free acid almost always found in commercial bichromate, and to a certain extent retards the spontaneous insolubility of the tissue. The latter difficulty I have never met with, as I never keep sensitised tissue for many days. The tissue having been immersed in the sensitising bath three minutes, until completely flaccid, is withdrawn and laid face downwards upon a piece of plate glass. A squeegee, made by screwing a strip of thick india-rubber between two laths, is passed over it, thus removing all excess of moisture.

Drying the tissue is with most amateurs somewhat of a trouble. I have seen several plans recommended, but have found none so easy and satisfactory as the following, which I learned from one of the photographic almanacs:—Sensitise at night; let the room used be freed from deleterious gas or other fumes by passing a draught of air through it for a few minutes. The kitchen is preferable, as it is usually warm in the evening, and not too hot after all the household have retired to rest. Suspend the tissue by American clips to a line stretched across the apartment, and come down early in the morning before daybreak, when you will find all the tissue dry and curled up. A door or doors of the drying-room should be, if possible, left open, as the object is not to dry so much by heat as by a current of dry air. When dry the tissue is, of course, ready for printing, before which operation, however, the negative must be prepared by making a "safe edge" to it. This I do by drawing round the reverse side of the glass for about a quarter of an inch in depth a margin of Brunswick black. This depth for 11 × 9, and proportionately less margin for smaller negatives.

Now place the tissue face towards the negative in a printing-frame, and as it is, of course, impossible to judge by appearance of the progress in printing an actinometer must be used. This being placed by the frame is your timekeeper, and an exposure to a certain number of "tints" is necessary for each negative, the meaning of the word "tint" being that the paper (exposed in the actinometer simultaneously with the negative you are printing from) has acquired a similar tint to that painted upon the lid of the actinometer, dividing all negatives into three classes:—No. 1, thin; No. 2, medium; and No. 3, dense. No. 1 will probably require one or one and a-half tint only; No. 2, perhaps two or or three tints (the general number from my usual run of negatives); No. 3, probably four tints or, at the most, five. Bear in mind that after removal from the frame the operation of printing still goes on to a certain extent; so that, although with experience advantage may be taken of this fact, it is best for the amateur to develope his prints as soon after exposure as possible. For this operation no chemicals are required, only plenty of warm water; and as we will say that we wish to imitate a silver print as much as possible, we will take a piece of plate glass, free from scratches, and which has been rubbed and polished with bees'-wax and turpentine, so that a slight film of that compound still adheres to it. Place this in cold water with the piece of exposed tissue. This latter will begin to curl up and then go quite flat. At *this moment* bring both glass and tissue face downwards upon it out of the water; apply the squeegee so that all air-bubbles are expelled, and place aside to drain for a few minutes. Of course, several pieces of tissue and glass may be similarly treated at the same time.

Now place the glass and adherent tissue in warm water at about 100° Fahr. Agitate a little until you see the dark pigment begin to ooze from beneath the edges of the paper, lift up one corner, and the whole may be lifted from the glass, leaving behind an apparently slimy mass; dash the warm water over this until you see the image distinctly, and the water comes off colourless.

At this stage it will be seen whether the exposure has been approximately correct. Should it have been too long a little warmer water may probably reduce the image; if too short, use cooler water containing a little alum; but, as in other processes, a correct exposure always gives the best results. After an immersion in alum and water place the glass plate with the developed image aside to dry. When dry take a piece of transfer paper which has been previously soaked in cold water until flaccid, then in warm water until just slimy; flood the glass plate with cold water, apply the transfer paper, squeegee, and again set aside to dry. This time the image will, if left to itself, adhere to the transfer paper and leave the glass, giving a highly-polished picture.

For more detailed information I refer you to Captain Abney's *Instruction in Photography.* In practice the carbon process is not a bit more difficult than silver printing; and although my description thereof has been somewhat lengthy I hope my demonstration has been none the less interesting, and that some of you, after surmounting the principal difficulty of exposing, will adopt what, although having been called a "blind process," is none the less a beautifully-scientific, and from the variety of its applications an exquisite, adaptation of a simple phenomenon to photographic purposes. W. B. Allison.

,, 13 ..	Manchester	Manchester Technical School.
,, 14 ..	Ireland (Annual Meeting)	Royal College of Science, Dublin.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on Thursday, the 30th ult., the chair was occupied by Mr. W. K. Burton.

Mr. J. T. Taylor said that, as the lantern season was approaching, the members would doubtless be interested in any improved methods in connection with the working of the instrument. The use of petroleum in any form he considered a nuisance, and he thought it might be superseded to some extent by a light which would be shown to the members—an improved method of obtaining illumination from platinum heated to incandescence. He was not to be understood as proposing this plan as a substitute for the higher class of illuminants, such as the lime and electric light, but as taking the place of the various paraffine burners. He would have the pleasure of introducing to the meeting Mr. Lewis, the inventor of the light, who had brought two of the burners with him, and would demonstrate them before the members. The essential principle was that a Bunsen burner was employed to raise platinum to such a heat that it gave out light by incandescence. In the two burners before them the draught necessary for strong combustion was obtained by means of the chimney. When, however, a blowing machine was used the heat was greater, and the light became white and more intense. Among other advantages this form of light was particularly adapted for Keevil's dissolving lantern, in which a single light only was used—one optical system having its illumination from the side of the flame and projected forward to the screen by means of a reflecting prism. It was obvious that for an arrangement of this kind it was necessary that the source of light should be, as was the case with the light now under consideration, equal when looked at from the side and from the front. The definition also, on account of the smallness of the light, would be found much better than with any of the forms of paraffine lamps, and, therefore, it was much better suited than the latter for the photographer's use in making enlargements.

Mr. Lewis was then introduced to the members, and answered several questions respecting the intensity and candle-power of the light. For photographic purposes the colour of the flame might be rendered of a pure white, but for lighthouse and fog-penetrating power a yellowish colour was preferable.

The lights were kept burning for some time, and a vote of thanks was awarded to Mr. Taylor and Mr. Lewis.

The adjourned discussion upon Mr. Ashman's lecture *On Toning* was resumed.

The Chairman, with reference to the statement in the work *On Silver Printing*, by Captain Abney and Mr. H. P. Robinson, observed that since the last meeting he had tried toning with gold merely neutralised. It could be done, but the action was quicker as well as better when more alkaline salt was used.

Mr. A. Cowan inquired whether Mr. Prestwich had tried toning as suggested last week with gold diluted with distilled water, and no alkaline salt.

Mr. W. H. Prestwich had done so, and succeeded in obtaining satisfactory tones. The paper he used was that purchased as ready-sensitised. In further discussion it transpired that Mr. Prestwich was in the habit of passing his prints into a solution of carbonate of soda before putting them into the gold solution, and this was considered to account for Mr. Prestwich's results.

Mr. W. E. Debenham said that as to the distinction which had been spoken of between substitution and gilding processes, the fact was that some gilding processes were substitution processes. If it was meant by calling toning a "gilding" and not a "substitution" process because gold was added to the deposit, without silver being converted into the compound from which the gold had been removed, he submitted that in such case the print would, as toning progressed, become much deeper from the additional metal, and not merely changed in colour by the substitution of one metal for another.

Mr. F. W. Hart remarked that with reference to toning with chloride of gold, with or without the addition of alkaline salts, much would depend upon the method of preparation of the gold itself, and upon how much alkaline had been added to neutralise it before being put up into the tubes in which it was sold. As to the washing of prints before toning, he thought it a mistake to advise, as some had done, that all trace of nitrate of silver should be removed from the paper before toning. In fact, when that was done the prints could scarcely be toned at all. In order to ensure that some nitrate of silver, and this a regular and definite quantity, should be left in the prints he employed a definite quantity of water for the washings. He put the prints into water in the proportion of one print for each sheet of paper. After three waters in this proportion the prints were ready for toning.

Mr. J. B. B. Wellington inquired what would be the effect if a large quantity of silver were left in the paper.

Mr. F. W. Hart replied that the toning would be unmanageable. As to permanency, he thought that the more gold there was deposited the better. Slow toning tended to bring about this result, and was, therefore, to be recommended.

Mr. A. Mackie said that, with respect to ready-sensitised paper, he thought the more it was washed before toning the better.

Mr. W. M. Ashman, in the course of his reply to the remarks of the various speakers, observed that Mr. Henderson had stated that sulphur toning was by far the best method. He would like to know whether Mr. Henderson was prepared to issue his prints toned by this method. As to whether toning was a substitution method, he considered it to be a process like that of coating a knife with copper by immersion in a solution of that metal.

Mr. McKellen was then introduced to the meeting and exhibited his camera, which met with much commendation.

The Chairman observed that there were more novelties in this camera than in half-a-dozen other new cameras. A description of the camera was given in our report, in last week's issue, of the technical meeting of the Photographic Society of Great Britain.

Mr. Henderson said that all modern dark slides allowed the plates to fog if they were kept for some time in the light. He suggested a return to the old plan of having them to open with a flap door inside the camera.

Mr. W. Cobb had used a slide of this description for his instantaneous pictures.

Mr. McKellen said that for large cameras he had not found the flap door for the dark slide to answer. He had recently been on a trip with the members of the Manchester Photographic Society, who all kept their dark slides carefully shielded with a cloth, and some of them assured him that he would find his plates fogged, as he did not use this precaution. He found, however, that they developed perfectly free from this defect. Of course, really good workmanship was necessary.

Some plates were shown by a member as having been fogged by emanations from the leather or American cloth of a dark slide.

Mr. J. Barker inquired whether Mr. Cobb had succeeded in curing the defect of this nature which he had mentioned as existing in some of his dark slides.

Mr. Cobb replied that age appeared to have remedied the evil in question. The slides did not fog now, although at first a few minutes even were sufficient to produce the effect.

Mr. Henderson read a letter from a gentleman in the provinces upon a method of producing a safe light. The writer said that if two holes were pierced in two pieces of card, and the holes were opposite each other, the cards being parallel, white light would pass; but if the cards were set at an angle to each other light could not pass. In order, therefore, to correct the inequalities in the several thicknesses of any coloured medium employed, he proposed to place these thicknesses at an angle to each other instead of keeping them close together and parallel.

The Chairman observed that the writer's idea was based upon the notion that defects in the transmitting medium took the form of tubes perpendicular to its surface, and if this were not so the remedy proposed would not meet the case.

Mr. W. H. Harrison was elected a member of the Association. It was announced that, at the meeting to be held on the 13th inst., the slides produced from identical negatives by various processes of transparency making would be shown.

POSTAL PHOTOGRAPHIC SOCIETY.

A committee meeting of this Society was held at the address of the Hon. Secretary, 3, Plowden-buildings, Temple, on Wednesday, the 29th ult. Dr. Horace Day was elected Chairman, and the minutes of the previous meeting were read and confirmed.

The Committee, after having inspected specimens of photographic work sent in by candidates for membership, elected the following gentlemen, some of whom had been provisionally admitted:—Hugh Heal (Hayward's Heath), C. J. Watson (Birmingham), S. H. R. Salmon (Croydon), C. F. Pritchard (London), Rev. W. Miles Barnes (Dorchester), Chas. Yeomans (Sheffield), and Chas. Baker (London).

The Chairman then proposed that in future albums, where a member exhibits more than one print, the votes which are given him in respect of each exhibit shall be added together; and the member so gaining the highest number of votes shall take the prize. This motion was carried.

The prints in album 14 were considered, and it was found that Mr. J. W. Leigh's No. 830 had the greatest number of votes, Mr. Mathewson being second with one of his pictures. The prize was accordingly awarded to Mr. Leigh.

Dr. Day was unanimously elected President for the current year, and, after several letters from various members had been read and other business transacted, the meeting dissolved.

AMATEUR PHOTOGRAPHIC ASSOCIATION.

The annual meeting of the Council of this Society was held on Tuesday, the 28th ult., at 12, York-place, Portman-square,—Dr. Arthur Farre, M.A., in the chair.

The minutes of the last meeting having been read and confirmed, the following members were elected:—Professor Butler, M.A.; Sir H. Hussey Vivian, Bart.; H. H. Williamson, F.R.A.S.; J. J. Brown; Miss Mary Egerton; Miss Maude Sullivan; John Hanmer; F. Trimmer, M.R.C.S.; J. E. Dumont; F. Grant; Mrs. Hobson; W. E. Pickels, F.R.M.S., &c.; D. B. Fraser; and F. J. Double.

The Secretary then laid before the meeting the pictures for the current year.

Mr. J. Glaisher, having carefully examined every single picture, read his report, of which the following is an abstract:—

Class I. contains 170 pictures; Class II., 210 pictures; Class III., 172 pictures. The remainder are comprised in Classes IV., V., and VI.

The pictures in Class I. are contributed as follows:—R. Leventhorpe, 17; C. Stephens, 6; The Right Hon. the Lord de Ros, 2; A. D. Halford, 3; F. Beasley, 15; R. Murray, 2; T. Brownrigg, 2; W. S. Hobson, 14; W. Adcock, 3; F. S. Schwabe, 6; General Sladen, 5; A. Hill, 5; Rev. H. J. Palmer, 6; R. O. Milne, 7; P. Gunyon, 2; W. Vanner, 9; W. Muller, 12; J. C. Hannyngton, 3; G. Brook, 2; S. Norman, 9; J. H. Robinson, 1; R. B. White, 13; H. O'Farrell, 2; A. Tagliaferro, 4; G. R. Fludder, 2; P. H. Emerson, 2; W. D. James, 5; S. Salmon, 1; H. R. Moiser, 4; H. E. White, 3; F. C. Borckhardt, 1; G. Western, 4; and J. H. T. Ellerbeck, 1.

Class II. contains the following:—C. Stephens, 7; the Right Hon. the Lord de Ros, 3; A. D. Halford, 1; F. Beasley, 11; R. Murray, 5; T. Brownrigg, 4; W. S. Hobson, 4; W. Adcock, 1; F. S. Schwabe, 1; Major Board, 7; General Sladen, 2; A. Hill, 1; Rev. H. J. Palmer, 7; R. O. Milne, 4; P. Gunyon, 4; W. Vanner, 3; W. Muller, 12; R. Leventhorpe, 3; F. Whitmore, 5; J. C. Hannyngton, 11; J. L. Ranking, 1; G. Brook, 3; F. H. Shaw, 3; Lieut.-Col. Bigg, 1; S. Norman, 3; J. H. Robinson, 5; A. R. Dresser, 5; J. W. Baxendale, 3; G. Smith, 2; Mrs. Abbott, 1; R. B. White, 1; C. H. James, 1; T. Perrot, 2; H. O'Farrell, 4; A. Tagliaferro, 5; Mr. Inspector Hirst, 1; the Hon. H. Prittie, 2; G. R. Fludder, 13; P. H. Emerson, 5; W. D. James, 6; S. Salmon, 3; Lieut.-Col. Nicholl, 7; H. R. Moiser, 3; H. E. White, 6; T. C. Borckhardt, 1; R. Bellringer, 3; G. Western, 14; and J. H. T. Ellerbeck, 10.

Class III. contains 172 pictures, contributed by the Right Hon. the Earl of Rosse, C. H. James, A. R. Dresser, J. W. Baxendale, Major Board, and others.

The following prizes were awarded:—The first prize to R. Leventhorpe, Esq., for Nos. 107, 111, and 114, a large silver goblet. The second prize to R. B. White, Esq., for Nos. 2, 7, and 15, a silver goblet. W. Muller, Esq., for Nos. 1,005, 1,019, and 1,020, a water-colour drawing in frame. R. O. Milne, Esq., for Nos. 8 and 9, a silver goblet. H. E. White, Esq., for Nos. 1 and 2, a silver goblet. F. S. Schwabe, Esq., for Nos. 3 and 5, an oil painting in frame. W. S. Hobson, Esq., for Nos. 305 and 310, an album elegantly bound. C. Stephens, Esq., for Nos. 59, 60, and 65, an album elegantly bound. S. Norman, Esq., for Nos. 6, 9, and 11, a silver goblet. W. Adcock, Esq., for Nos. 2 and 4, an album elegantly bound. W. D. James, Esq., for Nos. 14 and 15, a water-colour drawing in frame. W. Vanner, Esq., for Nos. 74, 77, and 80, a water-colour drawing in frame. Certificates of honourable mention were awarded to the Right Hon. the Lord de Ros, A. D. Halford, Esq., T. Brownrigg, Esq., General Sladen, A. Hill, Esq., the Rev. H. J. Palmer, F. Beasley, Esq., G. Brooks, Esq., A. Tagliaferro, Esq., G. R. Fludder, Esq., P. H. Emerson, Esq., and H. R. Moiser, Esq. A. J. Melhuish, *Hon Sec.*

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The monthly meeting of this Association was held at the Free Library, on Thursday, the 30th ult.,—Dr. Kenyon, President, in the chair.

The minutes of the September meeting having been read and confirmed, Mr. F. P. Paul, F.R.C.S., was elected a member.

The Chairman announced the donation of twelve prints to the album by Mr. W. H. Atkins, and, also, to the Library of guide-books to Carnarvon and Ruthin, by Mr. Maurice Jones.

The Rev. T. E. Espin read a paper on *Stellar Photography* [see page 714], and passed round some negatives and prints in illustration of his remarks.

The Chairman, after complementing Mr. Espin on the ability and scientific interest of his paper, asked if he considered that the sun had entered upon its yellow stage of existence.

The Rev. T. E. Espin said that spectroscopic observation tended to confirm this theory. He further adverted to recent experiments on the power of actinic rays in promoting vegetation and developing life.

The Rev. H. J. Palmer mentioned the case of a schoolmaster friend of his, who, under the conviction that the blue rays were conducive of brain power, had the walls of his school and class rooms coloured blue.

After some further discussion the Chairman proposed a cordial vote of thanks to Mr. Espin for his most interesting and suggestive paper.

The Rev. T. E. Espin, in replying, said that he should be most happy to show his apparatus to any photographer who would visit the Observatory of the Liverpool Astronomical Society at West Kirby.

Mr. W. H. Kirkby, after some observations condemnatory of combining the monthly meetings of the Society in July and August either with excursions or with social gatherings at the country houses of members, proposed the following addition to the rules:—"All the monthly meetings of this Association shall be held at the usual place of meeting, and within the city of Liverpool; and that at Council meetings five shall form a quorum, and at the Association meetings ten shall form a quorum."

Mr. Atkins seconded the resolution.

Considerable discussion ensued, in which the Revs. T. B. Banner and H. J. Palmer, and Messrs. Atkins, Beer, Corkhill, Ellerbeck, and Kirkby took part. The resolution, on being put to the vote, was lost.

Mr. C. A. Wharmby then proposed the addition to the rules as follows:—"Each member shall send in to the Secretary, at or before the meeting following his election, his *carte* portrait for insertion in the Society's album."

This resolution was seconded and carried.

Mr. A. W. Beer gave notice of his intention to move the following addition to the rules of the Association:—"All members elected on and after the January meeting, 1885, shall pay an entrance fee to the Treasurer of ten shillings and sixpence."

Mr. W. H. Atkins then gave a demonstration of his mode of making enlarged negatives with gelatino-bromide paper, and used an ordinary triplex paraffine lantern, with a Steinheil half-plate lens. The sensitive sheet was placed in an ordinary printing-frame, and the enlargement was one of five diameters, from a very good transparency from one of Mr. Atkins' own negatives. After exposure for some three minutes Mr. Atkins placed some non-actinic glass in front of his lantern, and proceeded to develope his picture with the pyrogallic acid and washing-soda developer. After applying a citric acid and iron clearing solution the enlargement was fixed in hypo. and washed, and passed round for the inspection of the meeting. The result was a brilliant success, and great interest was manifested by a crowded meeting in all Mr. Atkins' manipulations.

The Chairman expressed the pleasure and instruction all had derived from the sight of Mr. Atkins' dexterity, and his vote of thanks to the demonstrator was carried by acclamation.

Mr. Kirkby gave some account of his recent experiences with the platinotype process.

Mr. W. H. Atkins complained of the degraded whites of some of the prints he had recently made by this process.

Mr. Twigge showed some specimens of his work with the sepia-toned paper, and detailed his difficulties in working it satisfactorily.

Mr. Ellerbeck called the attention of the members to the inconvenience they occasioned the Librarian by requesting him to receive and give out books, &c., at all times during the meetings, and suggested that after 6.40 the library should be closed. He (Mr. Ellerbeck) spoke on the advisability of establishing an exchange department of the work of the Association.

The Chairman thought the Treasurer might with advantage utilise the funds of the Association to facilitate the exchange of prints.

Mr. Beer proposed that Mr. Ellerbeck's suggestions on this important matter should be included in the *agenda* of the next meeting of the Society, and this proposal was agreed to.

The exhibits of the evening were:—Prints coloured by the new Cundall process; a number of 15 × 12 enlargements, and a volume of views in England, Ireland, and Wales, by Mr. Beer; views in Wales, by Mr. Ellerbeck; stellar negatives and prints, by the Rev. T. E. Espin; a series of enlargements, by Mr. Cornish; and some home portraits on opal, by Mr. Twigge.

The meeting, which was a very crowded one, was then adjourned.

NORTH STAFFORDSHIRE AMATEUR PHOTOGRAPHIC SOCIETY.

A meeting of this Society was held on Wednesday, the 31st ult., at the Mechanics' Institute, Hanley,—Mr. Charles Alfieri, President, occupying the chair.

It was resolved that a presentation print (10 × 8) should be given to each member of the Society at the annual meeting held in November, the Secretary being instructed to advertise for the same.

A paper (with demonstration), *On the Carbon Process for Amateurs* [see page 716], was read by the Hon. Secretary.

After some interesting discussion thereon, and Mr. G. P. Bradford having been elected a member of the Society, the meeting was adjourned.

HALIFAX PHOTOGRAPHIC SOCIETY.

The monthly meeting of this Society was held on Tuesday last, the 4th inst.,—the Rev. W. E. Hancock, M.A., in the chair.

A letter was read from the retiring President, Mr. Thomas Birtwhistle, regretting greatly his inability to be present in consequence of indisposition.

The Chairman referred in feeling terms to the great respect and sympathy all entertained for their worthy President in his troubles, and of the great spirit and energy he had ever displayed in face of failing health. His heart was in the work, one of his greatest pleasures being to be among his old friends of the camera.

An unanimous vote of thanks was heartily accorded to Mr. Birtwhistle and to the rest of the retiring officers for their past services, and the following gentlemen were elected officers for the session 1884-85:—*President:* Rev. W. E. Hancock, M.A.—*Vice-Presidents:* Mr. Councillor John Smith and Mr. Joseph Whiteley.—*Treasurer:* Mr. E. A. Caw.—*Secretary:* Mr. W. Clement Williams.

Mr. Manley, of Halifax, and Mr. F. E. Berry, of Sowerby Bridge, were elected members.

The Chairman, in congratulating the Society upon the rapid increase of their numbers, trusted no individual efforts would be relaxed to further augment the rank and file of the Society, and so make it sufficiently prosperous to warrant the Committee in inviting from time to time some of the men great in photography to lecture before the Society. The past session had been a successful one, so far as the reading of papers and demonstrations were concerned; and, with the exception of a few serio-comic or, perhaps, tragic adventures, in the broken cameras and river duckings connected with the outdoor meetings, all had gone well. But zealous amateurs had now come to look upon mishaps of this character with something like stoical indifference, and were to be found prosecuting their craft in the most unlikely and dangerous places. Most of those who had availed themselves of these outings under the green, leafy canopy of woodland, of mountain, brake, and stream, would be able to look back with pleasure to days happily and pleasantly spent; and he trusted such gatherings would be largely repeated in the future. He was glad to find that members were beginning to contribute to the various exhibitions held elsewhere; for such praiseworthy emulation to compete with their photographic brethren of other societies was in itself a healthy sign, and likely to elevate the status of their own Society. He (the Chairman) proposed giving them a lantern evening shortly, when he hoped all the slides would be the work of the members. Slide-making was an intensely interesting branch of photography. After field work, possibly no more pleasing occupation could be followed when the dark days of winter came round; and, when exhibited, the scenes depicted passed before them again and again, vividly recalling pleasant recollections of past enjoyments.

A discussion on lenses then took place, when the consensus of opinion seemed to be in favour of the portable symmetrical for depth of focus when very near and fine detail had to be taken with the more distant landscape.

Pending the preparation of the syllabus, Mr. Fred. Myott promised a practical demonstration of emulsion making for the next meeting. The meeting was then adjourned.

Correspondence.

THE MEDAL AWARDS AT THE PHOTOGRAPHIC EXHIBITION.

To the Editors.

Gentlemen,—In view of the fight over the medal awards I shall be glad if you will allow me to say a few words as standing on neutral ground, being not only a non-exhibitor this year, but not even having had time to see the Exhibition.

The Rev. Mr. Macdona's strictures may or may not be too severe, but I certainly think that Mr. Marsh has dealt somewhat harshly with him. Mr. Macdona is not a mere personal acquaintance of mine but a very intimate friend, and, therefore, I can speak from knowledge of him. He has only worked at photography for a very few years, but he is one of the most enthusiastic amateurs that England possesses; and, so far from being "a dog in the manger," his friends who know him—at least as well as Mr. Marsh can conceive or picture him—would never tack such an epithet on so noble-minded and worthy a man.

And yet I can scarcely agree with my good friend in finding fault with the opinions of the judges. As a cricketer I should certainly think twice at least before I impugned an umpire's decision; and I can safely say with respect to Mr. Macdona that, being a man possessed of the uprightness and fairness which characterises an English gentleman, he would be the last to accuse other gentlemen of the possible absence of such qualities. The construction I put upon his criticism was this—that, if somewhat more prolonged and careful judging had been made, some few of the medals might have been differently awarded. But this only shows how slight must be the difference of quality between some of the productions decorated and some that are not; and, in most cases, where so thin a border-line exists, there must necessarily be a certain divergence of opinion between the judges and the public. Indeed, with regard to the judges, their very names are inscribed on the pillars of the temple of photography, and it is far from likely that they would ever think of risking their position amongst us by giving a medal to any but those whom they deemed to have deserved it. I have had the pleasure of knowing one of this year's judges for upwards of twenty-five years, when he stood without an equal or a rival within the classic precincts of Cambridge, and there are very few University men of his time who would ever venture to put their opinions into the opposite scale with his. Others can doubtless bear as high an encomium with regard to his *confrères*.

In view of such facts, I fear we amateurs must accept our beaten position, and only determine to bind on our armour more securely for future exhibitions. Nevertheless, the point mooted by Mr. Macdona, as to separate awards being made for amateurs and professionals, is one worthy of more than merely passing consideration. The amateurs of England are a very large and influential body, and I feel sure that if the judges of the future could see their way to apportion a certain moiety of the medals to amateurs—just as in every school each class has its prize for the head boy or boys—not only would the professional ranks be more stimulated to send in their very best work to compete for the fewer medals, but an incentive amongst the amateurs would be roused which would redound to the credit of the whole community, and urge us to greater exertions to reach that pinnacle of fame amid the glades of nature to which the professionals have arrived within the walls of their studios.

It goes without saying that we have not the slightest chance of competing with the professional men in portraiture; and, considering the truly pitiable productions of amateurs' portraits in general, it would be well if my brethren could be induced to reduce to a minimum the practice of "taking our friends' likenesses," and devote themselves entirely to that which, in my humble opinion, is the far more enjoyable work of vieing with the poet and the scenic painter in depicting the grand and open temple of Nature.—I am, yours, &c., J. CARTER BROWNE, D.D.

Thurning Rectory, Hants, November 3, 1884.

THE HYDROKINONE DEVELOPER.

To the EDITORS.

GENTLEMEN,—I cannot understand Mr. Ingall's formula for the hydrokinone developer, as stated in the Journals of the 17th and 31st ult., and write to ask if he will be so good as to take the trouble to make it a little more clear for the benefit of those who, in common with myself, would like to use a developer so highly recommended by Captain Abney, Mr. E. Howard Farmer, and others.

In the formula given in the Journal of the 17th ult., page 671, only one and a-half grain of hydrokinone is to be dissolved in five ounces of water. Is this what is really meant, as about one grain to the ounce is what is usually recommended?

In the letter which appears on page 702, "one drop of pure strong nitric acid" is advised in preference to the citric acid in the formula on page 671; but farther on Mr. Ingall says—"I think one grain (of hydrokinone) to the drachm of water will be found a convenient solution. It ought to be filtered then with ten drops of nitric acid made up to 100 minims with water." It, of course, cannot be meant that the 100 minims of diluted acid are to be added to one drachm of water containing one grain of hydrokinone; but, if not, to what must the diluted acid be added?

Perhaps Mr. Ingall will kindly, through your columns, give the formula which he has found to be the best, and very much oblige,—Yours, &c., F. W. B.

November 4, 1884.

Notes and Queries.

FRANKLIN says:—"Can you give me a reliable formula for the preparation of a phosphate toning bath for albumenised prints?"——Let our correspondent try the following:—

Chloride of gold	1 grain.
Phosphate of soda	20 grains.
Water	8 ounces.

J. A. S. very unnecessarily tenders a profuse apology for "troubling" us in the following matter, quite overlooking the fact that it affords us the greatest pleasure to render services of this nature to our readers, whether regular subscribers or not. The matter referred to is this:—He took a photograph of a certain vicarage. While doing so two gentlemen came up, and just as he was about to uncap the lens they stood still and stared at the camera. When he afterwards exhibited the photograph for sale one of the persons referred to objected to it, and threatened him (the photographer) with an action at law if he persisted in the sale. He wishes our opinion concerning this.——In reply: Our correspondent ought not to discontinue the publication under such threats. If an action be brought the plaintiff will only get himself laughed at. His presence there was an accident, and his standing still during the exposure is an admission that he wished to be taken in the photograph. Even if it were the means of bringing him into public ridicule, which is evidently not the case, he could have no claim against the photographer.

T. S. MATTHEWS would like to know whether it would be illegal were he to photograph a statue of (say) a Grecian undraped figure, and then have it painted and exposed for sale.——In reply: It is not possible to answer such a question unless we were made acquainted with all the circumstances of the case; but we may observe that many years have not yet elapsed since some one—a photographer, we think—was fined and reprimanded by a Glasgow magistrate for having sold coloured photographs of a statue of the class mentioned.

GEO. HAYNES asks whether there is any patent existing in the United States of America for the use of gelatino-bromide paper on which to produce positive prints.——In reply: We are informed that such a patent does exist; but, seeing that application for the same had not been made at the date when such invention had been made public in England, it is uncertain whether or to what extent the previous exhibition of the results of the invention, and the publication of the means whereby such results were obtained, might affect the patent taken out in the States.

QUERIST says:—"Can you inform me what would be the proper focal length for an object lens for an optical lantern, to produce a disc ten feet in diameter at a distance of fifteen feet from the screen? and, also, whether the ordinary double combination form of portrait lens would be a suitable kind to use for the purpose?"——In reply: To cover a ten-feet disc at the distance mentioned try a lens having an equivalent focus of five inches; but the dimensions of the transparency have something to do with this. We here assume it to be of the usual nature. The ordinary portrait combination, if properly corrected for flatness of field, will answer the purpose well.

S. D. A. inquires if any means exist whereby he will be enabled to take a group of three figures on an eighteen-inch plate by means of a whole-plate lens. He imagines it is to be effected by the agency of a concave lens, which may be placed between the two lenses that form the present combination, and asks for particulars as to focus, diameter, form, and price of such lens, together with information as to the precise place in which it should be inserted.——In reply: There is a better and far simpler system than that described which may be adopted for effecting the desired end. Let our correspondent remove the back cell, together with the lenses contained therein, from the tube and insert in room thereof the front cell with its lens remaining in an undisturbed position. Next insert a diaphragm in front of the lens, the flat side of which should now be directed to the outside, and the conditions for securing a large group on an eighteen-inch plate will have been complied with. Try a stop with an aperture of about an inch, and let it be placed a distance in front of the lens equal to its diameter. Precise directions cannot here be given, but these will afford a sufficient clue to the requirements of the case.

Exchange Column.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPHS REGISTERED.—

Messrs. Hall, Wakefield.—*Photograph of Norbury Church.*

Elijah Yeoman, Teesdale Studio, Galgate, Barnard Castle.—*Two Photographs of John Bowes, Esq.*

Thomas Mills, 53, Garth-road, Bangor.—*Photograph of the Council of the North Wales University*, also *Photograph of Opening Ceremony.*

JOHN BORDLEY.—The idea is by no means new, it having been introduced and used many years back.

O. O. O.—Make up a varnish by dissolving gum dammar in benzole twenty grains to the ounce, and coat the pictures with this. It will not require heat in its application.

A. B. C.—The picture is certainly much improved by your work. We have returned the prints as desired.

A. Felix.—Ferrotype portraits are coloured in the same way as glass positives, namely, with powder colours.

J. Robertsein (Glasgow).—Yes; the last volume of our Journal contains the most complete treatise on the subject.

T. B. P.—Any gasfitter will supply the burners; or you may get them direct from the manufacturer, Charing Cross, W.C.

Charles Waters.—Tinned vessels should not be used. Better employ stoneware or porcelain. The funnel should be a glass one.

A. Z.—1. About ten or eleven feet.—2. Fifteen to sixteen feet.—3. Five feet opaque at each end will be better than more.—4. To about two feet six inches from the floor.

Robt. A. Good.—Write to the gentleman himself if you are desirous of more particulars. We know nothing of his private affairs, or whether he would sit to you for his portrait.

Staffs.—There is no doubt whatever that the glass was not thoroughly cleaned before the emulsion was applied, and that the markings arise from this little piece of carelessness.

F. B. E.—We cannot do better than refer you again to the remarks we made when we reviewed the apparatus a short time back. We have nothing to add to what was then said.

Print-Washing Trough.—If the correspondent who last week desired to know where he could have one made will turn to our advertising columns he will see there is one advertised in the current number.

D. H. T.—Without seeing the pictures in question it is impossible for us to say how they were produced. We presume, however, that they were mounted in the ordinary manner before the prints were removed from the glass.

Robt. Ferguson.—As you have all the works you mention, the only addition we can suggest is the last edition of Hardwich's *Photographic Chemistry*, published by Messrs. J. and A. Churchill, New Burlington-street, W.

M. N. O.—Thanks for the strips of cardboard and the negative. We will examine the former chemically and let you know the result. Treat the stains first with dilute hydrochloric acid, and afterwards with pumice-stone. Ordinary black varnish is the best for writing the names on the negatives. They should be written on the film side, but backwards.

X. Y. Z.—The alterations we should suggest in your proposed studio are to make the side light higher—say nine or ten feet, and the ridge fifteen feet. Instead of having six feet opaque at the ends, five would be better. If possible, it will be advisable to have the studio longer than you propose. Twenty-one feet is rather too short when full-length figures have to be taken.

A. F. Bumford.—The cause of the fog is very evident if the developing solution was prepared according to the formula you enclose, as it contains no restraining acid. Add to each ounce of the solution twenty minims of glacial acetic acid, and try again. If your negatives still fog probably the fog is due to the bath, and a drop or two of nitric acid to each pint will, no doubt, set that right.

Opal.—As you say that, sometimes, your opal pictures are all that you can desire as regards brilliancy and colour, while at other times they are inferior although you use precisely the same materials, it is clear that the difference is due to your manipulation or want of skill. Unless we saw you actually at work we cannot suggest where you fail. Possibly more experience is all you require. Use the chloride of palladium, and dissolve it in water.

Touchstone.—You had better purchase one or other of the retouching mediums now in the market. The makers of them do not publish the formulæ by which they are compounded. Some mistake has been made; gum arabic is *not* soluble in benzole. All will depend upon the water supply. The larger the vessel and the more plentiful the supply of water the more perfect will be the washing. Better make the trough a little too large than too small.

W. H. W.—The machine mentioned in your letter will certainly yield sufficient light to enable you to take a portrait; but for practical purposes we should certainly advise you to have the next larger-sized machine. If you have the smaller one you must place the light much nearer the sitter than with the larger, and this is always a disadvantage. While you are incurring the outlay, the difference in cost and installation of the larger and smaller machines will not be so very considerable.

Received.—Ed. Liesegang, Ph.D.; "M. A." In our next.

Photographic Society of Great Britain.—The first ordinary meeting of this Society for the ensuing session will take place on Tuesday next, the 11th instant, at 8 p.m., in the Exhibition Gallery, 5a, Pall Mall East, when the medals awarded will be presented, and short papers read by Mr. Arnold Spiller on *Hydroxylamine Used as a Developing Agent*, and by Captain Abney, R.E., F.R.S., on *The Siemens' Unit Lamp Applied to Photography.*

Obtaining Money by False Pretences.—A man named William Cobbett was charged at the Maidstone Borough Police-court with obtaining money by false pretences from his employer, Mr. E. Hibling. Prosecutor, who is a photographer, engaged prisoner to canvas for orders for photographs on commission. He gave in the names of several persons to his employer with fictitious orders, and received his commission. It was proved that many of the orders were false, and prisoner was committed for trial at the Borough Quarter Sessions.

Photographic Club.—The subject for discussion at the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 12th inst., will be on *Emulsions in Collodion.*

Photographic Chambre Syndicale.—The photographers of Lyons have combined to form a Chambre Syndicale, the President of which is M. Bernand.

Canvassing for Photographs.—William Cunningham, 33, a respectable-looking man, who described himself as a canvasser in the employ of the Temple Photographic Gallery, 170, Fleet-street, was charged with obtaining the sum of 5s. 6d. from Catherine Evans, a widow, by means of false and fraudulent pretences.—Mr. Sims, from the office of the Solicitor to the Treasury, prosecuted.—The alleged false representation was that the prisoner came from the Photographic Gallery, Temple-bar, and asked prosecutrix if she wished to have her late husband's photograph enlarged like one he showed her. She gave him a likeness of her son's to get done, and 5s. 6d. He promised to bring it back in a week. She last week saw him in custody.—Detective-sergeant Martin said a number of frauds had been perpetrated in connection with photographs lately. It was shown that the prisoner had nothing to do with the above-named gallery.—The prisoner in defence said he handed the portrait and money to a young man, who said he was in the employ, and he thought it would be done.—Mr. Slade committed him for trial.

Herr Hennig's Gum Arabic Emulsion Process.—In the *Correspondez* Herr A. Hennig gives the following simple emulsion process:—"If a drop of a thick solution of gum arabic be placed in a test-tube containing some washed aqueous bromide of silver and left to precipitate, one will perceive that an emulsification of the bromide of silver takes place just as with a warm gelatine solution. This well-known phenomenon led me to seek a new way of avoiding the troublesome part of the work of making gelatine emulsion, namely, the washing of the nodules. The process is as follows:—Precipitate from the aqueous solution bromide of silver, which falls rapidly to the bottom on account of its weight; and, therefore, in a very short time—from a-quarter to half-an-hour, according to the quantity—it may be washed completely free from the nitrate salt by two or three changes of water. This precipitate is emulsionised by grinding in a mortar with gum arabic. This gum emulsion may be dried upon glass plates, then mixed with finely-divided gelatine, and thus a dry and keeping preparation prepared, which has the advantage over the troublesome-to-prepare and dear, dry gelatine emulsion of commerce, that it can at once be dissolved. When the precipitate taken from under water is emulsionised with gum arabic all that remains to be done is to add it to the necessary quantity of gelatine and water in a bottle, and leave it to digest for an hour at 50° to 60° C., after which the emulsion is ready. The sensitiveness may be increased by frequently agitating during the digestion, as the gum emulsion will thereby be the more intimately united with the gelatine. * * * Finally: if after digestion at 50° or 60°, two per cent. of ammonia, at 0·910 sp. gr., be added to the above emulsion (which is then further digested for a short time at 30° to 40° C.), a still higher sensitiveness would be obtained." Herr Hennig developes with 30 c.c. of Dr. Eder's ferrous oxalate emulsion, to which a couple of drops of a saturated solution of chloride of mercury has been added, or with Kramer's mixed ammoniacal pyrogallic acid developer, or with Dr. Stolze's potash developer. A large quantity of the emulsion may be prepared in a couple of hours, with but a twentieth of the quantity of washing water usually required, and has the further advantage of a store of it occupying but little space.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician,
For the Week ending November 5, 1884.

These Observations are Taken at 8.30 a.m.

PERCENTAGE SOLUTIONS.

"What is a ten-per-cent. solution?" is an inquiry we frequently hear, and it has been renewed this week by a correspondent, who further asks "a full explanation." As, notwithstanding the apparent simplicity of the question and its answer, a good deal of misconception and even ignorance exists on the matter, we shall meet our correspondent's request as fully as possible.

We need not wander through the numerous replies we have received to the question when directly put to several persons who "ought to know," and really do if they only stopped to consider, but they generally amount to something like the following:—"A salt dissolved in ten times its quantity of water;" "water one part, substance dissolved ten parts; or water (or other liquid) containing one-tenth part of some other substance in solution." Now, on the face of it, the two first definitions are absolutely incorrect, while the third is so ambiguous in its terms as to be scarcely intelligible to the seeker after information.

In the first place, in the case of "a salt dissolved in ten times its quantity of water," there would result a solution consisting of eleven parts by weight (accepting the "quantity" of the salt dissolved as a "part"), but of which the *volume* would be unknown. This could in no sense be considered a ten-per-cent. solution; for, even if both salt and solvent had been *weighed*, the solid contents would be one-eleventh of the whole. If measured the proportions would be an unknown quantity. A nearer approach to accuracy—so far at least as percentage by weight is concerned—is attained in one of our answers—"one part of a solid to nine parts of solvent;" but this would be worthless if the resulting solution had to be *measured* out in small quantities representing a definite quantity of the substance dissolved. In brief, the only method is to take one part of the substance to be dissolved and *make it up* to ten parts of solution.

But then a difficulty arises, in this country at least, in the system of weights and measures in vogue, which, even when the true meaning of a percentage solution is thoroughly understood, renders its preparation, except in a few instances which will be noticed, a matter of troublesome calculation, involving fractions and divisions of quantities necessary to such an extent as to practically bar these solutions from use. On the continent, however, where the metric or decimal system prevails, the term "five-" or "ten-per-cent. solution" is in general use, and is as familiar as our own "thirty grains to the ounce," &c.

There are, however, one or two instances in which the term is familiar to English photographic ears—notably in the case of the "five-per-cent." bichromate solution employed in sensitising carbon tissue. This is as readily prepared without calculation as could possibly be the case if the metric system were in use; but we doubt whether in nine cases out of ten a true five-per-cent. solution is made—not that for this special purpose it matters much. The five-per-cent. sensitising solution is usually made by dissolving one ounce of bichromate in a pint of water, but that is "how not to do it." If the bichromate, however, be first dissolved in a smaller quantity of water, and afterwards *made up in bulk to a pint*, a true percentage solution results. But how many operators attend to this?

With the exception of the ounce avoirdupois and the pint when a solid is to be dissolved, there is scarcely another instance in which fractions and calculations can be avoided with our English weights and measures; but here, at least, we are on solid ground. The ounce avoirdupois, which is equal to 437·5 troy grains, is the weight of 480 minims (of ·911 grain each); this forms the "fluid ounce," twenty of which make a pint, weighing 8,750 grains, or one pound and a-quarter avoirdupois, which latter consists of sixteen ounces, or 7,000 grains. Thus it will be seen that it is possible without trouble or calculation to form true percentage solutions for such figures as 1¼, 2½, 5, 10, 20, &c., per cent. where not less than a pint of solution is required; but beyond that we cannot go far without resorting to fractions.

For instance: if we wish to make so small a quantity as two and a-half ounces (a fraction by the way) of five-per-cent. solution, we must calculate the percentage quantity in troy grains and fractions (in this case 54·6875 grains), unless, indeed, we are in possession of a-quarter of an ounce avoirdupois—a rare weight in the laboratory, though common enough in the office or library on the letter scales. But as we depart from multiples or aliquots of five the difficulties become greater still, except, perhaps, in a few cases where accidental coincidences arise.

For small quantities it is, of course, possible to use troy grains and minims in conjunction. Thus, forty-eight grains of a salt made up to one fluid ounce would be a ten-per-cent., or one drachm dissolved in two ounces forty minims a six per cent., solution. But this is after all but a clumsy mode of procedure, and not at all comparable with the neat and perfect metric system.

Here we have the unit of weight in the gramme and the unit of fluid measure in the cubic centimetre, the gramme being the weight of a cubic centimetre of distilled water at 15·5° Centigrade. The two terms are, in fact, practically identical in measuring; for a gramme of distilled water is a cubic centimetre of water—so long, at least, as the temperature remains at 15·5. Variations in temperature as well as the presence of the salts contained in ordinary water produce so slight a difference in the specific gravity that for most purposes they are ignored, and the gramme and c. c. are used indiscriminately for solutions. It results from this that if we wish to make a solution of *any* percentage by the decimal system we have only to take the number of grammes, whatever it may be, and dissolve it up to 100 c. c. in volume, *et voilà!*

We have referred to the metric system for the purpose of calling attention to a system used by some chemists in this country, by means of which the advantages of the former are secured without discarding the English weights. This consists in the plan of graduating the vessels of capacity in "grain measures," "decems," and "septems"—the "grain measure" being, in fact, identical with the minim, and the "decem" ten minims. A measure of one hundred decems (or one thousand grain measures) then takes the part of the French hundred cubic centimetre measure. The septem, or seven "grain measures," is the one thousandth of a pound avoirdupois, and this, though less useful than the "decem" graduation, enables aliquot parts of the avoirdupois system to be dealt with. Measures of all descriptions, graduated in this manner, can be obtained of all dealers in chemical glass, and we should recommend every photographer to be the possessor of at least one.

Returning to the question with which we started—"What is a ten-per-cent. solution?"—it will be plain from what we have said that it is a solution *measuring* one hundred parts, each of which contains one-tenth of a part of the substance dissolved. To attain this result ten parts of the substance must be dissolved—not in any definite quantity of solvent, but in a much smaller quantity—and when dissolved the volume is gradually made up to one hundred parts. As we have shown, the "parts" used in correlation must consist either of avoirdupois ounces and pints, or their multiples or aliquots, or of troy grains and minims. For small quantities especially we cannot too strongly recommend the convenience of the decimal system spoken of, as it gives all the advantages of the French metric system, with the additional one of retaining our own English weights.

THE BICHROMATE DISEASE.

It will be remembered that previously, on more than one occasion, we have directed attention to the pernicious action of the bichromate of potash upon the skin. We revert to the subject again more particularly as the various processes in which the bichromate is employed are now being worked more generally than at any previous period, and, in all probability, will be still more extensively utilised as photomechanical photography becomes fully developed.

The last time we referred to this subject was on the occasion of Dr. B. W. Richardson, M.A., F.R.S., &c., bringing it before the Medical Society. Since then that gentleman has not allowed the matter to rest; for in the current number of *The Asclepiad* he has an article *On Disease from Bichromate of Potassa.* The article is rendered the more valuable because it is illustrated with a couple of coloured photographs of hands, showing the disease in one of its worst—or we hope in *the* worst—phases it is likely to occur in connection with photography. These pictures fully exemplify how valuable is photography in illustrating pathological works; for it appears that the bichromate disease, from a written description, very closely resembles one or two other cutaneous diseases, from which, without knowing the surroundings of the case, it is difficult to be distinguished.

The former portion of the article is principally devoted to the consideration of the action of the bichromate upon the system when employed in its more concentrated form, and also when it is taken internally. This is given principally from the observations of MM. Chevalier and Bécourt. From these gentlemen it appears that in the manufactories where the salt is produced many of the workmen suffer severely from the fine particles of bichromate, which are constantly floating in the atmosphere, being inhaled through the nostrils. In time this frequently causes an entire destruction of the septum of the nose, and, curiously enough, when once this is totally destroyed no further inconvenience is experienced; for the disease appears to stop here, as the other portions of the nasal organs remain unaffected. Another curious fact is that those of the workmen who are habitual snuff-takers experience immunity from this nasal disease, and snuff is now actually employed as a preventive.

In connection with the manufacture of the salt, it is mentioned that if the epidermis be intact "the bichromate exerts no baneful influences. The hand may, in fact, be plunged into a concentrated and hot solution of the salt without fear. The hand may also remain covered with the salt for an entire day without any observed effect. But if the skin be torn or abraded, however slightly—by the prick of a pin, for example—a sharp pain is felt upon the exposure; and if the salt be left in contact with the wound the caustic character of the salt is brought out intensely, the cutaneous tissue is decomposed, and violent inflammation is established. These symptoms are accompanied with intense pain, especially in winter when the cold is severe. The action of the salt does not cease until the cauterisation has penetrated to the bone." This shows how careful we should be in using solutions of the bichromate, as, for instance, in sensitising carbon tissue that the hands should never be immersed in it if there be the slightest abrasion of the skin; or, if there should happen to be such, the salt should be at once removed by washing the part copiously with water and afterwards sucking the wound. These painful sores are not altogether unknown to several photographers.

The second portion of the article is that with which our readers will be the most interested, inasmuch as it deals with the particular form of disease experienced by photographers, which, by the way, is characterised as a "new form of disease." In it is the author's own valuable observations on the disease, as well as several extracts from The British Journal of Photography, on the pernicious action of the bichromate. The author, in describing the appearance of the disease, says that in the first case that came under his notice some of the affected parts very much resembled acute eczema, and others psoriasis palmaris.

In another instance Dr. Richardson says:—"The appearance in this case was not of eczema, but was so singularly true to *pityriasis rubra* that I should have entered it in my notebook as a good example of that disease in its sub-acute stage." This example, it may be mentioned, forms the subject of the photographic illustration, and shows that when the disease is far advanced it must necessarily be an exceedingly painful one, as the backs of the hands and knuckles appear to be covered with deep cracks or fissures, while the skin looks like hard leather which cannot be bent without producing other cracks.

Dr. Richardson mentions several other cases that have come under his notice, but the symptoms and appearance of the disease—at least in the eyes of a layman—do not differ from those already described. In the earlier stages of the disease the symptoms appear to be precisely those we have described in our previous articles on the subject. According to Dr. Richardson it requires many months' constant working with the bichromate to develope the disease, and it is consoling to photographers to learn that the disease is quite local—rarely extending beyond the parts that are in continual contact with the solution, or water used for developing the picture; also that it is only some workers who suffer, while others enjoy perfect immunity from the action of the bichromate. As an example, one case is quoted by Dr. Richardson of an operator having worked constantly at carbon printing for fourteen years without experiencing any ill effects whatever, except, on two occasions, when sensitising the tissue the solution had come in contact with an abrasion on the skin, and deep and painful ulcers were produced. These took many weeks to heal and have left deep scars behind. Once, however, during this period he suffered severely in the nasal organs for a few hours through inhaling fine particles of the bichromate.

On the question of treatment—the part of the subject with which many of our readers will be most interested: in the case of abrasion of the skin it is recommended to wash the affected part with feebly-alkaline water, then to poultice, and afterwards apply freely sub-acetate of lead in solution. With reference to the treatment of the disease itself, Dr. Richardson again quotes from our pages, and adds:—"In the cases I have seen I very much question whether any treatment was of much avail. It seemed to me that recovery commenced when the cause of the evil was withdrawn and nature followed her own course. I see quite well how recovery would follow on removal of the local cause without other aid, and I do not see any *rationale* for the remedies that were tried, with one exception. It is clear that the local application of the sub-acetate of lead is attended with good results in relieving the local irritation, and perhaps in arresting the discharge. I have used it with certain benefit in the cases under my care."

As a preventive of all forms of bichromate disease, it is recommended to avoid the salt or its solutions coming in contact with any of the surfaces of the body. "The wearing of a mask while at work, or while exposed to the bichromate dust, would prevent the nasal affection; and the wearing of an impermeable glove or gauntlet while working with the solution would prevent the cutaneous affection." We may add that india-rubber gloves are now being used by several workers of the carbon process who have previously suffered from the cutaneous disease, and they now experience no ill effects whatever from following their avocation.

In a pathological commentary—the major portion of which will be better understood by the medical profession than by the bulk of our readers, but from which we cannot refrain from giving an extract, as it contains a speculation as to the part that light may possibly play in certain diseases—Dr. Richardson, after concisely describing the action of light on bichromatised gelatine and the details of the carbon process, adds:—"By a process similar to this or identical with it the bichromate, I believe, acts upon the gelatinous structures of the body. It changes their molecular conditions, and renders them insoluble. That leads to an arrest in the living dialysis and in the transudation of fluid. The arrest leads, in turn, to perversion of function, to congestion, and to all the subsequent phenomena. Here, then, is a suggestion for a new departure in research. Are there no other substances capable of producing similar changes? Is it not very probable that on the surface of the body some oxidised products locally evolved may lead to similar molecular changes on gelatinous structures, and to similar local manifestations? I think it is most probable, and that in the study of the action of light on local diseases we touch, etiologically and pathologically, some great discovery."

NATURE AND ART.

When we recollect that it is only some thirteen or fourteen years since the retouching of negatives in this country became at all well known (or, indeed, recognised) as a legitimate mode of treating a portrait negative, it may well cause surprise to see how universal the practice has become—a surprise which, unfortunately, we may say, is too often coupled with dismay when some examples fall under our notice. With regard to the fell mode in which beautiful photographic work may be treated by the mechanical stippler we must, in justice, remember that with retouching, like all other arts, there are many grades of skill—not only grades of skill in the worker, but grades of appreciative power in the sitter. The photographs that would satisfy Bond-street would scarcely find appreciative critics in the New Cut, and between these there are all shades of skill and of criticisms.

The original idea that actuated the retoucher—how this very word itself, now a recognised term, used to be objected to!—was the softening of harsh wrinkles and the smoothing down of rugosities produced by the unequal power of colours in their reproduction by photography. Gradually, however, the work of the retoucher assumed a more important position, and now so important a factor has he become that not only would the public reject any picture not handled by him, but photography has become secondary to retouching—artists of great skill being employed to do this work. There is, still, a limit to the retoucher's power, and certain work has to be done external to his. The hold that retouching has obtained is to be deplored on many grounds; but the visibly growing taste for truth and art, and truth in art, leads us to hope that the future may see improvement rather than retrogression in the character of the photographs that are to be.

Still, human nature has to be considered. Most people have some little vanity, and prefer a little flattery rather than a caricaturing of their lineaments such as a plain photograph not unfrequently perpetrates, and to prevent which the successful photographer will resort to all kinds of expedients. A just photograph does not necessarily give a mathematical delineation of the sitter's face and form as a rule and compass would set them out. We all form a mental conception of our friends which is usually very different from the actual facts of the case, as a tape measure would show, and we should like to have that conception realised when the photographer sets to work. If he sometimes exceed that conception and produces a grossly-exaggerated portrait it must be charitably put down to his good nature, and a hope may then be expressed that he will improve in the future. In giving any hints as to methods adopted we must be understood as describing them for the benefit of truth as well as harmony, and not as a presentation of aids to pictorial frauds.

A correspondent asks us about a method of producing dimples. The experienced retoucher knows that, unless the negative be locally reduced and then retouched to form, no amount of ordinary retouching will produce a shadow or hollow except by the aid of the needle-point, which in skilful hands is capable of very marvellous effects. What is really referred to is, we expect, a treatment of the sitter's own face; and, to show the extent to which vanity will prompt some people to tamper with nature, we here give an extract from the *Chicago Herald*, though as to its trustworthiness we have to say we possess no means of forming an opinion:—"The artist in dimples places a small glass tube over the spot where the dimple is designed to appear. The air is sucked out of the tube, thereby raising a small protuberance of skin, which is ligatured, or tied with a piece of fine silk, and then duly snipped off with a keen knife. The wound is next bound up, a silver cone, inverted, being placed over it so as to mark its centre. The part is 'dressed' daily, and after the lapse of five days, as a rule, the injury has healed, and in its place appears the 'coveted dimple.'"

Then, again, freckles are positively said to be in demand, a peculiar sand termed "freckle sand" being commonly employed to produce them, though the more superior description are hand-painted at half a dollar a freckle and are warranted to last three days! With examples like this before him, can it scarcely be wondered at if the photographer, too, while professing to hold the mirror up to nature, allows his hand to waver a little, and so cause a few peculiarities to remain hidden, while beauties are rendered visible that were hitherto undreamt of.

If there be one thing more than another that a lady is sensitive about it is her figure. The days of tight lacing have most decidedly not gone by, and the photographer has to do his share in producing a similar effect. In many establishments it is the custom uniformly to take a few inches from every lady's waist by carefully stippling out a portion of the figure and adding it to the background. This, which we can assure our readers is practised to a very considerable extent, may be much more readily done when the background is not quite plain, after the style affected by some artists. It is almost impossible to do it thoroughly successfully with a plain background, and in any case a little "spotting" is usually required upon each print to hide the retoucher's work.

If any of our readers will examine an album full of portraits, he will find that the bulk of them are represented with eyebrows which, from the centre of the arch outwards, seem to dissolve away into nothing, no matter how thick they may be as they approach the nose. The reason of this is the overmastering property of light-coloured objects to swamp any delicate shades or colours in near proximity to them. The outer portion of the eyebrow is always thinner and more sparsely furnished with hair, the consequence being that in a photograph they become "killed." To remedy this many photographers instruct their operators to carefully pencil each portrait where the eyebrows do not show well. By far the better plan, however, is to pencil the sitter himself. A little black crayon rubber over a piece of brown paper, and a small artists' stump to take it up and pencil the eyebrows with, particularly the side nearest the light, costs next to nothing, and may be applied so as to give a far more truthful representation of the sitter's appearance than if nothing had been done to cause them to come out with due distinctness and depth beyond working upon every individual print. This expedient is as legitimate as it is useful.

As to freckles: there is little to be done with them but to paint them out of the negative one by one. It has been recommended that just before being photographed the sitter should wash the face with warm water, which, by producing a ruddy glow upon the skin, would prevent the freckles showing. We can only say that we never heard of any professional photographer adopting any such plan, and indeed it is not likely he would attempt it.

A well-known lady photographer on the continent used to surmount all difficulties by carefully painting not the negative but the sitter himself, who before being placed in front of the camera was so bepowdered and painted that his (or her) features were quite a work of art to contemplate—eyebrows, face, mouth, nose, all being painted; the result was that the photographs possessed an extreme delicacy which in some cases, especially with ladies, was most effective. We doubt, however, if English sitters, in their own country at anyrate, would permit such preliminary liberties to be taken with their august persons. Powder may be, and is, used to aid in giving delicate complexions; but it has to be most dexterously applied to the face to avoid a patchy effect, which at once would tell what had been attempted, and which is next to impossible to eradicate on the negative by the use of the pencil.

We may conclude by giving a few hints upon the treatment of hair. We well remember a number of years ago being induced to take a picture of a friend whose hair was the extremist of reds, and, besides, lay flat and devoid of gloss. If his locks had been of raven hue they could not have come out blacker in the photograph than they did; but, having heard that powder was the thing to employ, we spread a towel over his shoulders and well powdered his hair before taking the next negative. The result then was that his hair was white. By degrees we found that the needful effect in the photograph was to be obtained by a mere sprinkling of powder to so small an extent that at half-a-dozen yards' distance it could not be noticed. It will be found that when so-called "red" hair, as also the yellow and tawny shades, is very slightly grey no powder will be needed to cause the photograph to suggest the right depth of shade. These little hints which we have gleaned in conversations with our professional friends may be of use to the less experienced of our readers; but we would earnestly recommend them to use them as sparingly as possible, to put as much pure photography in their works as they can, and, instead of making artifice and the *retouch* the main object, let them rather make art subservient to nature.

THE PHOTOGRAPHIC EXHIBITION.

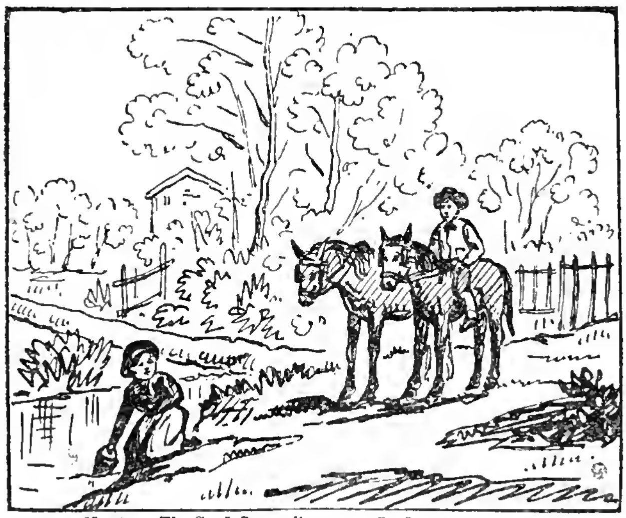
[Final Notice.]

A medal has been awarded to Mr. Herbert B. Berkeley for a series of excellent little landscapes printed in platinotype. The variety of tones now attainable by this process is well shown in the few specimens exhibited by Mr. Berkeley. *The Keep, Corfe Castle* (No. 208), presents a pleasant, cold grey tone, while the next (No. 209) reminds us more of an old sepia. *A Drowsy Day* (No. 221), is a clever composition of landscape and river, with a number of cattle lazily cooling themselves in the stream.

Mr. T. M. Armstrong exhibits a few clever instantaneous pictures of steamers in motion, but his best picture is a quiet piece of nature, *The Silver Sea* (No. 277), in which the "moonlight" effect is very pleasing.

Mr. Robert Slingsby only shows two pictures this year—*Tales of Other Lands* (No. 281), a couple of children deeply engaged in an interesting story book, and *A Portrait* (No. 372)—both of which are excellent in technical qualities.

Mr. Lyddell Sawyer has quite a number of studies, in which figure and landscape are combined. Of these we have chosen *The Good Samaritan* (No. 315), though there are, perhaps, others



No. 315—*The Good Samaritan.* By Lyddell Sawyer.

equally good in the collection. The "good Samaritan" takes the form of a girl, who is drawing water from a brook to give a drink to a couple of thirsty horses returning from their day's toil. The suggestion of sunset or twilight conveyed in the picture is very clever. *Come Along, Granddad* (No. 316), and *The Sisters* (No. 500) are also well conceived.

The Rev. H. J. Palmer's *Portrait of Mr. Gladstone* (No. 290) is a thoroughly good production by an amateur under the difficult circumstances of having to operate in an ordinary room. Mr. Palmer's *Porch of the Cathedral of Chartres* (No. 404) is also a clever piece of photography, as well as a fine architectural study.

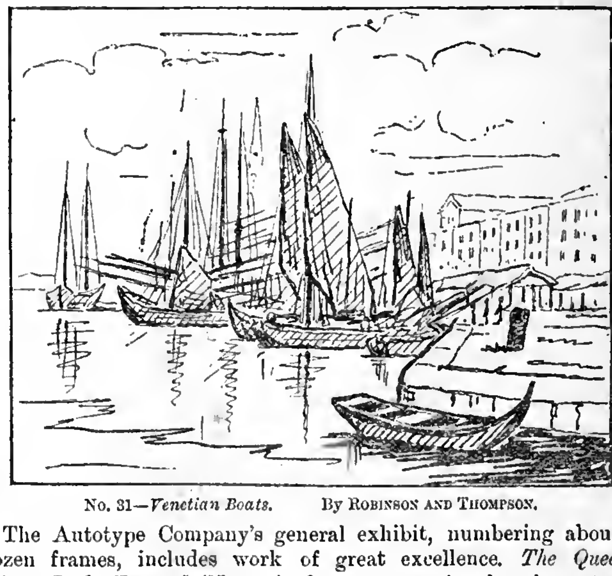
The Rev. H. B. Hare is well represented by a number of pictures of different types—landscape chiefly. *Too Deep; Neddy Won't Go* (No. 334) tells its own story of the "donkey who is not fool enough" to go out of his depth in crossing a doubtful ford. *The Deserted Mill* (No. 336) is a quiet and suggestive piece of landscape.

The Woodbury Company do not exhibit profusely, but the quality of the work shown is quite up to the average mark, if not beyond it. *Lady and Dog* (No. 364), from a negative by Messrs. Downey, is a really charming picture, and it is difficult to decide which to admire most—the admirable posing of the subject or the excellent rendering, in the enlargement, of the various textures, especially the silky coat of the little terrier. A three-quarter length portrait of *H.R.H. The Princess of Wales* (No. 165), and busts of *Miss Maud Branscombe* (No. 166), and *Miss Mary Anderson* (No. 196), all from negatives by Messrs. Downey, are fine works.

No. 364—*Lady and Dog.* By The Woodbury Company.

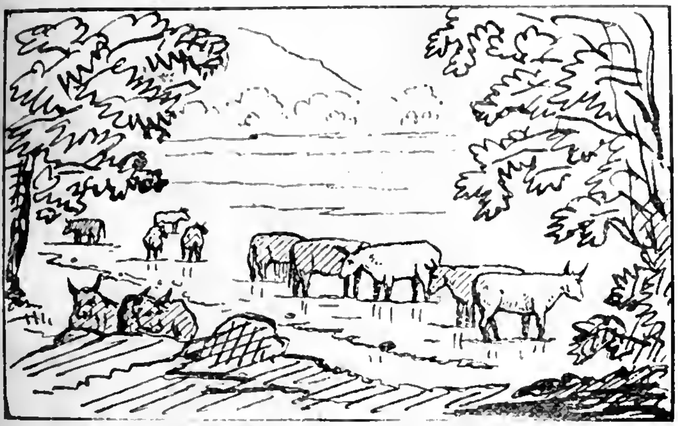
Mr. William England shows a single frame containing four large Swiss views, measuring something like 18 × 15. Mr. England's work has been familiar to not only visitors to the annual exhibitions, but to nearly the whole world, for years past; but, however good it has been previously, we are constrained to confess that his first venture into a large size seems to us to show better work than ever.

Messrs. Hunt and Thornton exhibit four frames of enlargements on opal, which possess good qualities. No. 434 is especially good in tone, though the subject is not a very prepossessing one.



No. 31—*Venetian Boats.* By Robinson and Thompson.

The Autotype Company's general exhibit, numbering about a dozen frames, includes work of great excellence. *The Queen's View, Loch Tummel* (No. 10), from a negative by the veteran G. W. Wilson, forms a handsome picture of a well-known piece of Scottish landscape. *A Peep at Derwentwater*, by J. G. Sinclair (No. 135), to which in conjunction with No. 217 a medal has been awarded, is of mammoth size, and, despite our dislike to these immense pictures, we must confess it to be one of the finest enlargements we have seen, Mr. Donkin's *Matterhorn* (also enlarged by the Company) being the only one of similar dimensions that can approach it. *The Interior* of the *Church of the Knights of Malta* (No. 217), from a negative by Signor A. G. Tagliaferro, is the much-abused picture several correspondents have told us about; but, as we remarked in connection with the smaller picture, whatever its mathematical defects may be it is a good photograph *and* a picture, and the enlargement rather enhances its beauties than its defects. *Cattle at Noontide* (No. 472), a sketch from Ulswater, by Mr. J. G. Sinclair, and exhibited in its enlarged form by the Company, is chosen for illustration; but it is impossible to convey in a mere line block the idea of delicate distance and bold foreground which the picture itself shows.



No. 472—*Cattle at Noontide*. By The Autotype Company.

Mr. H. Forsyth is specially good in his landscape work, and it is a pity his subjects are not more varied that we might see his powers in other classes of landscape. Of his three views, *On the Wharfe* (No. 428) strikes us as decidedly the best, the atmospheric effect, delicacy of the distance, and boldness of the foreground combining to make it a most exquisite picture. His two views in *Bolton Woods* are also fine pieces of work. One further word in Mr. Forsyth's favour is that he makes his own plates. Perhaps a good many who "score" medals know what that means, especially when 15 × 12 is the size.

No. 550—*A Reverie*. By Edwin Smithells.

We shall group together (though not so in the catalogue) the frames of Messrs. W. Wainwright, Jun., and J. C. Stenning—two members of the Amateur Field Club—whose subjects in the main appear to have been selected from very much the same source—the Lake District, the *locale* of this year's *rendezvous* of the Club. Mr. Wainwright's *Colwist Force* and *Stybarrow Crag*, in No. 366, are remarkably good, both as pictures and as photographs; and in the same frame is a fine piece of woodland scenery in a view in Bromley Hill Park. Mr. Stenning's *Stybarrow Crag* (No. 423)—two views, if we mistake not—will compare with Mr. Wainwright's; but the best picture in the frame is the centre one—a study of ferns and foliage—one of the most exquisite "bits" it is possible to find. Mr. Stenning's *Swiss Scraps* (No. 502) are also good.

Mr. Charles Andreæ (also a member of the Field Club) exhibits a *Stybarrow Crag*, but devotes his attention chiefly to other subjects. His *Interiors of Worcester Cathedral* (No. 430) are especially good, and also his instantaneous *Views of London Streets* (No. 410).

Mr. Wm. Brooks's picture, *The Wreck* (No. 538), is aptly described in the accompanying lines from *The Tempest*—"A brave vessel, dashed to pieces!" It represents an actual wreck—or what remains of it—on the Cornish coast. If we recollect rightly it is the ill-fated steamer "Brest." Whatever the vessel may have been, the picture shows the probable results of venturing too near the picturesque but dangerous coast of our most southerly county.

There are, no doubt, many more pictures in the Exhibition which fully deserve notice; but life is not long enough—or, rather, the days at this time of year are not—to permit us in our spare moments to get to know *all* the exhibits. For our sins of omission we must, therefore, in closing our notices, beg our critical readers to excuse us.

APPARATUS.

Although not entered in the catalogue, having been received too late, there are two well-made examples of the patent multiplex back, patented by Messrs. J. Hare and H. J. Dale. These, with the other exhibits, receive much attention from the visitors.

The leading feature in a camera exhibited by Mr. Herbert S. Starnes is that which is implied in the catalogued title, "combined camera, changing-box, and plate-box." The plates are stored in a box to which admission is gained from the interior of the camera, and, by inserting the hands through light-proof coverings, they may be raised up to the place of exposure and again removed and placed in the grooves of the box below.

A shutter, the movement of which may be either instantaneous or protracted at will, attests to the inventive faculty of Mr. Thomas Furnell. It consists of two flaps, one above and the other below the lens, moving in succession, so that when the lens is uncovered by the motion of one it is quickly capped by that of the other. By mechanical means this action is either instantaneous or very slow, or it may even be arrested midway. The shutter is operated by a string or piece of twine, which is enclosed in a rubber tube. Pressure upon the end of a ball at its termination effects a loosening of the tension upon this string and a corresponding action upon the mechanism.

The exhibits of Messrs. Sands and Hunter are somewhat numerous, and are such as to keep up the excellent position this firm has secured in the world of photographic mechanics. They exhibit a book of an ingenious construction for containing plates; a camping lamp, which, we think, must prove very convenient indeed; a whole-plate reversible camera; a camera of same dimensions fitted with their "patent swing," and another with reversing action. The workmanship of these is all that can be desired as regards fitting and finish.

Messrs. J. L. Lane and Sons have a useful class of exhibits, well made and well finished. This applies to three cameras which we examined, as well as to a large slide and a stand.

Mr. H. Moorse appears to be one of those who have not been up to time, by which we mean sufficient time to have had his exhibits entered in the official catalogue. We, however, noticed among the various contributions a light yet very steady stand, bearing the name of this maker.

Concerning the apparatus as a whole, we may say that this department appears to have been a most attractive feature in the Exhibition; and, such being the case, it ought to be encouraged and special arrangements made in order to its being duly managed so as to be productive of most good.

It may here be observed that hitherto no medal has been awarded for apparatus; but (we quote from the address of Mr. J. Glaisher the President, when awarding the medals on Tuesday evening last) certain features of novelty in a camera exhibited by Mr. S. D. McKellen, of Manchester, were, in the estimation of the Committee of Awards, so excellent as to warrant them in giving a medal to that gentleman.

We learn that the Exhibition of the Photographic Society of Ireland (Dublin), which will be opened on Tuesday next, the 18th instant, in the presence of the Lord Lieutenant, promises to be of exceptional excellence. There are upwards of six hundred frames, forming almost a representative collection. The medals will be awarded—not, as usual, by appointed judges, but by the general vote of the members.

At the Exhibition of the Newcastle and Northern Counties Photographic Association, which was opened on Tuesday last, the exhibits, which are confined to members, number upwards of one hundred and twenty. Mr. J. P. Gibson, of Hexham, took the medal for the best set of three pictures; and Mr. Goold, of Newcastle, the prize for members who had not previously taken a medal or diploma. The competition for the presentation picture of the Society will not be decided until Tuesday next, the award being made by the votes of members. We hope to give a more detailed report of the exhibition next week.

Mr. W. W. Winter, whose name will be familiar to those of our readers who take notice of the medallists of the year, and whose works at the Exhibition in Pall Mall have received favourable comment, does not appeal to the artistic feelings of his *clientèle* through his photographs alone. He caters for a still larger public, and the inhabitants of Derby and its neighbourhood have lately had an opportunity of seeing at his extensive premises—which embrace large exhibition rooms in addition to his portrait studios—a large collection of works of art contributed by competitors drawn from many and distant quarters. Yesterday week, as we learn from the *Derbyshire Advertiser*, he was honoured by the presence of the Mayor and Mayoress of Derby, many town councillors, and a large and influential gathering of ladies and gentlemen to witness the distribution of the prizes and diplomas to the successful competitors. The proceedings passed off with complete success.

The name of Dr. Kayser, in connection with photographs of lightning flashes, is well known; but at a meeting of the Berlin Meteorological Society last month he exhibited a photograph very unlike the ramified pictures now so familiar. This particular picture showed four unramified, irregularly-undulatory lines, running in exact parallels from top to bottom, which must, by reason of their parallelism, have arisen simultaneously or immediately after one another in order that their discharges should have pursued the same track. The first flash was further distinguished by a series of light layers attached to one side of it. Dr. Kayser assumes that a double discharge had taken place, and the course had been displaced by reason of a strong wind. Knowing the rate of the wind he was able to calculate approximately the time between the discharges to within some hundredths of a second.

Our readers have heard of the identiscope and the Claimant, the inventor of which instrument asserts he has discovered a true means of establishing identity by superposing two portraits upon one another, when, if certain fiducial points coincide, he holds it proved that the pictures are of one and the same individual. The theory is very pretty, but Mr. Francis Galton—who ought to know more than anyone else of the effect of superimposed pictures—utterly demolishes the theory and completely exposes the fallacy in *Nature* of the 13th ult. At the commencement he points out that in the campaign which, according to the *Pall Mall Gazette*, is about to be run in the country on behalf of the Claimant by "six of the best orators whom money can collect, * * * supplied by a hundred identiscopes, the pictures to be combined will be not photographs, but drawings in bold lines made from them." However, even with photographs Mr. Galton shows the untrustworthiness of the method of the identiscope, and in every way points out its uselessness. He concludes—"First, that the fact of two photographs blending harmoniously is no assurance of the identity of the persons portrayed. Secondly, when drawings made from portraits are shown to blend, it does not follow that the portraits from which they were drawn would blend equally well. And, lastly, the photographic print of the iris of the eye (the point of departure in this comparison of identities) does not afford a trustworthy unit of measurement." We are, therefore, enabled to hope that photography may not be called in to aid in this gigantic imposture.

Speaking of experimental photographs, we read in *Science* that among the papers announced to be read at the Newport meeting of the National Academy of Sciences, on October 10th to 16th, is one on an experimental composite photograph of the members of the Academy.

Readers of Professor Tyndall's *Forms of Water* will be familiar with the fact of the gradual flow of the huge glaciers, the "sea of ice," &c., with his modes of measurement for proving the existence of the flow. To achieve the same object Professor Simony has recently taken a large number of photographs of the summit of the Hohe Dachstein, of the Gosan Glacier, and the Karls icefield, in order to execute future measurements. The plan is certainly excellent, and will enable the more laborious part of the work to be performed in the study, instead of upon the face of the ice with the mercury of the thermometer almost out of sight.

An interesting paper on thermometers was read before the same meeting as that to which Dr. Kayser's photographs were exhibited. In it the writer, Professor Förster, reported several series of experiments in the measurement of heat carried out by the Standard Commission under his direction. As a result of these investigations it appeared that the possible errors, even for the best thermometers, were very considerable—so much so that it was found a displacement of the fixed points by several degrees might be brought about by repeated heatings up to 100° C.

"Wanted, a photograph!" Any photographer who can obtain a photograph of the latest addition to our knowledge of natural history would be sure of an immense sale for his picture. He will have no further to go than a small island on the river Amazon, and the object to be photographed is a small bird called a "gipsy" by the inhabitants, but whose claim to fame rests not upon its name but upon its possession during the early period of its existence of four feet. The fact that monotremes were oviparous with mesoblastic ovum was considered to be the most important intelligence ever sent by Eastern cable; but this fact, if fact it be, of a four-footed bird is still more wonderful. Who will produce the first photograph?

If a little time ago we gave our readers extracts from the works of some eminent astronomers which were the reverse of encouraging to those who have the welfare of photography at heart, we may this week point to the words of one of our foremost English astronomers who, so far from depreciating the usefulness of photography for scientific purposes, reaches a pitch of enthusiasm in describing what has been done, and what under certain easily-realisable contingencies could be done, by the combined aid of optics and photography. The Cantor lectures, delivered by J. Norman Lockyer, F.R.S., on *Some New Optical Instruments*, are most interesting to read, and the latter one, which is devoted in the main to photographic astronomy, will be given in a future number.

Twenty years ago the man who would have predicted that photography was likely to prove such a stepping-stone to fortune that the high office of Lord Mayor would be held by one who had attained a commanding position by the commercial pursuit of the art would have been a fair butt for sarcasm. Yet, as our readers are aware, such a hypothetical vaticination has been fulfilled this year in the election of Alderman Nottage as Lord Mayor of London. Mr. Justice Grove, acting in the absence of the Lord Chief Justice at the official reception of his lordship, made a happy allusion to the Stereoscopic Company, tracing the invention of the stereoscope to Leonardo da Vinci's discovery of the true functions of the eyes in binocular vision, he having pointed out (in his treatise *Trattato della Pittura*), that each eye saw a different picture, the coalescence of which enabled the sensation of relief to be felt. The speaker also bore high testimony to the present position, and the possible future, of photography. We are sure that all our readers will join Mr. Justice Grove in his congratulations to the Lord Mayor upon his acceding to the dignity of the high office, and they cannot but possess a feeling of gratification at the dignity of their profession in reading the learned justice's further congratulations to the Lord Mayor, upon "having in your honourable pursuit been connected with matters of such great interest, differing so greatly from the common matters of business with which most Lord Mayors have been concerned."

RECENT RESEARCHES IN THE CHEMISTRY OF THE HALOGENS.

All students of photographic chemistry will be careful to note anything which is done towards extending our knowledge of the reaction of the halogens. A great deal has been written of late upon the affinities of the halogens and the inverse displacements—so difficult to comprehend—which the haloid silver salts can be proved to undergo under certain conditions. Thus, it has long been known that, in the general way, the affinities of the halogens are in the order—chlorine, bromine, iodine, fluorine; but that, under certain circumstances, the affinities appear in the inverse order. Berthelot, who has given much attention to this question, has recently published some most elaborate researches, which seem to prove conclusively that these displacements are in perfect accordance with the law of "thermic maximum;" that is to say, that the system which disengages the most heat is formed by preference. It is not, however, very comforting, from a photographic point of view, to know that thermo-chemical laws are able to explain the apparent capriciousness of certain elements, inasmuch as the reactions which take place in photographic operations are generally too complex and on too small a scale for calorimetric investigation.

Some light has recently been thrown upon the peculiar properties of silver iodide when heated. Rodwell found that the iodide suddenly contracts considerably between 142° and 145·6°, and afterwards expands regularly. Mallard and Le Chatelier have recently shown that silver iodide is dimorphous. These investigators found that on reaching 138° the colour of silver iodide suddenly changes from deep yellow to a yellowish-white, and, when examined by polarised light, it is proved to pass from the hexagonal to the cubic system at a temperature of 146°, absorbing 6·8 calories in the change. This change of crystalline form and absorption of heat would sufficiently account for the sudden contraction observed by Rodwell.

A great deal of attention has lately been paid to the methods of separating the mixed halogens in analysis, and, as this is a question which intimately concerns the quantitative analysis of photographic chemicals, it will perhaps be useful to give a brief summary of some of the more recent methods which have been suggested. The following method has been proposed for detecting traces of iodine in mixtures containing large quantities of chlorine and bromine. It is in reality a modification of Duflos' process for determining the iodine in iodides by boiling with ferric chloride, and condensing the vapours in a concentrated solution of potassic iodide. This method is not applicable when bromides are present, as bromine passes over with iodine; but if ferric sulphate be employed instead of the chloride only the iodine is volatilised. This reaction may be conveniently used for testing commercial potassic iodide for chlorine, as all the chlorine remains behind in the retort, quite free from iodine.

Bloxam has proposed a simple plan for separating silver cyanide from silver chloride by treating the mixture with hot dilute nitric acid, in which the cyanide is soluble.

A simple method for the estimation of mixed chlorides, bromides, and iodides is based upon Field's observations on the conversion of silver chloride into bromide by the action of potassic bromide, and of the bromide into iodide by potassic iodide. The mixed haloid silver salts are dissolved in an aqueous solution of potassic cyanide of just sufficient strength to dissolve them completely. Potassic bromide is now added equal to the weight of the original silver salts, and the excess of cyanide is decomposed by sulphuric acid. The precipitate now contains only bromide and iodide of silver. It is weighed, and again dissolved as before. Potassic iodide, equal to one and a-quarter times the original weight, is added, and the excess of cyanide decomposed as before. The precipitate now contains only silver iodide, which is weighed, and the proportion of chlorine, bromine, and iodine is calculated from the difference in the three weighings.

J. Vincent Elsden.

FIXING SILVER PRINTS WITHOUT HYPOSULPHITE.

It is a well-known fact that small quantities of chloride of silver are soluble in ammonia, as well as in the chlorides of sodium, ammonium, &c., and though solvents are not sufficiently powerful to be used as fixing agents for silver prints.

Being engaged in the production of transparencies on glass by the aid of the collodio-chloride process a few days ago, I was struck by the thin layer of chloride and citrate of silver contained in the films, and at once tried the action of the above-named solvents on them.

Liquid ammonia cleared the films immediately; a concentrated solution of common salt took about five minutes to dissolve the whitish film, the chloride disappearing before the citrate.

I next tried to fix untoned collodio-chloride prints upon paper in the same way. Ammonia has the same effect as the usual five-per-cent. solution of hyposulphite, but one cannot think of using it in large quantities in open trays, because of its fumes.

Solution (concentrated) of chloride of sodium is a little slow in action. I, therefore, tried a saturated solution of chloride of ammonium, in which I left the prints for an hour. It may be that a shorter time is sufficient or that longer soaking is necessary, but my observations lead me to think that one hour is a safe time. The prints came out of the bath with the same brownish-yellow colour which also the hyposulphite imparts to them. I washed the prints for one minute under the tap, dried them, and exposed them—one half being covered with black paper—to the light. Till now they have had only a few hours of sunshine and ten days of diffused light; not a trace of difference is observable in the protected and the exposed parts. Of course, this time is not at all sufficient to prove that the fixing is perfect. I shall leave the prints in the window and report on their behaviour.

I next toned a batch of prints in an old toning bath of tungstate of soda, very weak in gold, for the usual time of ten minutes, and kept them for an hour in the chloride of ammonium. After drying they had an unpleasant slate-blue colour, showing that too much gold had been deposited on them. I, therefore, prepared another batch of prints, which I left only one minute in the gold bath; in the chloride bath they took a vigorous purplish-brown colour, but showed to be somewhat over-exposed, although I had taken care to print less than for hypo. fixing.

Now, if this way of fixing prints will prove to be safe—which only time can teach us—we shall have the advantage of doing away with hyposulphite, of using less gold for toning, and shortening the time of printing.

Comparing the prints with others fixed with hyposulphite, I find that the finest half-tones are better preserved, and that from under-exposed negatives better results are to be obtained.

If the chloride of ammonium do not sufficiently fix the prints I am sure we shall succeed by adding to it some ammonia. The fixing might be done in the upright vessels in which the prints are hung.

Since writing the above I have tried to fix bromo-gelatine plates of different makers in the saturated salt solution, and I think with perfect success. It takes from two to three and a-half hours to clear the film; addition of liquid ammonia hastens the process.

Albumen paper prints lose their chloride in the bath, but the albumenate of silver remains and deepens in colour by light.

The collodion prints show no sign of alteration in light up to the present time.

Ed. Liesegang, Ph.D.

SULPHITE OF SODA IN THE DEVELOPER.

After a careful consideration of the several experiments described in the editorial article last week, I am inclined to think that the difference of opinion concerning the true function of sulphite of soda in the developer (there referred to) is not satisfactorily explained by the hypothesis that sul*phate* of soda was present in my previously-recorded experiments, which had led me to suppose that sulphite of soda greatly retarded development. My reason for doubting the sufficiency of the explanation will appear directly.

In the meantime I may just say, in reference to the Editors' remarks on "things of an opposite character," I am willing to allow the stricter accuracy of their phrase—"different degrees of the same character;" but the general sense of my argument seemed to require the word "opposite." Further: respecting the assumption that because an agent is a developer it, therefore, cannot be a retarder of development, I respectfully refer the Editors to an article at page 501 of The British Journal of Photography, on *Gallic Acid in the Developer—A New Restrainer*, for confirmation of the seeming paradox.

Now for my reasons for venturing to question the Editors' explanation of the difference of opinion before referred to. If they will take the trouble to look at the details of my experiments, as previously described, they will see that I make my sulphite of soda by adding sulphurous acid to a solution of carbonate of soda immediately before development; and, therefore, it is not likely that sulphate of soda could be present (unless the acid were impure), because there was no time for oxidation to take place. Still, a developer thus prepared was found to work much more slowly than pyro. and carbonate of soda alone, so I came to the conclusion that sulphite of soda exercised a retarding action on development.

However, the admirable experiments recorded in the editorial article under consideration appear to leave very little room for doubting that I was mistaken in my supposition. I now think that the fault which was ascribed to sulphite of soda was, perhaps, due to another agent, unsuspected at the time, namely, carbonic acid; for, according to Fownes, "even boiling water absorbs a perceptible quantity of this acid, so, of course, more or less of it would necessarily remain in the developing solution." It is probable the action of this acid, *and not the sulphate of soda*, as alleged by the Editors, may explain the difference of our conclusions, and this conjecture is supported by the facts that the bicarbonates do not promote development, and the subcarbonates are more energetic than the carbonates. Moreover, all this seems to agree with a new fact which I have observed when mixing pyro. with one or the other of the sulphites to preserve it. Thus, when the pyro. is dissolved first in a given quantity of sulphurous acid, and a saturated solution of carbonate of soda, potash, or ammonia is added until neutralisation takes place, the mixture is clearer than when the pyro. is dissolved in a solution of sulphite of soda directly. I was perplexed with this fact, but the theory that carbonic acid is a powerful restrainer of development fully explains it.

In conclusion: I will only ask that my remarks from first to last may be regarded from a practical point of view. It has not been my intention to attempt to cope with the Editors on theoretical ground, for I well know their strength and my own weakness thereon. W. Hanson.

[We are glad our valued correspondent is willing to (shall we say?) meet us half way. With regard to the question of sulphurous acid we may, however, say that that is quite as likely to oxidise before as after conversion into sulphite if kept in solution. As regards the gallic acid parallel—or suggested parallel—there can be no analogy, since gallic acid, though a developer in conjunction with silver, is not necessarily so in conjunction with alkali. The *crux* of this particular question lies here:—Sulphite of soda *plus* pyrogallol will develope a picture; gallic acid *plus* pyrogallol will not. Therefore it is not on all fours with sulphite. Turning to carbonic acid: we called attention to its restraining action when Mr. J. McKean published his *New Departure in Alkaline Development*, and we are at present engaged in a series of experiments with a view of fixing its actual restraining power, of which there is not e least doubt.—Eds.]

PHOTOGRAPHIC INDUSTRIES.

A LANTERN SLIDE PAINTER'S STUDIO.

The leading characteristic in the painting of a lantern slide, as contrasted with any other class of painting extant, consists in this—that the former must be so finely executed as to bear being examined through a somewhat powerful magnifying glass. In the small space of three inches, more or less, such an amount of detail and finish has to be compressed as to stand critical examination when enlarged to twenty or thirty feet.

Photography, when employed as a means of reproducing a sharp original, does so in a manner which is quite as perfect as the most fastidious can desire, even when such reproduction is on a scale of magnitude far transcending the original as measured by angular extent. But, in every instance in which the peculiar skill of the colourist or painter is employed in the construction of the picture that is to be examined under these enlarged conditions, the skill must be of an order altogether different from that displayed by ordinary painters on canvas, because the result of the artistic ability of the latter is to be submitted for the examination of the public under conditions of diminution, this being dependent upon the distance intervening between the spectator and the painting; whereas, in the former case, every detail is intended to be practically examined through a magnifying glass having a considerable degree of power. The skill required by the lantern transparency painter is, therefore, much in excess of that of the painter on canvas, seeing that he must produce an effect similar to that of the artist who works on the large scale of delineation, while he must do so with microscopic skill in almost microscopic dimensions. The painting of a lantern slide is, therefore, a work involving a far higher degree of skill than when the result is a picture of large dimensions.

London can justly boast of being the residence of several artists who make a *specialité* of lantern transparencies, and who have made for this city a name and reputation. A special request preferred to one of these artists, Mr. Chatham Pexton, of Bryantwood-road, Holloway, whom we had known as the producer of several excellent works for the lantern, secured us an immediate invitation to visit his establishment and describe to our readers everything we should see likely to prove of interest to them.

Having been ushered into a studio in which a number of young ladies were seen seated at easels, and engaged in one or other of the multifarious branches of transparency painting, we first of all inquired of Mr. Pexton if there were any secrets in his profession that we would witness, yet which he might not consider desirable to be described to the public. The reply of Mr. Pexton was—"Write and describe whatever you see; we have no secrets here; we trust to skill alone, and not to any fanciful methods of mixing or applying colours."

While watching the painting of a lantern transparency on a photographic basis, we could not but admire the skill displayed in making a sky possessing uniformity, and which is considered a difficult feat. This was effected in the following way:—The transparency having been placed on the easel, and the palette set with a range of colours from oil tubes, the blue pigment, previously modified with an admixture of varnish, was applied at the top with broad sweeps from left to right in such a manner as to become lighter and lighter as the horizon was approached. But just previous to this stage being reached other colours, of the rose madder class, were blended so as to bring the sky down to the horizon in a warm and pleasant tone. The sky was now ready for having the colours blended together and made to run into one another with such imperceptible grading as to present the appearance of one harmonious and continuous whole rather than a succession of tints. The deft application of the point of the finger effected this, and although it appeared to be accomplished with much ease, yet we could plainly see that it required great care and skill to ensure a uniform result. In reply to our question concerning the advantages of other methods of equalising skies or broad tints—such as dabbing brushes, the fingers of leather gloves, and expedients of a similar kind—Mr. Pexton informed us that he found the finger to be the best means for obtaining this effect. Smoothness of texture of the skin and the most scrupulous cleanliness were essentials towards producing the highest class of results. To show the perfection that could be attained, he requested one of his lady assistants to lay a uniform tint upon a piece of plain glass. This was done, and such was the smoothness and uniformity secured that, had we not witnessed the operation, we would have thought it had been produced by pouring a clear-coloured varnish over the surface of the glass.

The sky having been laid in, the production of clouds is the next step. This involves a high artistic perception. Everyone knows how exceedingly beautiful are some of the clouds in a high-class lantern slide. Nay, so beautiful and fascinating may they be rendered as sometimes to prevent the eye from readily resting upon the scene below; and the character of this scene is greatly modified by the clouds. In no department of slide painting is there greater scope for artistic revelling than in the formation of clouds and skies. Taking up a photographic transparency of a Scottish coast scene, in which were several fishing boats careering upon a glassy sea, Mr. Pexton said that to paint such a scene in the most effective manner, so as to "bring down the house," it ought to be made a moonlight study. At our request the transparency was treated in this manner, and never was a more magical change presented. The moon, which was "picked out" after the sky and sea had been draped in the solemn blue and green characteristic of moonlight, shone brightly and tipped the edges of the sails and rigging of the boats, and by the skilful use of what we may designate "delicate little artistic scalpels" its beams danced upon the scarcely-rippling water.

We inquired concerning the production of what is known in the lantern trade as "tales," and were told that these subjects are first drawn upon cardboard on a somewhat large scale, and finished in light and shade with the most scrupulous care. The test for good finishing in this drawing consisted in enlarging a three-inch photograph obtained from it up to forty feet. The production of these originals was attended with great cost, as a high degree of artistic skill was involved; and, although many figures were frequently introduced, it was necessary that the *likenesses* of each characteristic figure should be maintained throughout the whole series. Mr. Pexton showed us the original drawings of some sets which are now being brought out commercially, and so fine were they that we have conceived a respect for pictures of the fairy tale and kindred classes we had not previously experienced.

"What about preserving a becoming distinction between painting photographs intended for strong lime-light illumination on the one hand and the oil lamp on the other?" we inquired. We were informed that this received special attention when photographers or dealers specified the nature of the light to be employed; but in the absence of such information there was a medium degree of force employed which suited both systems of lighting. A room immediately over the studio was furnished with lanterns of the various classes, and even during broad daylight, when it could be rendered quite dark, a customer desiring to see any special effect could be shown, on the screen, the picture on a disc of any determinate demensions and by any class of light. This was found to be very convenient for those who desired special effects of painting to be produced in their photographs, and who at the expense of waiting for a brief period could witness the precise effect produced before the transparency was mounted.

We may say, in passing, that in the show-cases of Mr. Pexton we saw many beautiful specimens of single, biunial, and triple lanterns of elegant designs. He appears to give the preference to albumen as the medium upon which to produce the photograph; but as we saw many exquisite paintings which had been produced upon the works of York, Wilson, Valentine, and others who are understood to use collodion, as well as upon those of Mr. George Smith, of the Sciopticon Company, whose works are on gelatine, we arrive at the conclusion that if the photographic transparency be really fine it matters but little by what process it is produced. The test for excellence in the transparency, as regards the chances of its producing a fine effect when painted, consists in laying it, face down, upon a sheet of white paper, and observing if there be any degradation of the purity of the paper when seen through the high lights. If there be, then the photograph is unsuited for being transformed into a picture of the highest class.

RECENT PATENTS.

PATENT SEALED, NOVEMBER 7, 1884.

No. 10,950.—"Improvements in Cameras;" a communication from C. Rae Smith, New York. A. H. REED, 90, Cannon-street, London.—*Dated August* 5, 1884.

DARK SLIDE FOR PHOTOGRAPHIC CAMERAS.

By ARTHUR FULLERTON HOWMAN, George-street, Oxford.

MY invention relates to a simple and inexpensive construction of slide for photographic cameras, whereby I provide effectually against admission of light to the sensitised plate within.

It consists of an outer rectangular frame with a back fixed thereto, the two sides and bottom of the frame being made with grooves to receive the edges of a thin metal slide which forms the front cover, and the bottom having also an under groove to receive one edge of the sensitised plate. The top of the frame has on its inside a recess containing a rebated strip pressed downwards by a spring, and has above that a groove holding a strip which is pressed forwards by a spring. There is also a spring on the back which presses against the sensitised plate, keeping it steady against shaking. When the plate is in the frame it is held at its lower edge in the groove at the bottom of the frame, and at its top edge by the rebate of the strip pressed downwards by a spring, and it is covered by the thin metal plate which is slid in from the top and is held in the grooves of the two sides and bottom. On withdrawing this slide the sensitised plate is exposed in front, and light is prevented from entering by the top of the frame by the strip, which is pressed forward by a spring closing the slit by which the metal plate is withdrawn.

[Certain drawings accompanied the complete specification which it is unnecessary here to give.]

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
November 18	Bolton Club	The Studio, Chancery-lane.
" 19	Photographic Club	Anderton's Hotel, Fleet-street.
" 20	London and Provincial	Masons' Hall, Basinghall-street.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

THE first ordinary monthly meeting of this Society for the present session was held on Tuesday last, the 11th inst., at the Gallery, 5A, Pall Mall East,—Mr. James Glaisher, F.R.S., President, in the chair.

The minutes of the previous meeting having been read and confirmed, the following gentlemen were elected members of the Society:—Messrs. W. M. Crouch, F. Machell Smith, E. Smithells, G. E. Thompson, T. Furnell, W. Brooks, Henry Smith, W. P. Marsh, Ernest E. White, G. H. M. Whish, J. J. Smith, J. Mason Harrison, Charles Harrison, C. F. W. Sage, W. E. Halse, A. Spiller, F. Harrison Low, M.R.C.S., M. Loring, S. Stagall Higham, T. C. Turner, Jun., B. G. Wilkinson, Jun., T. Scanlan, F. Maude, T. E. Freshwater, J. G. Gibbs, H. G. Moberly, M. H. Clerk, Rev. J. S. Knight, R.N., H. S. Mendelssohn, T. Whitehead, A. Mackie, K. B. Murray, F.R.G.S., F.S.S., G. H. Hunt, D. Barnett, M. Auty, G. Hadley, W. W. Winter, J. Lafayette, S. D. McKellen, J. Bracebridge Hilditch, Hon. Slingsby Bethell, B. Myles, J. Harris Stone, M.A., F.L.S., F.C.S., and J. Duncan Peirce.

In reply to the Chairman's inquiry respecting the Exhibition medals, The HON. TREASURER (Mr. W. S. Bird) stated that through some little hitch the medals had not arrived in time for the meeting. He had a promise that they should be delivered by nine o'clock, and he hoped they would arrive before the meeting closed.

The CHAIRMAN said it would gratify the members to learn that the number of attendances at the Exhibition was even better than last year. In 1883 the number of members was 718; this year it was 781, being 63 more than that of the previous year. In 1883 the number of tickets reached 4,046. This year the number was 3,732. In 1883 the number who paid was 4,057. This year there had been 4,177. The amount received at the doors last year was £227 9s.; this year they had taken £244 3s. As each year the attendance was larger than that of the previous year, and the money takings likewise increased, so he hoped it would continue; it was also satisfactory for the Society to know that their work was so much appreciated. Speaking of the jurors, he said their work was laborious. Every picture was separately examined by each juror, who assigned a certain number to it; these figures were summed up, and from the totals obtained the highest received the medals. The jurors had accomplished their difficult task in the most faithful manner, and he asked that the usual vote of thanks be accorded to them.

The vote being accorded,

The CHAIRMAN requested the members to accord a vote of thanks to the Hanging Committee, which was done. He then called upon Mr. Arnold Spiller to read a paper on *Hydroxylamine Used as a Developing Agent.*

Mr. A. SPILLER, having traced the history of hydroxylamine, said he first brought it under notice about two months ago in an article published in the *Photographic News*. Since then he had made further experiments, and now took the earliest opportunity of bringing it before the Society. Hydroxylamine, he said, was one of the numerous ammonia compounds, having the formulæ NH_3O. By replacing one atom of hydrogen with hydric oxide there was a bond of affinity obtained which might be represented thus:—

$$N \begin{cases} OH \\ H \\ H \end{cases}$$

Hydroxylamine chloride or hydrochlorate could be easily produced in an aqueous solution, and it had the property of decomposing silver bromide when in the presence of a caustic alkali into metallic silver, bromide of sodium, water, and nitrous oxide, as shown by the following equation:—

$$2NH_3O + 4AgBr + 4NaOH = 4Ag + 3H_2O + 4NaBr + N_2O.$$

This was illustrated by mixing the components in a beaker, when metallic silver was shown to be reduced. Mr. Spiller further stated that, unlike pyrogallol, this substance does not absorb oxygen from the atmosphere, neither does it stain the film. It is now an expensive salt, but if in constant use there is no reason why it should not be cheap. The developer, suited to an ordinary good commercial plate, was given as follows:—

Hydroxylamine chloride	2 grains.
Caustic soda	5 "
Bromide of potassium	½ grain.
Water	1 ounce.

The caustic soda takes the place of ammonia, and hydroxylamine supplants pyrogallol. It admits of a wide latitude of exposure, and, not being an oxygen absorbent, enables better colours to be obtained—especially so with gelatino-bromide paper. The only drawback is a reticulation of the film in those plates where soft gelatine had been employed. Examples of negatives and bromide paper so developed were passed round. By modifying the proportions several colours could be obtained on gelatino-chloride plates, many of which were admirably suited for the lantern. In conclusion: he hoped photographers would give the new developer a trial, and make known their results.

Mr. W. E. DEBENHAM remarked that Mr. Wellington had shown transparencies on bromide plates, developed with hydroxylamine. The colours were very beautiful, but they had a defect, viz., a puncture somewhat like that of a needle point all over them. The plates were a slow batch, made expressly for transparencies.

Mr. J. SPILLER remembered pyrogallol being sold at 16s. per ounce. There was not the least reason why hydroxylamine should not come down from its present high price—10s. 6d. per ounce—as pyro. had done.

Mr. LEON WARNERKE inquired whether it was found to be a more powerful developer than pyro. or ferrous oxalate.

Mr. A. SPILLER, in reply, said the punctured markings referred to were caused by the use of a soft gelatine; they were due to an evolution of nitrous oxide in the film. It was not so powerful an agent as pyro. or oxalate, but by increasing the alkali there would be more detail obtained.

A hearty vote of thanks having been accorded to Mr. Spiller,

The CHAIRMAN said he was glad to find a new member making a good beginning. He hoped to hear other papers from Mr. Spiller, and that other new members would follow his example.

Owing to the absence of Captain Abney from London, his paper on *The Siemens' Unit Lamp Applied to Photography* was read by the Honorary Secretary, W. F. Donkin, Esq., M.A., &c. Captain Abney mentioned several forms of unit lamps hitherto recommended, but few worked as well as "Siemens'." The principal points in this lamp were the fixed diameter of wick 2-16ths of an inch, and a gauge fixed at a suitable distance, the top of which was 2.6 inches from the level of the flame. Acetate of amyl, a substance very cheap in Germany, was found to be best suited to burn in this lamp, and in case of draught Captain Abney suggested the addition of a glass chimney or cylinder; also an extinguishing screw-cap to prevent evaporation when out of use. He (Captain Abney) had tried it with a sensitometer 18 inches off, and obtained the same illuminating power as the phosphorescent tablet, and found it was thoroughly reliable. Any ordinary spirit lamp could be utilised if the burner was of the same dimensions as that previously mentioned; and, as acetate of amyl was easy to obtain, anyone could have a standard light much better than the ordinary standard candle.

Mr. J. SPILLER remarked that there would be no difficulty in making perfectly pure acetate of amyl, should it be required for this purpose.

Mr. W. BEDFORD referred to difficulties he met with when testing standard lights due to reflections, and said that, as so much depended on the surroundings, an absorber was required as well as a reflector.

Mr. T. SEBASTIAN DAVIS, having experienced similar difficulty, now took the precaution to place a reflector one metre behind the flame of his lamp.

Mr. DEBENHAM suggested that Mr. Bedford use the simple flame direct from the lamp, lining the lamp with black velvet and making use of a velvet-lined tube, thus cutting off all reflection.

A vote of thanks having been passed to Captain Abney for his paper,

The CHAIRMAN congratulated the following, who were awarded medals by the Society:—Mrs. S. G. Payne, Messrs. Vittoria Sella, W. P. Marsh, H. P. Robinson, The Autotype Company, Messrs. C. Grassin, G. Renwick, H. B. Berkeley, Sig. A. Tagliaferro, H. S. Mendelssohn, J. Werge, on behalf of the family of the late Mr. J. Hubbard, G. West and Sons, Adam Diston, G. Hadley, J. Lafayette, T. and R. Annan, J. Atkinson, M. Auty. Extra medals:—J. Gale (transparencies), S. D. McKellen (improvements in cameras). The medals not having arrived, the Chairman was unable to present them as usual.

The CHAIRMAN said there were many others who had sent pictures of great merit, and to whom he should like to have presented medals, among whom were the works of Miss Coteswerth, Messrs. Dixon, Willis, Pointer, Gillard, Malcolm Clerk, Sutcliffe, Captain Abney, A. and G. Taylor, Seymour Conway, Myles, School of Military Engineering, Robinson and Thompson, W. Wainwright, Jun., &c., &c., all of which were so good that he only wished medals had been awarded to them as well. Mr. Furnell's shutter was beautiful in its arrangements, and none the worse for the hard usage such things usually get. Mr. Cadett's new shutter was also good, and he could speak highly of all the apparatus shown. Their's was not a professional Society, yet professionals had a majority of the awards this year. Hitherto, amateurs had taken the majority of medals; but he must say that the amateurs were getting a little behind. He had noticed that elsewhere as well, and hoped that they would strive to keep up with, if not to surpass, their professional brethren.

Before closing the meeting he wished to congratulate the Society on its large accession of new members. He hoped they would be all workers, and that the Society would do as good scientific work in the future as it had done in the past.

It was announced that the next technical meeting will take place on Tuesday, the 25th inst., and the next ordinary meeting on Tuesday, December the 9th.

Some of the medals having arrived before the meeting closed, the Chairman presented them to the respective winners who were present; after which the meeting was adjourned, to allow the members to take a final view of the pictures.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society, held on Thursday, the 6th instant, the chair was occupied by Mr. W. E. Debenham.

Mr. HERBERT S. STARNES referred to the proposal, brought before the previous meeting in a letter read by Mr. Henderson, to use the screens of coloured medium for dark-room illumination set at an angle to each other. He thought that the idea was of no use for the dark room.

The CHAIRMAN quite coincided with the view expressed by the chairman (Mr. W. K. Burton) of the previous meeting—that the setting of screens at an angle to each other would only be useful on the supposition that the irregularities of the medium took the form of tubes perpendicular to the surface. With textile fabrics not filled up by a glaze this condition obtained to some extent, but with glass and the mediums in general use there would be no advantage in the plan suggested, and it would occupy considerable space.

Mr. J. J. BRIGINSHAW, alluding to what had been said about toning with a solution of gold without alkaline salt, said that he had made a very dilute solution of gold and found that an ordinary washed print toned in it in the space of half-an-hour. A print that had, before being immersed in the same gold bath, been passed through a solution of carbonate of soda toned in ten minutes.

Mr. T. WALTENBERG had had a new experience with ready-sensitised paper, a batch recently taken into use giving red spots and toning slowly.

Mr. STARNES and Mr. J. BARKER had also recently found the same trouble, and the latter gentleman thought it was due to decomposition of the albumen.

The CHAIRMAN did not think that this was the probable cause. Some twenty years ago there was a paper introduced into the market that smelt horribly, but it gave particularly rich prints free from mealiness.

A MEMBER inquired whether there was any method, other than the tentative and experimental one, of finding the chemical focus of the object glass of a telescope.

Mr. J. B. B. WELLINGTON suggested sloping the plate and noting the portion that came the sharpest.

Mr. S. G. M. McKellan was elected a member.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE ordinary monthly meeting of this Society was held on Thursday, the 6th inst., in the rooms of the Society of Arts, John-street, Adelphi,—Mr. W. Ackland in the chair.

The SECRETARY having read the minutes of the last meeting, and these having been approved, proceeded to give the result of the circulars issued to the members requesting each to give his opinion as to whether the Society should be carried on or not. Twenty-five replies had in all been received. Of those who replied seven were against the continuation of the Society, nine were in favour of it, and nine were doubtful. He (the Secretary) then went on to say a few words in favour of the continuance of the Society, and suggested that it should be announced at the present meeting that certain proposals for alterations of the rules of the Society be brought before the next meeting. These proposed alterations were briefly as follow:—To do away with the five shillings subscription for country members, except in the case of ladies. To alter the rule with regard to members in arrears with their subscriptions. To have only three vice-presidents. To have twelve members on the committee.

It was proposed by Mr. W. M. ASHMAN, and seconded by Mr. W. K. BURTON, that Mr. Ackland be elected President.

The following gentlemen were then proposed as Vice-Presidents:—Mr. H. Trueman Wood, Mr. F. York, and Mr. T. Bolas.

The following were proposed as members of the Committee:—Messrs. W. M. Ashman, A. Mackie, W. K. Burton, E. Dunmore, W. Cobb, J. A. Harrison, J. J. Briginshaw, A. L. Henderson, E. Cocking, J. Nesbit, H. Wilmer, W. H. Prestwich, F. Hollyer, W. Brooks, and T. Bolas. The officers were to be balloted for at the next meeting.

Mr. J. TRAILL TAYLOR then gave a discursive lecture *On Florida*, illustrated by numerous photographic transparencies exhibited on a twenty-foot screen, some of which were beautifully coloured. He described the whole process of forming a plantation, from the clearing of the land to the husbanding of the orange and other crops. He spoke of that State as a paradise for sportsmen, and as one which was well worthy of the attention of those who inquire—"What shall we do with our boys?"

A vote of thanks (which was carried by acclamation) was proposed by Mr. William Cobb, who recited a poem he had composed for the occasion.

It is fitting that it should be placed on record that the lantern service was on this occasion imperfectly rendered, doubtless owing to the fact of a new and apparently-inexperienced individual being called upon at the last moment to officiate.

The annual dinner is fixed to take place at the Holborn Restaurant, on Tuesday, December 16th.

THE PHOTOGRAPHIC CLUB.

THE annual general meeting of this Club was held at Anderton's Hotel, on Wednesday, the 5th instant.

The report of the year was submitted to the meeting by the officers, showing a steady increase in the prosperity of the Club by the number of attendances, which have been largely augmented during the past year—the number amounting to 1,296, against 1,027 last year, and 872 the previous year. A laboratory has been built and fitted with the necessary appliances and chemicals, to which the members have free access. The number of members is steadily increasing and the financial condition of the Club is extremely satisfactory. During the winter months the optical lantern has been a source of interest. Many new or valuable modifications of apparatus or processes of development have been shown or demonstrated. One very useful feature is that if any new invention connected with photography or new process, &c., is laid before the Club it has its practical value fairly and impartially ascertained. These considerations, together with the thoroughly-pleasant and sociable manner in which the meetings are conducted, offer special advantages to both professional and amateur photographers that were quite unattainable previous to the establishment of this Club in 1879.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE twenty-fifth annual meeting of the Society was held in No. 5, St. Andrew-square, on Wednesday, the 5th instant, at eight o'clock,—Mr. W. Neilson, President, in the chair.

The minutes of the last annual general meeting and last ordinary meeting having been read and approved of, the ballot box was opened, and the following gentlemen declared duly elected: — Messrs. F. W. Palmer Edward Binning, Charles Waterson, and Alfred Tagliaferro, Malta.

The following gentlemen were proposed for election at next meeting:—Messrs. W. A. Bryson, G. Napier, Charles Murray, Aitken, W. Skinner, J. W. Miller, Henry Cowe, Herbert W. Bibbs, Robert Lindsay, Donald Mackenzie, and Mr. Alex. Thompson.

The Secretary read his report for the past year as follows:—

ANNUAL REPORT.

THE Council, in presenting the twenty-fifth annual report, have pleasure in congratulating the members on the continued prosperity of the Society.

At the commencement of the session the Society mourned the death of Mr. John Lessels, who for seven years had been the esteemed President of the Society. At the funeral, amidst a distinguished gathering, the Society was officially represented.

During the past session the Society had lost four members by death and thirty-seven members by removal or resignation—total, forty-one. Fifty-five new members have been elected, making an increase of fourteen. Total now on the roll, 406.

The following papers have been read:—*A Ferrous Oxalate Developer*, by Mr. Norman Macbeth, R.S.A. *Various Photographic Conveniences*, by Mr. William Crooke. *A New Lantern Carrier*, by Mr. J. M'Kean. *Camera-Lucida—Paletta Obscura*, by Mr. Hume Nisbet. *Canary Medium*, by Mr. J. W. Knolles. *Recreation in Art*, by Mr. John Simpson. *Notes on the Lime Light*, by the Rev. T. Hardwich. *Notes on the Lime Light*, by Mr. Lewis Wright. *Photographers and Sitters*, by Mr. G. G. Mitchell. *The Calotype Process*, by Dr. Alexander Hunter. *Sulphite of Soda in the Developer*, by Mr. J. J. Turnbull. *The Potash Developer*, by Mr. A. B. Stewart.

The following items have been exhibited:—An ether generator, and Dickson's improved burner for the lantern, by Mr. J. J. Turnbull. Collection of views by Mr. Foster, of Coldstream, by Mr. J. Crichton. Mr. M'Dougall's lantern carrier, by Mr. J. J. Turnbull. Collodio-chloride transparencies, by Mr. Cowan. Series of photographs by Mr. Reid, of Wishaw, by Mr. G. G. Mitchell. Landscape studies by Mr. Andrew Pringle and others, by Mr. J. Annan. Series of photographs illustrating the Passion-Play at Oberammergau, by Mr. G. G. Mitchell.

The annual display of work took place at the December meeting, and was of exceptional interest.

The Society has been presented with photographs by the late Mr. Lessels, a portrait of the late Mr. John Lessels by Mr. Bashford, and a non-actinic lantern by Mr. Wardale.

Packets of hydrokinone and samples of gloy have been distributed among the members. One ballot for photographs has taken place. A revised edition of the laws of the Society has been adopted.

Three popular meetings have been held in Queen-street Hall, and were much appreciated by large audiences:—1. A miscellaneous collection of transparencies illustrating the work of members.—2. The temples and palaces of Japan.—3. A voyage round the world with a camera, with descriptive lecture, by Mr. Andrew Pringle, of Langholm.

The annual trip took place on the 10th July, when, by the kindness of R. Dundas, Esq., a most enjoyable day was spent at Arniston.

The presentation print for 1882-3, entitled, *Brambling*, by Mr. Slingsby, of Lincoln, has been distributed, and that for the past session will be issued shortly.

The proceedings of the Society have been printed in "Transactions," a copy of which has been sent to each member; but the Council does not express an opinion as to the continuance of this publication, preferring that members should state their wishes at this annual meeting.

The large increase in the attendance at the monthly meetings noted last year has still been maintained, the crowded state of the room causing some inconvenience; but for the present the Council does not feel justified in recommending the Society to change its place of meeting.

The thanks of the Society are due to the donors of the several presentations; to the Curator, Mr. J. M. Turnbull, who, with his usual kindness, has allowed the use of a room for several committee meetings, and for still continuing to store the property of the Society; and to the retiring office-bearers.

This report was unanimously approved and adopted.

The Treasurer then read his report, of which the following is a condensation:—

Condensed Report of Treasurer's Intromissions, 1883-84.

Dr.						
To Balance from last year				£87	11	9
,, Arrears of Subscriptions from last year............				10	10	0

Edinburgh, *3rd November*, 1884.—Having examined the books of the Edinburgh Photographic Society for year ending 31st October, 1884, and compared the entries with vouchers and other instructions, I find the books correctly stated and sufficiently vouched and instructed, and I certify that the foregoing abstracts, framed by me, exhibit a true state of the Society's affairs as taken from the books.

(Signed) A. T. Niven, C.A., *Auditor.*

This report was also approved of.

The Curator stated that he had prepared no written report, but that a sub-committee had been appointed during the past year, who had catalogued and examined all the property of the Society, and to their report he referred. The Society's property, as there specified, was in good condition.

The Society then proceeded to the election of office-bearers for the ensuing session, and on the recommendation of the Council the following gentlemen were unanimously elected:—*President:* Mr. Norman Macbeth, R.S.A.—*Vice-Presidents:* Mr. J. G. Tunny and Mr. Wm. Forgan.—*Secretary:* Mr. W. T. Bashford.—*Treasurer:* Mr. A. M. Forbes.—*Curator:* Mr. J. M. Turnbull. In room of the four members of Council who retire by rotation, Messrs. W. Neilson, Jas. Crighton, Wm. Crooke, and G. G. Mitchell were elected, and, to fill the vacancy caused by the election of Mr. Forbes as Treasurer, Mr. Hugh Brebner was proposed and also unanimously elected.

Mr. Neilson, on vacating the chair, said that it had given him very great pleasure, at the desire of the Society last year, to fill the honourable post which he was now about to vacate. It was the practice in most societies for the retiring chairman as well as the chairman elect to make a few remarks on some subject connected with the objects of the Society, and as he had omitted to perform this duty on his election he would read an article he had prepared at the request of the Editor for the forthcoming Almanac. In this he (Mr. Neilson) directed attention to the greatly-extended usefulness of photography, especially as applied to scientific research. He also stated that he had to thank the members of the Society for their support during the time he held office, and trusted that with harmony and good feeling (without which no society could possibly prosper) the Edinburgh Photographic Society would have a long and useful career. He had very great pleasure in welcoming Mr. Macbeth to the chair.

Mr. Norman Macbeth, who was received with loud applause, then took the chair, and said that last year when asked to assume office as Chairman of the Society, which post had become vacant by the death of Mr. Lessels, he, though very desirous of meeting the wishes of the Society, was, on the advice of his medical adviser, his health being far from good, reluctantly compelled to decline the office. This year, however, his health having been to a great extent re-established, he felt quite able to perform the duties, and it gave him very great pleasure to comply with what appeared to be the unanimous wish of the Society, and accept the honour which had been offered. He then read the following address:—

We have now reached the twenty-third year of our Society, and have good reason to congratulate ourselves on the life it still manifests. It has attained not only a high position in point of numbers, but many of its members have distinguished themselves in the production of beautiful work, as these walls tonight testify, exhibiting general intelligence in every branch of the art.

I had the honour of being called upon by the Photographic Club of Edinburgh during its last session to make a design for the diploma of its members. I represented photography there, not merely as a handmaid to nature, science, and art, but I designated her as the daughter—*filia naturæ scientiæ artisque*—a much higher and more endearing relationship, ever ready, ever willing, and ever lovingly endeavouring to meet the wants and profoundly respect the claims of each.

Something more than mere service is necessary in promoting the interest of any of its departments. It is love and devotion to any worthy pursuit that is felt to be the mainspring of successful effort. Any society depending upon mere awards for stimulus, apart from disinterested exertion, soon ceases to have the most wholesome influence. Emulation is good when it can be carried out without giving offence; but, in the case of many professional men competing, I find it is the opinion of several of our best members that adjudication and the giving of awards is fraught with considerable danger, apt to make shipwreck of the best of feeling, and, at least, introducing elements of unavoidable jealousy and dissatisfaction. However, there may be an exception. In the case of young beginners in the study of any profession some stimulus is not only necessary but helpful, and a prize becomes an object. It is especially for the younger members of our Society that I had in view the institution of a monthly competition, and at the end of the session to award a prize. I do not see that this could be reasonably objected to, limiting it to amateurs within (say) four years' experience with a camera. Indeed, I believe were these competitions well managed and conducted in a good spirit they would be a great inducement for many young men to connect themselves with us, forming, apart from their ordinary calling, a pleasant hobby which would gently lead them into the higher studies of chemistry and art, and so deliver them from many evils which arise from indolence and the neglect of self-culture.

A Society like this has many attractions, and none greater than the opportunities which it presents for the cultivation of taste. We cannot enter upon the smallest detail of any department of its study without feeling the need of acquiring proper methods of procedure; and we always find that the photographer who succeeds most is one who well directs his work, and spares no pains in cleanliness and great carefulness of manipulation.

It hardly becomes me to say anything regarding the education essentially necessary to a photographer. Nothing seems to me—who am but a novice in chemistry and mechanical arts—more important and desirable for anyone proposing to follow photography as a profession than by every means in his power to acquire a sufficient practical knowledge of chemistry and its nomenclature, so as to be able at once to read and work out formulæ as they come from our best authorities. I think, also, he should be well read in and familiar with some of our best books containing workshop receipts, enabling him to make good use of these in mechanical appliances, such as photogravure work or blockmaking to accompany type—arts which are fast encroaching upon the hitherto laborious and very expensive efforts made in the interests and requirements both of science and art.

As most of our young men who are following photography as a profession find, they are best educated in the manipulative part of their work when their services are engaged as general assistants. It is a long time before they are entrusted with the arrangement of the sitter—seldom indeed till they are their own masters. During this early period they should not only be watching how their employers treat their subjects, but they should have an intimate acquaintance with all artistic arrangements, as so well explained and inculcated by Mr. H. P. Robinson and others, but more especially exemplified in the works of some of our standard painters, such as Velasquez, Rembrandt, and Vandyke. The possession of a few good prints from the works of these or of men of our own country—such as Reynolds, so famous for originality of design, and also Raeburn, for great breadth of light and shade, giving effect to the more important parts of character.

The regular sizes of canvas common to portrait painters are so good that little can be advanced in the way of improvement; but the introduction of many mere fanciful sizes, irrespective of their bearing on the subject, is much to be deprecated. We cannot prevent the introduction of novelties in any art; but surely that which ministers most in giving effect to the subject is somewhat more sensible than that which subordinates the subject to inappropriate boundary lines.

Then I would have the beginner to discard all painted backgrounds with the ordinary photographic accessories upon them. As the work is derived directly from living subjects, so should the background and surroundings—if such be desired or needed—be composed from real objects, and these as much as possible conforming to the associations of general good society, Any subject is greatly lessened in interest when the same painted background crops up under every arrangement. Much ingenuity has yet to be exercised in directing the light and shade of a background, so as to give full effect to the head and figure. It is in the practice of this treatment that the photographer, apart from development, will manifest his artistic knowledge and judgment.

In making such remarks I cannot express an honest opinion without fear of offending some one. But permit me to say that photographic portraits are never finer than when thrown out in simple relief from a plain background. It may be painted in certain forms of light and shade, and by turning it round to any position it may be easily adapted to any pose. Simple dark or light cotton fabrics make beautiful drapery. Tapestry and real oak panels made plain, without ornament, are very serviceable. There is nothing more convertible nor more likely to produce variety than these. When special objects—such as the old hackneyed pillar and balustrade—present themselves you feel that they are allied to a past age in art. I hope the day is not far distant when there will be a demand for photographic portraits taken in one's home, with the individual associations about them. This would be a great advantage over the painter, unless he, too, availed himself of such. It would be telling on the originality of portraits were this more recommended and acted upon.

As an artist I have taken a deep interest in those efforts of photography which are now unquestionably making some worthy appearance in the way of artistic arrangements. I refer more particularly to the treatment of subjects of ordinary human life. Hitherto such attempts have been greatly prevented by many unavoidable obstacles; but I am now not without hope that, through general intelligence in the requirements of the picturesque, much will be apprehended, especially through instantaneous work, of many beautiful compositions as seen in the unconscious and charming incidents of everyday intercourse, which without the highly-sensitive plate would never be secured. Success in the gathering of such subjects is only to be had by the concealment of the instrument. I am told that Mr. Edwards, of London, carries nothing with him but apparently a small travelling-bag, with only the front of the lens exposed; and, the focus always being suitable, he secures some wonderfully-picturesque subjects in every way worthy of being completely treated on canvas.

"Knowledge is power." Permit me, then, to advise all young aspirants aiming at the cultivation of an acquaintance with the beautiful in nature and in art to look to the works of men famous in design, such as Sir Frederick Leighton, Burne Jones, or one of the most recent, Walter Crane, whose wonderful fertility appears in that beautiful work entitled the *First of May*. Works of such men as I have just mentioned may not be considered at all applicable to photography, because it does not pretend to be creative; but then such works make the best examples of arrangement and composition. Familiarity with good designs becomes educational; at least, to admire such makes one very difficult to please, and puts one in the pursuit of higher attainment. No photographer is to be excused who does not very frequently look at such publications as *The Century*, *Harper*, or the very cheap and interesting work, *The Magazine of Art*. A close and careful acquaintance with these will go far to foster a taste for art, and enable one eventually in some measure to imitate them.

I sincerely trust that there is much good before us this session in the study of every department which photography embraces, and that each member will find scope in the working out of his own proclivity. In the analysis and the construction of the picturesque I hope that every facility will be given to the new effort we are about to make, by setting apart, if possible, every alternate monthly meeting for a friendly conference on the works of those members disposed to submit them for that purpose. But, as knowledge is what we aim at, I do not see that we should confine ourselves solely to our own productions. Anyone in possession of a photograph which he admires should bring it to the meeting for inspection and consideration, if not for discussion; but in every case it should be distinctly labelled whether for discussion or not, always reserving the name of the author. As I have said, we cannot look for examples for discussion from professional men unless they are pleased to be generous enough; but from amateurs, who have no object but the acquisition of knowledge and experience, I would fain hope there will be no lack. I trust that they (distinctly keeping the object in view) will send in occasionally photographic pictures for the purpose.

There is no department of study in either science or art that is making more progress, or is so varied and rich in its results, as photography. From the very wide range of its adaptation and usefulness our members are most likely to be very varied in their callings in life. This fact makes our membership very interesting. Every one in his own sphere may be useful in ministering to what he conceives to be the interests of photography and the Society's success. Everyone, therefore, should feel that he may and can do something, whatever his place may be. With such a Society it may be truly said that the head cannot say to the hand—"I have no need of thee;" nor the hand—"I have no need of the head." We are all bound by mutual dependencies, and the consciousness of this should keep us from falling into conceited and vain notions of ourselves; for assuredly nothing tends more to lessen the respect we are bound to have for each other.

In closing these remarks, allow me to say one word in acknowledgment of the honour you have done me in appointing me to the Presidentship of this Society. I am deeply conscious of my ignorance in many matters affecting its constitution and working. This renders me very unable to speak with expertness. However, I am sure you will always give me credit for seeking after nothing but the interests and prosperity of the Society, and the maintenance, as far as I can, of the best of feeling amongst all the members.

Mr. Neilson, in proposing a vote of thanks to the Chairman for his paper, remarked upon the great strides which photographers had made in the æsthetic department of their profession, and he asked the members to compare some of the pictures (?) which were still to be found in some of their old albums, where the fluted pillar and the vice-like head-rest predominated, with the artistically-posed groups and other lovely specimens of the photographic art displayed on the walls. And not only that, but he observed a very marked improvement in the pictures from those of last year, both in artistic treatment and in manipulation. But there was still room for improvement, and he thought what was principally required was the artistic training of children. Nursery walls should be hung with really fine engravings instead of the vile abortions which were usually displayed. He only wished he had ten thousand children that he might train them according to his own ideas.

The Chairman then proposed a vote of thanks to those gentlemen who retired from office. He also welcomed the newly-elected office-bearers, and hoped that every facility would be afforded them and himself to do the work of the Society amicably. Nothing was gained by fighting and quarrelling; on the contrary, nothing would produce greater health and vigour in the Society than hearty co-operation and a real desire among the members to further its interests.

Mr. Neilson then, on the part of himself and Mr. Craig-Christie, expressed his gratification for the cordial vote of thanks accorded to them.

Mr. Pillans thanked the meeting for the expression of its approval of his services, and stated that while he had retired from office he would continue to serve the Society as far as lay in his power.

Mr. Simpson, as one of the retiring Councillors, thanked the members for their cordial recognition of the services of the Council. He also expressed his satisfaction at the election of Mr. Macbeth to the chair, and he believed that satisfaction was shared by every member of the Society. He believed the result of the appointments made would be that the Society would have a new lease of life, and that it would go on and prosper.

The Chairman then called the attention of the meeting to the display of pictures on the walls, which, the Curator explained, had been sent in by members for exhibition. There were altogether 113 pictures, the majority bearing evidence of careful thought; indeed the display was by far the finest that had been before the Society at any of its annual exhibitions.

The Chairman then said:—The next thing I have to call your attention to is in the form of a question. You know we have been in the habit of getting the *Transactions* of the Society printed hitherto, and a copy sent to each member. There is no doubt that by giving up this practice we should save some money; at the same time, I should like the members to express their own views on the matter. If the printing and circulating of the *Transactions* serve any good purpose, and there is a general desire to continue them, it would be a pity to give them up. There is a good deal of information supplied in the *Transactions*, and you have the advantage of reading the papers over quietly at home. At the same time, everything we do in the shape of writing appears in the journals, and I suppose most of the members take one or other of these. As to the financial aspect of the question, our late Treasurer will be able to give more information than I can.

Mr. Pillans: I hold that the publication of these *Transactions* pays. We receive payment for advertisements, and certain allowances for early proofs of the reports of meetings, and although these do not amount to anything like the cost of printing, yet if the cost of printing the billets be deducted you will find that the cost to the Society is not great, while the information afforded to the members, many of whom do not subscribe to any journal, is an inducement to many people to join the Society. I believe their stoppage now would cause the withdrawal of many of our members, especially country members, who seldom have an opportunity of attending our meetings, but whose interest in the Society is kept alive by the regular monthly receipt of our *Transactions*.

A first and imperfect proof of the presentation print for the past session was laid on the table.

Members were reminded that subscriptions for the current year were due, and, after a vote of thanks to the Chairman, the proceedings terminated.

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

The second monthly meeting of this Association for the season was held in Lamb's Hotel, Dundee, on Thursday, the 6th instant. Mr. J. C. Cox, President, occupied the chair, and there was a good attendance.

After the routine business had been disposed of there ensued a discussion on the advisability of holding another photographic exhibition. Owing to the great success of the previous one the idea was warmly taken up, and it was agreed to hold an international exhibition in the beginning of 1886. The Committee will be elected at the next meeting.

Dr. Tulloch then gave a lecturette on *Photographic Optics*, illustrating his remarks by means of blackboard diagrams.

Dr. Tulloch was most attentively listened to, and at the close of the paper he indicated his willingness to answer any questions relating to the subject. A number of inquiries were made and readily answered.

On the motion of the Chairman a hearty vote of thanks was passed to Dr. Tulloch.

The Council have made arrangements for a lantern exhibition to be given in December, and the Chairman also intimated that a practical demonstration of the process of development would be given in the Society's dark room on Monday, the 1st December. Members were invited to bring exposed plates with them, and an experienced member will be present to develope them.

The customary vote of thanks brought a pleasant meeting to a close.

The following gentlemen are now members of the Society:—F. C. Caffin, C.E., James Smieton, D. J. T. Gray, J. Schleselman, and A. Walker.

BRADFORD AMATEUR PHOTOGRAPHIC SOCIETY.

The first business meeting of this newly-constituted Society was held in the Free Library, on Thursday, the 6th inst., when there was a full attendance of members.

Mr. Duncan G. Law, President, delivered a short address touching on the use and development of photography down to the present time.

Mr. G. D. Scorah, Secretary, afterwards gave a lantern exhibition.

We understand the Society commenced work with a full complement of members, and we congratulate the promoters on having made so successful a start.

The following are the officers for the current year:—*President:* Mr. D. G. Law.—*Vice-President:* Mr. W. Townend.—*Hon. Treasurer and Secretary:* Mr. G. D. Scorah.—*Committee:* Messrs. F. Illingworth, F. B. Muff, W. Townend, M. B. Wallace, J. Cotton, and H. Forsyth.

COVENTRY AND MIDLAND PHOTOGRAPHIC SOCIETY.

The monthly meeting of this Society was held at the residence of Mr. C. Ambrose, 38, Crosscheaping, Coventry, on Thursday, the 6th instant,—Mr. W. Andrews, President, occupying the chair.

After the nomination of officers for the ensuing year, &c.,

Mr. H. W. Jones, F.C.S., exhibited a very convenient method of using ordinary gas in his "Lancaster" ruby lantern, with an arrangement by which he could turn on the ruby or white light at will.

Mr. A. Seymour also sent some negatives, which were thought very fine —not only for their artistic merit, but from the fact of their being developed by the soda developer.

The Chairman then called upon Mr. T. Baynton, manufacturer of the "Coventry" dry plate, for his paper on the making and development of gelatino-chloride plates.

Mr. Baynton said: I must commence by stating that I am indebted to Mr. A. Cowan for the emulsion formula, and to Mr. B. J. Edwards for the developing formula, although I have made some slight alterations in them. The members will find that they can with this kind of plate [sample transparencies from negatives taken during the summer were here passed round] make very beautiful lantern slides, and so entertain their friends and amuse themselves at the same time on these dull winter evenings. For the convenience of those members who wish to make their own emulsion plates I will now give the formula:—

Silver	1 ounce.
Water	10 ounces.
Gelatine (hard)	1 ounce.
Sodium chloride, pure	½ ,,
Water	10 ounces.

Let the gelatine soak for some time; then dissolve by placing the vessel in water at about 110 Fahr., and warm the silver to the same temperature. Now take into the dark room and mix by any well-known method so as to get a very fine emulsion. It may now be cooled by placing the vessel in running water, and when cold wash and filter in the usual way. Expose five seconds (more or less according to the density of the negative) to diffused daylight, and develope with—

No. 1.

Neutral oxalate of potash	2 ounces.
Chloride of ammonium	40 grains.
Citric acid	2 drachms.
Distilled water	20 ounces.

No. 2.

Sulphate of iron	4 drachms.
Alum	90 grains.
Distilled water	20 ounces.

Add one part of No. 2 to an equal part of No. 1, but do not reverse this by adding No. 1 to No. 2, or the effect will not be so good. If the plate be properly exposed the result will be a fine purple-black tone in the transparency, but if you want a warm brown tone expose double the time and mix the developer with an equal bulk of water. The development in this case will be much slower. Many different tones may be obtained by using the various developers given by Mr. Cowan. To fix the picture, use one part of hypo. to eight parts of water. After fixing and washing put the plate for half-a-minute in the following:—

Alum	1 ounce.
Sulphuric acid	1 ,,
Water	20 ounces.

This will dissolve the opalescence caused by the oxalate. The plate must now be well washed, dried, and varnished in the usual manner.

The transparencies passed round were very fine and much admired, especially when shown in the lantern by Mr. Ambrose.

After a hearty vote of thanks to Mr. Baynton the meeting was adjourned at a late hour.

ST. HELENS ASSOCIATION FOR THE PURSUIT OF SCIENCE, LITERATURE, AND ART.

Photographic Section.

A meeting of this Section was held on Wednesday, the 5th instant, at the Association Rooms, 4, Salisbury-street,—Mr. Heather in the chair.

After the ordinary business of the Section was over,

The Chairman showed six views of the moon, taken during the eclipse of the 4th ultimo with his camera, the exposures varying from one to five seconds.

Mr. Sherlock warmly complimented Mr. Heather on his success.

Mr. Taylor showed about twenty views of Dutch life and scenery.

Mr. Sherlock said, in regard to a difficulty some members appeared to have in filtering emulsion, he found it an excellent plan to use the vacuum pump, and suggested the use of asbestos or powdered glass for filtering through.

A few transparencies made by members were passed round for inspection.

A discussion then took place on the action of excess of H Cl in emulsion, ction of Ag No$_3$ in Fe$_2$ CC$_3$, toning bath, &c.

The meeting was then adjourned.

Correspondence.

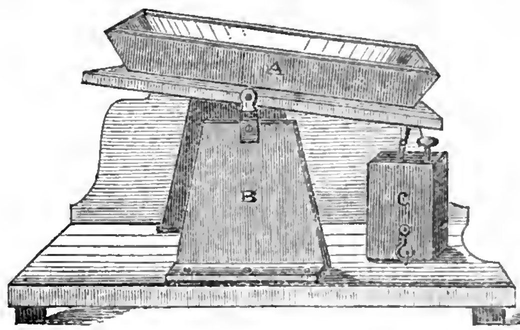
November Meeting of the Photographic Society of France:—A Socket for Lenses.—Presentation of Mr. Cobb's London Street Scenes.—An Oscillating Machine for Baths.—Instantaneous Shutters.—A New Varnish.—Flashed Red Glass for the Dark Room.—Markings in Dry Plates.—Great Photographic Proofs.—On Sodium Chloride as a Fixing Agent.—A New Solution for Plate Cleaning.—M. Laurencie on Actinometers.—A New Use for Boca's Chronometrical Shutter.

The Photographic Society of France held their *seance d'overture* on Friday, the 7th inst.,—M. Davanne occupying the chair.

M. Thierry presented a universal socket for holding a lens. By means of this socket the lens can be made to point in any direction. The inventor claimed for his idea that all swinging fronts and backs to cameras could be done away with. This assertion raised a storm of incredulity among the members, and to stop the discussion the invention was handed over to the experimental committee to report thereon.

I had the honour to present to the Society a collection of instantaneous proofs representing the street scenes of London, taken by our energetic friend Mr. W. Cobb, of Woolwich. These proofs were very much admired. Mr. Cobb was congratulated, and described under what difficulties they were taken (from the top of an omnibus, &c.). The view representing the London Meat Market caused a little hilarity, as some of the members recognised a countryman in the gentleman so closely following up the lady in the scene.

M. Léon Baluze presented a very ingenious apparatus which he calls "*balance curette.*" This is an instrument intended to keep in constant motion any solution in the photographer's tray. In these days of gelatino-bromide of silver an apparatus such as this can render great service by keeping the developing solution continually going on and off the plate to be developed; in fact, the operator can leave the plate in the bath and attend to other business, and thus a great saving of time can be secured. The apparatus consists of a flat board



A, Dish or tray. B, Stand. C, Clockwork.

supported upon an axis in its centre like a pair of scales. One end of the board is attached by a connecting rod to a strong clockwork jack, which, being wound up, continues its work for about two hours without any noise or jerks. The rapidity of its motion can be regulated at will, and it can be started off or stopped immediately. It is a very pretty apparatus, and was very much admired by the members.

M. Arwin presented an English instantaneous shutter upon the same principle as that given by the late Mr. Noton in The British Journal of Photography, November 21, 1879, and resembling very much one patented by me in conjunction with M. Collin and presented to the Society. In the first plan I employed a square opening from the centre; in the second idea I used an eclipse, and this was afterwards modified to have a parallel opening in the centre. This rapid shutter, being in the memory of the members when the other was presented as new, gave rise to much discussion.

M. Parrayon presented to the Society a new varnish for negatives, its chief value being that it can be used cold. Bottles were distributed among the members to be experimented upon.

M. Pelletier, the great glass manufacturer, presented some panes of yellow glass flashed with red.

M. Hiékel made the remark that he had employed such glass years ago, and had had fog. He now employed only cathedral-green glass backed up with yellow paper, and, although he had very much light, it was of the right kind, for he was now secure from fog and other evils.

An important discussion took place upon the best mode of lighting. I gave my opinion that it is better to use, in conjunction with any transparent medium, such as glass—whether red, yellow, or green—a sheet of paper, tissue, or ground glass in order to disperse the rays of light as much as possible.

M. Audra requested the members to inform him by what means the markings known as "slugs marks" could be cured, and what was the cause of their appearance.

M. Franc was of opinion that they were caused by a kind of scum on the surface of the emulsion, which was itself generated by the employment of silicate of potash in plate-cleaning.

I gave a method which I thought would cure it. As it had been remarked that those who measured out the exact quantity of emulsion for each plate, and spread it over by means of a glass rod, were more liable to these markings than manufacturers who spread the emulsion on by means of machinery, I suggested that more than the sufficient quantity of emulsion be poured on the plate, and that the excess be thrown into a filter. Thus, if any scum should be floating upon the emulsion, it would be taken off the plate with the excess of emulsion, and probably the repeated filtrations would at last eliminate the scum from the surface of the emulsion. In my own practice I have never had to complain of these markings, owing, perhaps, to the fact that I act as I have suggested here.

M. Chalot presented some splendid proofs, 20 × 24 inches, of the Chateau de Chantilly, the residence of the Duc d'Aumale. Such fine specimens of the photographic art are very rare, and the artist who undertakes such a task ought to meet with encouragement, as it wakens up energy and stimulates to further exertions. M. Chalot merits every praise, and has won a famous name in the profession. At first a simple amateur, his love for photography made him purchase a photographic establishment, and by his energy and perseverance he has made his studio second to none in Paris.

Dr. Liesegang, of Dusseldorf, made a communication to the Society on the value of common salt in fixing. I could not understand if this gentleman suggested common salt as a fixing agent when no hyposulphite of soda was at hand, or what advantage chloride of sodium or ammonium can have over the well-known fixing agents.

M. Frank de Villecholle informed the members that he had experienced great inconvenience in the use of the silicates in plate-cleaning. He had tried M. Audra's sugar solution and many other processes without being completely perfect; but he had now hit upon an old dodge which had proved very good and useful. He gave us the history of the discovery, which could be made romantic if desirable. He was making a tour in the south of France, and was no little astonished to see the peasants cleaning their windows so differently from the mode employed in Paris, where the panes of glass are bedaubed with whiting. He made inquiries, and found that the liquid employed was produced by making an infusion of a plant called "pariétaire." 300 ounces of boiling water is poured upon two ounces of pariétaire and allowed to infuse about two hours. Seeing that this new kind of "wash" did indeed clean the windows very well (no doubt a great deal of "elbow grease" was not wanting in the sturdy peasant girls), the thought came into his mind that as photography had succeeded in making use of coffee, honey, sugar, tannin, tea, and what not, another kind of tea could be as well introduced for plate-cleaning; so he tried the formula, differing from the generality of persons who only find very expensive formulæ good. He found the cheap one did every thing to his satisfaction, and, having found it so, most generously offered his discovery to his colleagues, who are now at liberty to try it and, if possible, gain a fortune by this imparted knowledge.

M. Laurencie, President of the Photographic Society of Angoulême, wrote a long letter to the Society on the advisability of creating a standard sensitometer, by which the different gelatino-bromide of silver plates now in the market could be controlled as to their rapidity. He said that makers of dry plates wrote indiscriminately upon their boxes twenty times and sometimes thirty times more rapid than wet collodion, and very often when tried no two boxes marked with the same number gave the same results. He proposed that the Society should adopt his method, which was to superpose forty thicknesses of dioptric paper, beginning by one and finishing by forty, forming by this method a square actinometer like a draught board—a black line to be drawn between each square. This system, according to M. Laurencie, if adopted by the Photographic Society of France, would create a standard in which we could have confidence.

To the honour of the Photographic Society of France a great objection was manifested regarding the opinion of M. Laurencie. One of the members proved that it was impossible to procure in the market three or four sheets of paper exactly alike.

I informed the members that I had long ago employed the system of superposing paper in order to make an actinometer of my own, a description of which was published in THE BRITISH JOURNAL OF PHOTOGRAPHY; but as soon as Mr. Warnerke had passed his into the market, and the trade began to adopt it, I put mine aside to employ his, hoping by this means to be able to judge of rapidity. In hearing the number of the sensitometer evoked as a standard in any journal or treatise on photography, opposition became rife against Mr. Warnerke's actinometer, as no two were precisely similar The phosphorescent surface did not give the same luminosity, &c., &c.

In reply, I said that until a better was found I would continue to use the one I had experienced to be the best in the market. I would never go back to paper machines, which were still more defective.

M. Chabanon presented a volume of his travels through the *Gorges du Jarn*, illustrated by photography.

M. Vidal drew attention to the value of photography for the true illustration of such books, and regretted that it was not more often brought into requisition. He showed the difference between a woodcut published by the journal *La Nature* and the same view produced by photography in the publication of M. Chabanon. The photographic proofs were produced by different processes—silver chloride, platinum, fatty ink, and pounne laque.

M. Vidal made a communication on the value of Boca's chronometrical shutter in measuring the rapidity of all other shutters. He takes a piece of cardboard, such as is used for visiting cards, with a glazed surface. This white surface is covered with printers' black ink, by passing it over the inked surface of a lithographic stone. With a compass a segment of a circle is drawn; the point of the compass scratching off the ink leaves white lines visible. The divisions are obtained by the same method. This dial is placed over the dial already on Boca's shutter. A long dial hand is affixed to the axis of the dial, and the instrument is ready for use. I omitted to say that the dial hand must be painted white. In order to operate the dial is placed in full light, and a camera is put in front of it to reproduce on a standard plate the whole apparatus, so as to judge of the rapidity of the instantaneous shutter to be experimented upon. Boca's shutter is now wound up, the plate is in the camera, and the shutter is placed upon the lens. Everything is ready. Boca's shutter is set going, and when the needle or hand has traversed three parts of the dial the exposure of the plate is made with the instantaneous shutter the speed of which requires to be known. When the plate is developed the distance travelled over by the dial hand of Boca's instrument is carefully measured, and knowing that it requires three seconds for the dial hand to make a revolution one needs not be a very great mathematician to make the calculation as to the rapidity of the motion of the shutter to be tried.

As for myself, I see another use for this instrument as arranged by M. Vidal. It will make an excellent machine for judging the rapidity of dry plates. For instance: a *standard* light is thrown upon the apparatus, the plate or plates exposed are developed, and the distance travelled over by the dial hand in each case will give the different rapidity of each plate. The correctness in conjunction with Warnerke's actinometer can thus be judged of. E. STEBBING, *Prof.*

25, Rue des Apennins, Paris, November 11, 1884.

APPARATUS AT THE EXHIBITION.

To the EDITORS.

GENTLEMEN,—You have been kind enough to mention in your Exhibition critique a developing dish or frame accidentally left by me in the room at Pall Mall. The prime idea of it is, of course, to make the plate the bottom of its own dish. About 1878 I had made a frame on this principle, but, having no rubber padding, the developing liquid was apt to run out if the plate did not fit accurately. At the studio of Mr. Carruthers, photographer, in Langholm, I saw a printing-frame adapted for the same purpose, whereby the liquid was kept from escaping; and afterwards, with the help of my gardener, I adapted a cheap travelling printing-frame in the same way. Being satisfied that this frame did not after considerable use stain the plates, as I feared it might do, I got Mr. Hume, of Edinburgh, to make the frame now on the Exhibition table. I am told that Mr. McGhie, of Glasgow, has made several, with the advantageous addition of a "well."

To those who wish to economise solution, who like clear edges to their plates, who are afraid of frilling, and who do not want dirty fingers while examining their plates under development, I can heartily recommend this dish, and, if desired, will describe the method of making one.—I am, yours, &c., ANDREW PRINGLE.

Craigcleugh, Langholm, N.B., November 10, 1884.

P.S.—I claim no priority in this matter for either myself or Mr. Carruthers. I neither know nor care who first adopted the main principle. Mr. Warnerke told me he had used a similar dish for his films, but I did not inquire to what time he referred.—A. P.

A NEW DEVELOPER.

To the EDITORS.

GENTLEMEN,—I should last week have sent you a correction of the obvious error in my former week's letter, for which I think the "printer's devil" is responsible; but I hesitated to take up any more of your valuable space on a matter that did not appear to be of sufficient interest to your readers. However, if your correspondent will send me his address I shall be happy to reply to him.—I am, yours, &c., W. T. F. M. INGALL.

Greenhithe, Kent, November 7, 1884.

MEDAL AWARDS AT THE PHOTOGRAPHIC EXHIBITION.

To the EDITORS.

GENTLEMEN,—I thank Mr. W. P. Marsh for the exquisite delicacy of his satire. It is certainly worthy of the reign of Queen Anne—the golden age of polite literature. But may I be allowed to take a little exception to the "dog in the manger" illustration contained in his playful letter. I shrink *in toto animo* from the implied compliment, inasmuch as I had no vested interest whatever to protect like that lucky dog. If he had selected another of the animals of Noah's ark his genial banter would have been more to the point. However, that is neither here nor there so far as the real issue is concerned.

Was the negative in question retouched, or was it not? We have Mr. W. P. Marsh's own statement to the effect that it was not. For my own part that is quite sufficient to allow me to offer to your successful and distinguished correspondent my most unqualified apologies for doing him an unintentional injustice. I did not write as I have done in any haste, for I gave (I was going to say) a monopoly of my attention to that special instantaneous study of breaking waves, and left it with a distinct impression that it was "faked." Certainly I no longer entertain that disagreeable impression, and I am heartily glad of it for everybody's sake.

There is another point in Mr. Marsh's letter which leaves no margin whatever for either surprise or apology—that is, his doughty advocacy of the Hanging Committee. He, however, in his usual vein of satire, unconsciously misses the thrust of his foil when he suggests that the gentlemen of that Committee "ought to be executed;" and he assigns to me the congenial office of "executioner." In this wish we are entirely of one mind. Although the apostle of mercy by profession, I think I would at a pinch compromise my apostleship and lean to the side of inflexible justice, condemning them, one and all, without hope of a reprieve.

It is awfully kind of Mr. Marsh to suggest that next year I should hang all the pictures as well. Here, gentlemen, I must draw the line of refusal. The office of hangman to a committee would be an easy task compared with that of hangman to the photographic masterpieces of the amateur nd professional artists of England and Europe! I shrink from the responsibility so unselfishly suggested in my honour.

With reference to Mr. J. Harmer's defence of Mr. Marsh's *Sea Study* negatives, I have only to remark that his rhetoric is more consistent than his logic; for in his letter he lovingly vindicates the unsophisticated quality of his friend's work by the very slipshod defence that "in consequence of having made transparencies from *most* of his plates I am in a position to state that *they* are not retouched." *Verbum sat sapienti.*

However, in spite of the loose logic of Mr. Harmer and the loving banter of Mr. Marsh, I reiterate my tender of full apology and make *pro bono publico* the *amende honorable.*—I am, yours, &c.,

H. VICTOR MACDONA, M.A.

The Vicarage, Cheadle-Hulme, November 1, 1884.

[This letter was inadvertently omitted from our last issue.—EDS.]

MAGIC LANTERN TRANSPARENCIES.

To the EDITORS.

GENTLEMEN,—As I have experienced considerable disappointment in the results obtained in my experiments with transparencies on gelatine plates, I hasten to give corroborative testimony to all that one of your contributors has said in favour of the use of common washing soda in the developer.

Having placed one of Eder's German plates in contact with a fairly-plucky negative, I gave it an exposure of six seconds to an ordinary gas burner at a distance of about four feet from the jet, and then immersed the plate in a dish containing about three ounces from the following stock solution:—

Washing soda	1 ounce.
Water	10 ounces.
Bromide of potassium	8 grains.

For each ounce of this solution I added one grain of dry pyro. When development was completed I rinsed and fixed as usual, and after a further operation of the same kind I placed the quarter-plate in the following clearing solution:—

Alum	1 ounce.
Citric acid	1 ,,
Sulphate of iron	3 ounces.
Water	20 ,,

When I removed it from the dish, judge of my delight to find as clear and sparkling a transparency as I could possibly wish to see—quite as plucky and brilliant as any I have ever seen from those of the plates now in the market advertised as a speciality for transparency work.

This is a formula the credit of which is entirely due to Mr. H. Norwood Atkins.—I am, yours, &c., H. VICTOR MACDONA, M.A.

The Vicarage, Cheadle-Hulme, Stockport, November 7, 1884.

PACKING SENSITIVE PLATES.

To the EDITORS.

GENTLEMEN,—It has been the common practice of makers of dry plates to put a piece of *tissue* paper between them to prevent contact. This, if kept in its place equally, is all right; but the plates not being all flat—some being thick and some thin as they come up in cutting—when sorted into dozens for packing, in the turning them up to get them square the paper shifts, and in many cases goes awry across the plate, leaving an insensitive mark, which necessitates the cutting off from the picture when printed from a-quarter to half-an-inch all round—more or less according to the displacement.

This may be obviated easily by the adoption of a pure *felt* paper, which, not being rolled, but of the nature of blotting-paper, keeps in its place and enables every plate to truly tell its own tale. The price of the plates need not be altered thereby for those who like a first-rate article.

It is to be hoped that this may catch the attention of manufacturers and lead to the general adoption of a paper which shall make all plates perfect. —I am yours, &c., W. HARDING WARNER.

November 5, 1884.

Notes and Queries.

P. G. writes:—"Kindly inform me what is the cause of a circular spot of brightness which I sometimes get in the centre of my negatives?"——In reply: This is owing to an image of the aperture in the diaphragm. To effect a cure, let the distance between the lens and the diaphragm be altered.

GEORGIUS asks if it would not be permissible, when strengthening a negative by means of bichloride of mercury, to add to this salt one which had an acknowledged reputation for stability.——In reply: We have had some experience with such admixtures, and can recommend one of chloride of platinum, the proportions being nearly equal parts.

VERAX has a number of proofs which have been much over-printed, and he is at a loss to know what steps to take so as to prevent their being altogether lost.——In reply: He can either use them as transparencies, or reduce them by immersion in a weak solution of cyanide of potassium for a period of time varying from a-quarter of an hour to three or four hours.

B. T. inquires if a registration which shall be legal, and consequently valid, cannot be procured for the design of a new camera.——In reply: A design can be registered, but what good would be a *design* in the case of a camera if it were not supplemented by some description of its various parts? These (the latter) cannot, however, be protected under the Designs Act, but must form a subject for a patent.

B. J. T. writes:—"I have heard much concerning the Fothergill process. What is it?"——We answer: It is a dry collodion process not now used, or, if so, to only an exceedingly limited extent. A plate of glass having been coated with collodion is excited in the usual way; then partially washed, flooded over with diluted albumen, and finally washed in a very thorough manner. Many admirable negatives have been obtained by this process.

"WHAT are the simplest and best means of getting rid of blisters in prints. —G. G. B."——We reply: Let the prints, after washing, be transferred to the hyposulphite of soda, and after that to a solution of chloride of soda the strength of which is less than that of the hyposulphite. This is the way that is recommended by several practitioners. Still, it is difficult to indicate one method as being either simpler or better than another, for different samples of paper require different systems of treatment.

"WHAT system would you recommend for cleaning plates with special reference to the adhesion of collodion emulsion, which, as you doubtless know well, shows a strong tendency to leaving the glass, especially if the development be protracted?—O. G."——To this we reply that an application of powdered French chalk answers every purpose. It certainly has done so in our hands. We have seen a rather neat way of applying it which may have been published, although we do not remember having read it. This consists in mixing the chalk with alcohol and pouring a little of the mixture upon the plate of glass, followed by firm friction with a linen cloth.

"I HAVE been told that in America they have some dodge for producing dimples. Can you tell me anything about this, or any other "wrinkle," as it would be rather a good thing to be able to send out one's fair sitters' portraits with a pretty dimple upon each face, particularly with those where nothing of the sort has been seen for the past half-dozen years. I have tried no end of retouching, but cannot find out any satisfactory method.—VERAX."——Our correspondent's signature is belied by the tenor of his note. A certain amount of retouching is a legitimate addition to a good photograph; but such pictorial falsehoods as he suggests are, to our mind, illegitimate—to use a very mild form of words—and are to be deprecated by all right-thinking artists. Still, there are little plans in the direction he indicates that may with advantage be made use of, and they will be found treated in a leading article in another portion of our columns.

"CANNOT the front lens of a portrait combination be made to answer quite as well for taking landscapes as a lens specially constructed for such purpose? I have tried it, and do not see anything specially amiss in the system. Kindly enlighten me on this matter, and oblige—OLD SUBSCRIBER."—In reply: When a single achromatic lens has been ground with special reference to landscape purposes it is usually somewhat deeper in its external curves than the front of a portrait combination. This being the case, it can the better transmit an oblique ray than a lens of a plano-convex form, which form, subject to scarcely appreciable modifications, is that preferred in the case of a regular portrait combination. The deeper the meniscus form of a lens the less it is qualified for becoming part of the anterior element in a portrait combination; but, on the other hand, the better is it adapted for fulfilling the requirements of a landscape lens required to transmit a wide angle.

Exchange Column.

Wanted, negative or enamel collodion in exchange for 10×8 and $7\frac{1}{4} \times 4\frac{1}{2}$ water-tight baths.—Address, PHOTO., Bridge-street, Usk, Mon.

I will exchange the *Photographic News* for THE BRITISH JOURNAL OF PHOTOGRAPHY, posted on Monday.—Address, G. SMITH, The Castle-hill, Dudley.

I will exchange two splendid gasometers for anything useful in photography, or musical instrument.—Address, G. B. BRADSHAW, Oxford-road, Altrincham.

I will exchange my 40-inch "Meteor" tricycle, in good condition, for a first-class dry-plate apparatus.—Address, J. LIGONIER, 106, Corbyn-street, Hornsey Rise, London, N.

I will exchange a whole-plate portable landscape camera, two double backs, new, for a gas bag, pressure boards, and safety jet.—Address, FRED. DAKING, 108, Bramford-road, Ipswich.

I will exchange THE BRITISH JOURNAL OF PHOTOGRAPHY for the years 1882 and 1883 for the following books:—*Art and Practice of Silver Printing*, by H. P. Robinson and Captain Abney; *Pictorial Effects in Photography*, by H. P. Robinson; *Instructions in Photography*, by Captain Abney, fifth edition.—Address, W. STUART, 53, Chapel-road, Worthing.

I will exchange a large truck, box wheels (sides to take off), useful for tent travelling, cost £4 10s., in good order, and about a-quarter of an ounce of eighteen-carat gold for chloride.—Address, Photo., 14, High-street, Wincanton.

What exchange offered for a six-lens gem camera, takes eighteen in three shifts, and a four-lens gem camera, takes twelve in three shifts, both in perfect order?—Address, A. Hopkins, photographer, 21, Bartholomew-street, Exeter.

Wanted, a first-class burnisher, about half-plate, or portable whole-plate camera, in exchange for Woodbury and Marcey's patent sciopticon lantern in case complete.—Address, H. C., Jevens Hall, Milnthorpe, Westmoreland.

Wanted, ferrotype plates, cabinet mounts (no consequence if printed on one side), and outdoor background, in exchange for a quick-acting short-focus *carte* lens or gem camera and nine lenses, or cash.—Address, Photographer, 28, East John-street, Exeter.

I will exchange an exterior background, in oil (new), desk with three changes, good half-plate camera, one dark slide, four carriers, also two glass baths, full-plate and half-plate, for a good full-plate lens.—Address, H. Wootten, 128, Ellen street, Preston, Lancashire.

Wanted, Dallmeyer's 1B and 2B lenses and good archimedean camera stand in exchange for a nearly new $7\frac{1}{2} \times 7\frac{1}{2}$ sliding-back camera and about 800 clean negative glasses, and make up the difference with cash. —Address, N. E. White, 77, Crofton-road, Camberwell, London, S.E.

I will exchange a 10×8 Kinnear camera complete, half-plate rigid camera, half-plate retouching-desk, Squire's cabinet portrait lens, Grubb's half-plate view lens, Jamin's quarter-plate portrait lens, quarter-plate instantograph complete. Wanted, studio accessories.—Address, Fritz Camera, 41, High-street, Sydenham, Kent.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

Photographs Registered.—

William Henry Batten, 4, Oxford-grove, Ilfracombe.—*Photograph of James Whitehead, Wesleyan Minister.*

Horace Dobell, Sheate-place, Bournemouth.—*Four Photographs of Water-Colour and Pencil Sketches of Bournemouth.*

J. J. K. will find the information he requires in another column.

York.—We shall write to you privately after trying the experiments.

Arthur C. Heilbroun.—The matter is really not worth any further consideration.

G. Austin (Birmingham).—The address of Mr. Lewis is 12, Clerkenwell-green, London.

Lens.—No photograph of the machine was sent, nor is it so stated in the letter. You have evidently misread the letter.

Ajax.—See article on the subject in the Journal of October 24th, and leading articles in the same and following numbers.

W. W. A. (Notts).—Too much alum has been added to the gelatine solution in the first instance. You can do nothing with it now. You will have to prepare a fresh batch.

Several Correspondents this week have not complied with our rule by sending their names and addresses; hence, as usual on such occasions, no notice is taken of their communications.

G. Bailey.—Write again and give a fuller description of your troubles. We have no doubt that we can assist you; but it is impossible to do so at present from the scanty material supplied.

Camera.—1. The leather enclosed will answer the purpose very well.—2. Quite a matter of taste. For our own part we prefer the rack and pinion. —3. Messrs. Nettlefold and Sons, High Holborn.

A. Simms.—If the prints refuse to leave the glass when they are dry it is clear that it has been imperfectly waxed. Try treating the plate with French chalk. Perhaps you will get on better with that.

Ferrotype.—The light will no doubt answer quite well for the purpose. Whether its cost will allow of a profit on cheap pictures will, of course, depend upon the price charged for such "cheap pictures."

M. S. Y.—Read the article in which the preparation of the albumen is described, and you will at once perceive the cause of your failure. Throw away that you have, and prepare fresh according to the instructions.

A. S. S. B. complains of the bad glass that some manufacturers employ for their dry plates. This is true as respects some makers, but not all. It is an old grievance that has been well ventilated from time to time in our columns.

T. Wilson.—A copperplate press will answer quite well for rolling photographs. Such presses are frequently to be met with second hand, and at a comparatively low price. An advertisement would, doubtless, secure what you require.

J. C. Winsor.—There is no question whatever, notwithstanding the name on the mount, that the lens is a very inferior instrument. Take the lens to the maker whose name it bears and we doubt not he will repudiate it. From your description it is doubtless a forgery.

A. B. C.—Get "French chalk litho. ink No. 3." From what you state we imagine the fault is in the plates, and not in the ink. Judging by your description of their behaviour we should say that from some cause or other they are insoluble, and therefore do not absorb the water when it is applied.

Sep. George.—We are not aware that tissue suitable for the Woodburytype process is an article of commerce at all, so cannot say if it be supplied both in a sensitive and insensitive condition. You had better communicate with the Woodburytype Company. No licence is necessary for working the process.

Wm. G. McGregor.—In the studio, of which you send a photograph, you should certainly be able to produce much better specimens than those forwarded. It is true the studio may not be one of the most convenient in which to work, but still excellent results are turned out of many which are infinitely worse in design than yours.

Z. Z.—The failure in your reducing operations is due to insufficient heat. The small lump you have forwarded shows this clearly. The application of the heat from the blowpipe for a few minutes proves it conclusively, and also that plenty of flux has been added. The sole cause of trouble is the want of sufficient heat to ensure the reduction.

Artist.—From the plan we should say the studio will answer very well, and the price quoted for erecting it very moderate. We should prefer felt, in preference to the other material, as a covering for the opaque portion of the roof; but zinc is to be preferred to either. In such a studio, if you do not turn out first-class work it will not be owing to any fault in its construction. The portrait enclosed is very good, but it wants a little more brightness.

Received.—Andrew Pringle; Benjamin Wyles; J. H. Harvey. In our next.

Photographic Club.—The subject for discussion at the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 19th inst., will be—*On Collodion Emulsions.*

Lantern Catalogue.—We have received from Messrs. Wilkinson and Company, Sunderland, their new illustrated catalogue of lanterns and slides, models of steam engines and parts, opera glasses, microscopes, and other optical instruments, together with magneto-electric machines and mathematical instruments. It forms a useful and instructive compendium of works, artistic and mechanical, in the directions named.

The Late Mr. J. Hubbard.—Many of our readers will learn with regret the death of Mr. J. Hubbard, whose picture, *Mother's Love*, was awarded a medal at the exhibition just closed. Mr. Hubbard was originally a portrait painter, but some quarter of a century ago bought from Mr. England the photographic business in Oxford-street, with which his name has been connected almost up to the time of his death. Having been for some time in failing health he was ordered by his medical man to seek a change of air, and in consequence of this advice so recently as September last he removed from Oxford-street to New Wandsworth, where he died on the 5th instant, at the age of 60; and was buried on Monday last, the 10th. Mr. Hubbard will be remembered chiefly by his pictures *Stolen Moments*, *Pensive Thoughts*, and his last one, *Mother's Love*, over all of which he spent much time and lavished a great amount of artistic care. For some years past he had done very little practical photography, but devoted his time chiefly to the production of negative varnish, for which he had acquired a considerable reputation.

OUR FORTHCOMING ALMANAC.

We shall be glad to receive at once the contributions of those friends, English and continental, who have already promised articles for our Almanac for 1885. Those who intend to contribute to its pages, but have not yet signified their intention of doing so, we would ask to forward their valued *quota* by an early post.

We have been informed by the Publisher that he can receive a few more Advertisements, if forwarded not later than Friday next, the 21st instant.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician,
For the Week ending November 12, 1884.
These Observations are Taken at 8.30 a.m.

Nov.	Barometer.	Wind.	WetBulb.	Dry Bulb.	Max. Solar Rad.	Max Shade Tem.	Min. Tem.	Remarks.
6	30·02	SE	50	50	—	57	49	Raining.
7	29·86	SW	50	56	—	62	49	Bright & Clear.
8	30·35	W	42	44	—	55	40	Hazy.
10	30·63	E	48	51	—	56	48	Foggy.
11	30·45	SE	45	47	—	51	45	Foggy.
12	30·29	SSE	45	48	—	—	45	Overcast.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1281. Vol. XXXI.—NOVEMBER 21, 1884.

THE PRODUCTION OF PLEASING TONES IN COLLODION TRANSPARENCIES.

The subject of lantern transparencies is one that has been a good deal before the public of late, and the present is the season when that class of work is most in favour with amateurs who employ their winter evenings in the production of, perhaps, the most pleasing form of picture that can be produced by photography. The recent tendency appears to be in favour of albumen plates for the purpose; but, beautiful as undoubtedly are the results obtained by the Taupenôt or collodio-albumen method, we are by no means sure that the majority of amateurs will not prefer a simpler process if results at all approaching those of albumen are obtainable.

Next to albumen it is generally conceded that the best results, both as regards quality of image and beauty of tone, are rendered by collodion emulsion. We do not mean to say that *any* collodion emulsion will answer the purpose; for such is not the case, as those preparations which are best suited for landscape work from their rapidity are, as a rule, unsuited for the highest quality of transparency. But a specially-made collodion emulsion has scarcely a rival in the field. Wet plates still hold their own—rather as a matter of convenience than because they are capable of giving the highest class of result—in the commercial production of lantern slides. Their ease of preparation as compared with albumen, and rapidity in comparison with emulsion plates, render it almost necessary that for production on a large scale for the market the wet plate should retain its position; but the comparative coarseness of the image and the limit of tone obtainable is distinctly inferior to what can be produced upon the dry plate.

Recent experiments have demonstrated that by judicious variations of the exposure and development almost any class of tone is obtainable upon gelatino-chloride and even gelatino-bromide films; and what is true of gelatine is at least equally so in the case of collodion, but with this addition—that by altering or modifying the "organifier" a still further range of colour is attainable. This is well known to all the older workers of dry plates, though not, perhaps, to the newer generation, whose alpha and omega in dry-plate work are gelatino-bromide and gelatino-chloride. The beautiful variety of *colours*—for they are something more than variations in *tone*—which have been produced upon gelatino-chloride films have nearly all had their prototypes produced by means of collodion and of silver bromide.

Thus tannin, as the organifier, produces various shades of brown, and Major Russell, in the first edition of his *Tannin Process*—published upwards of twenty years ago—directed attention to the alteration in colour which the combination of tannin, gallic acid, and pyrogallic acid (in the preservative and the developer) effected. Gallic acid alone gives red shades, pyro. black or blackish-brown, coffee rich brown, while a combination of "beer and albumen" (at one time a favourite organifier) gives greenish-brown or olive tones. In some extreme cases we remember the colours being a pure, rich green. All these tones, however, are modified in character by the exposure and development just as in the case of gelatino-chloride, the same rule prevailing, viz., the longer the exposure with a correspondingly-restrained developer the redder or warmer the tone.

But the most remarkable colours we recollect in connection with developed and untoned images—colours, moreover, which were eminently suited to the purpose of transparency making—were some we obtained on the early plates of the Liverpool Dry Plate Company in 1867. These varied from a rich, clear claret colour to a nearly pure scarlet, and were the invariable result of long exposure and well-restrained development. Under those conditions it was easy to reproduce these colours at will; shorter exposure of the same plates produced a pleasing warm brown. The development almost invariably employed at that period was a two-grain solution of carbonate of ammonia, with pyro. and bromide of potassium to taste. What preservative or organifier Mr. P. Mawdsley employed we do not know, but it was mainly tannin with, we believe, gum and gallic acid. Whatever it may have been, very similar colours are obtainable with a combination of tannin and gallic acid.

The emulsion best suited for transparency work is a slow one. A collodion composed of pyroxyline five grains, crystallised bromide of cadmium six grains, and bromide of ammonium three grains in each ounce will answer well, if treated as we shall direct. The pyroxyline may be any good wet collodion sample, and the solvents which are used in equal parts should be as highly rectified as possible, in order to permit of the addition of a few drops of water without producing crapiness or texture in the film. To sensitise the collodion: for each ounce take eleven grains of silver nitrate, and dissolve it in a test tube or small flask in a very small quantity of water by means of heat; five minims of water will suffice for each eleven grains of silver. When dissolved add half-a-drachm of warm alcohol, bring the solution to boiling point, pour it in two or three doses into the collodion (which should be in a bottle capable of holding at least twice the quantity), and shake well after each addition. Transfer the emulsion to the flask, or, at anyrate, rinse the latter out with a portion of the emulsion so as to secure every trace of silver, and then set the preparation aside to ripen. After a few days two grains of bromide of cadmium are added (in crystals), and the emulsion will then keep indefinitely and go on improving.

In preparing the plates the glass is first polished with powdered talc, dusted, and coated with emulsion, which should be allowed to set very thoroughly, but not to become dry. When sufficiently set the plates are passed through three or four changes of water to remove the free bromide. The last change may, with advantage, be hot, as it then opens the pores of the collodion film and causes the latter to absorb more of the organifier when plunged into the cold solution.

The organifier we prefer is made as follows:—First of all prepare a *cold* saturated solution of gallic acid. Do not use heat in the preparation of this solution or it will become supersaturated, in which condition it is liable at any time to deposit minute crystals of gallic acid *in* the film, causing spots. To each ounce of this solution add ten or twelve grains of tannin and filter. The solution will probably not be clear, however carefully it may be filtered; in which case add a few drops of dilute albumen, 1 : 5, shake up well, and again filter. The plates are removed from the hot water, plunged into this organifier, and allowed to remain for from three to five minutes, drained thoroughly upon blotting-paper until surface dry, and then allowed to dry in a closed cupboard or box free from draught.

Instead of the tannin, a solution of coffee, made by infusing one ounce of freshly-ground coffee in a pint of boiling water, may be used; this is filtered, and saturated when cold with gallic acid. This gives very good brown tones.

The exposure of the plates so prepared will be comparatively long if warm tones are required—probably from thirty seconds to a minute (by contact) before a good fish-tail burner. For very red tones a brief exposure to daylight will answer better.

The development is performed with equal parts of solutions of pyro. and carbonate of ammonia, each of four grains to the ounce, and as much of a ten-grain solution of bromide of potassium as the exposure may necessitate; but in this experience only must be the guide. Fix in hypo., wash well, and tone if necessary with very weak gold.

The process, of which the above is a brief *résumé*, will yield results which are little inferior to albumen, without one tithe of the trouble the albumen process involves.

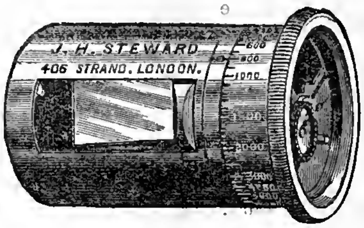
TELEMETRY FOR PHOTOGRAPHERS.

While photography was still young, and long before it had attained its present advanced state, it was predicted that it would ere long assert its usefulness to the traveller and explorer in so marked a manner that the camera would form a cherished *vade-mecum* with this class. This prophesy has been fulfilled. No tourist or explorer would now think of journeying into distant and unknown regions without the means of reproducing the scenery and salient features of such countries.

But the estimation of form is one thing, while the ascertaining of dimensions of such form is quite another. There has hitherto been insuperable difficulty interposed in the way of this estimation of dimensions, on account of the fact that the camera cannot estimate or indicate the distance of the objects it can so faithfully depict. The late Sir David Brewster devised a telescope—which, however, was never made an article of manufacture—by which the distances of objects from one another, and these from the point of observation, were so distinctly marked as to render it possible to pronounce with a tolerable degree of accuracy upon the distance of any object under observation.

If an inaccessible object were photographed from a point of view at a distance, and if this distance were accurately known, then, by having also a knowledge of the precise focus of the lens, the dimensions of the inaccessible object might be ascertained from the two factors mentioned superadded to the size of the image, which would, by a rule-of-three process, enable the dimensions of the inaccessible object to be ascertained. But the obstacle to be overcome has been to obtain the second term of the proportionate rule, which may be thus roughly expressed:—As the focus of the lens is to the distance of the object, so is the dimension of the object depicted in the photograph to that of the natural object. This rule may be considered as correct—to a suggestive extent, at least. But a difficulty has hitherto been experienced in ascertaining the distance of objects far removed from the camera. We are quite well aware that by the aid of a sextant the distance of any inaccessible object can be ascertained with a tolerable degree of accuracy; but we need scarcely point out that the employment of such an instrument is attended with some trouble, and involves much subsequent calculation.

We are pleased to be able to state that, through the enterprise of Mr. J. H. Steward, optician, Strand, a very neat little instrument has been introduced—so small as to be capable of going into the waistcoat pocket, yet by which the distance of objects can be ascertained without any calculation whatever. It is designated the "Labbez telemeter," and it forms a surveying instrument as well as a pocket range-finder. Heretofore range-finders have required not only calculations but also the services of two qualified individuals to use them; but in this telemeter—which is in the form of a tube little more than the thickness of one's middle finger, and scarcely exceeding half its length—everything is arranged in such a manner as to enable a single individual to ascertain, in the brief period of thirty seconds, and without assistance or any calculation whatever, the precise distance of an object, no previous training being required.



We shall not here attempt any description of the mechanical construction of the telemeter beyond saying that, by rotating a small toothed wheel on the end, and placing the zero mark upon the zero line, the object is viewed by looking in a direction at a right angle to it, the conditions for this being supplied by a small mirror placed at an angle in an opening in the side. The observer then walks a short distance in the direction towards which he looked, and once more brings the object that is being examined in the same line as before, this being effected by rotating a movable portion of the tube, on which are divisions, until coincidence is effected. He then finds that one of these divisions is opposite the zero, and that is the actual distance of the object in question given in yards.

We have in this description omitted some small details, but the whole operation is substantially as described. The value of this tiny pocket telemeter is evidenced by such men as Colonel Maurice, R.A. (special officer of Lord Wolseley's staff), Sir C. Warren and his A.D.C., Sir Bartle Frere, and others of equal eminence, having secured them for use during campaigns in distant countries. We contend that they may be rendered as serviceable to the photographer as to the military man; and we hope to see them in general use as an accessory to the camera of the tourist photographer.

PHOTOGRAPHING THE NATIONAL PICTURES.

Allusion has frequently been made to the alleged superiority of the copies of works of art produced on the continent over those produced in this country. Indeed, in the eyes of some, English photographers appear to possess but a second-rate reputation as copyists of oil paintings, or at least of those in our national collections. One thing seems pretty certain, namely, that photographic reproductions of the pictures in foreign collections are to be obtained commercially of a far superior quality to those procurable in our own galleries. In fact, so far as we are aware, there are really no copies of our national pictures of moderate dimensions, or, at anyrate, comparable in size to those from foreign galleries.

Various reasons, more or less erroneous, have at different periods been assigned for the alleged superiority of foreign over our home productions—such as the superiority of the light abroad, secret processes of working, greater skill on the part of the operators, elaborate retouching, and the like. But practical men, who have had experience in this class of work both here and abroad, affirm that the superiority of the continental reproductions is principally due to the greater facilities which are afforded for photographing the pictures in the foreign galleries; also, that if equal facilities were granted by the custodions of our own pictures, similarly good results would be produced.

All who have had experience in copying any of the pictures in our national collections knows full well the difficulties with which they had to contend. Very great difficulty is usually experienced in obtaining the necessary permission in the first instance, and when it is obtained the restrictions placed upon it are generally such as to render it quite impossible to produce anything like a presentable reproduction. For example: the painting must not be removed from the building; that is quite out of the question. Neither may the glass be taken off, or in many instances even the picture removed from the wall upon which it is suspended. Hence, if the picture be copied at all, it must, perforce, be done as it hangs, and through the glass, should it happen to be glazed. With such restrictions it is by no means surprising that the copies when made—if they be made at all—are far inferior in character to those seen in the shop windows, and produced on the continent. In the face of such facts it is not very astonishing that publishers, competent to execute work of the first order, have not undertaken the reproduction of the paintings in our national collections on a scale similar to that of other countries.

Now, we are not for a moment going to suggest that there should be no restrictions placed upon photographing these pictures, or that anyone should have *carte blanche* to do as they liked, simply because the paintings are public property. Such an idea would be simply absurd on the face of it; indeed, no one would dream of entertaining such a thought. But when application is made by a respectable firm prepared to incur considerable expense in the execution of the work, and whose reputation must, at least, be a guarantee that it would be creditably carried out, while every care would be taken of the pictures, permission should be accorded, and at the same time the restrictions placed upon the due execution of the work should not be of such a nature as to render the permission equivalent to a refusal.

Some few months back considerable excitement was created by the erection of a mysterious and exceedingly ugly iron building in front of our National Gallery in Trafalgar-square. It was soon explained that this building was simply a photographic studio erected for the purpose of copying the paintings, and that in due time students and others would be able to obtain copies of our national pictures of a character much superior to any hitherto produced, and this by reason of the greater facilities given for copying them. It was also commented upon at the time that the trustees had at last seen the advisability of giving similar facilities to photographers for reproducing the pictures to those afforded to them in continental galleries.

Many were under the impression that this unsightly erection was put up expressly for the use of any one who could obtain the necessary consent of the authorities to make copies of the paintings—similarly as the trustees of the British Museum have provided a studio and dark room for the use of photographers in making copies of the ancient prints and manuscripts in their collections. Not so, however, for it soon became rumoured in photographic circles that this iron building was only of a temporary character, and was erected solely for the use of a certain foreign firm of publishers in photographing the pictures. Also, that the restrictions hitherto imposed as regards taking the pictures from the main building, removing them from the frames, &c., were not to be enforced in this case, and that this firm could do pretty much as they liked in the matter. In a word, MM. Braun and Co., of Dornach, had obtained concessions which had hitherto been denied to English photographers.

It is by no means unnatural that some persons should feel somewhat aggrieved at this, particularly after the rumours that were afloat some time ago that certain foreign photographers had acquired privileges in copying the paintings in some of the royal palaces which could not be obtained by English photographers. If all this be true, it is scarcely to be wondered at if the work of foreign artists should get the credit of being superior to that of the English in the reproduction of works of art, and that the latter are compelled to occupy a lower position in the estimation of the public.

In the daily papers, last week, the Secretary of the Fine Art Society published a correspondence between himself and the Director of the National Gallery. This we reprint in another column. From these letters it will be seen that the Fine Art Society obtained permission, some time back, to reproduce by the process of photogravure a series of pictures in the National Gallery. But the permission was, as usual, accompanied by such restrictions as regards taking the pictures from the frames, removing the glass, &c., that it was practically valueless. It is manifest to all that it would never do for any firm to incur the expense of reproducing the works by such an expensive process as photogravure unless they could ensure such results as would sustain their reputation, and this would simply have been impossible under the circumstances. Hence the idea had to be abandoned.

Since then MM. Braun and Co. have not only obtained permission to photograph the pictures, but to take them down from the walls, remove the glasses, and actually carry them out of the building into the temporary iron shed erected for the purpose. With this the Fine Art Society and, we believe, other English publishing firms very naturally feel aggrieved. The correspondence shows that the privilege denied to the Fine Art Society, though granted to the German firm, had also on a previous occasion been accorded to a French firm. The explanation of the director of the National Gallery is one that we have little doubt will not be accepted by English photographers as altogether satisfactory.

As the matter now stands, many of our readers will fail to see why privileges, which under the circumstances amount to nothing less than a monopoly, should more than once be granted to foreign firms in photographing our national pictures, while they always have been, and—as will be seen from the correspondence given in another page—are even now, though not solicited, denied to their own countrymen.

TELESCOPES AND PHOTOGRAPHY.

In the early part of last month we gave a brief sketch of the connection between photography and astronomy, as seen by American astronomers, and we ventured to express our dissent from the very depreciatory tone which they used in regard to the capabilities of photography for some kinds of observational work. The position we took has been amply and fully justified by one of the first of living astronomers, Mr. Norman Lockyer, who, in one of the Cantor lectures—only recently published though delivered some months ago—gives a very complete account of the past records of photographic progress in its application to astronomy, and speaks in a tone of complete enthusiasm as to what it may achieve in the future. Concurrently with the publication of Mr. Lockyer's lecture we find in the columns of *Nature* the commencement of a series of articles by Mr. Common on *Telescopes for Astronomical Photography*, and in both the paramount importance of the science to astronomy is lavishly admitted; indeed, each gentleman goes further, and points out in no uncertain language that astronomical observation has been revolutionised by its aid. In a very brief manner we may, therefore, bring before our readers some description of the mode in which photography has enabled such progress to be made, of the modification of the instruments employed for the various purposes indicated, and the difficulties attendant upon the work.

In effect a telescope is used as a camera, putting the dark slide in place of the eyepiece, and special arrangements have to be made for, on the one hand, solar, and, on the other, stellar photography. The difficulty with regard to the sun is the intensity of the light, while with stars, nebulæ, &c., its feebleness has to be counteracted.

Mr. Lockyer, in his lecture, exhibited and explained Dr. Janssen's arrangement for securing views of various portions of the sun's surface. It is as simple as ingenious, and its action will be readily understood by photographers who are familiar with instantaneous shutters, as it simply acts as a drop shutter, but is actuated by a spring whose accelerative action ceases the moment the exposure commences, and so an equable rate of movement is obtained. The aperture of this drop shutter is a mere slit whose width is capable of adjustment, and thus the action is but momentary over any one part of the plate. The advantage of the "brutal copy," which Professor Young describes that given by the sun camera, may be understood upon reading Dr. Janssen's statement that "an interval of two seconds is quite enough to change the physical distribution of the bright and dark portions of the solar surface near the spots." "Dr. Janssen finds," said the lecturer, "alone by this means—it is not a thing visible to the eye, the eye gets too tired and strained—that these markings are distributed over the whole sun's surface," &c. Here we see that but for photographic aid we should have absolutely no knowledge of these and many other important phenomena.

With regard to the stars a very opposite state of things exist. Their light is so feeble that with the full aperture of the lens, so to speak, acting at once, a considerable length of time is required to obtain an impression, and in the meantime the object, the star, is not stationary. For eye observation, however, a requisite amount of motion can be given to the telescope by clockwork to cause it to follow the moving object automatically, and thus for hours the star can be kept in sight. "In sight," we say advisedly, for, though the image of the star remains in about the same place in the field of view, it is not exactly stationary; hence any star picture, including, of course, clusters and double stars, would be quite useless for scientific purposes, either as representations of a portion of the heavens or as records of magnitude.

Here the trained human eye and hand are found to act better than any mechanism hitherto devised in keeping the image of a star exactly stationary in the field of view. The telescope is provided with two wires crossing one another, and the object to be attained is to bring and keep a star's image continually bisected by the cross wire for as long a time as possible. Mr. Common, in making his photographs, arranges an eyepiece for his own use and a prepared plate for the photographic action; and his gigantic task was to keep his eye at the telescope the whole time the plate was being acted upon, and so supplement the action of the clock by a set of adjusting screws he had devised to be worked by his hand as he found necessary, that for no appreciable time did the star leave the one point.

If our readers will devote a little consideration to the magnitude of this task they will see the enormous strain it must be upon the faculties of the observer. Mr. Lockyer gave half-an-hour as the probable length of time the average human observer could stand such a strain without breaking down; yet, he informs us, Mr. Common was able to keep it up for an hour and a-half.

Dr. Huggins adopted a somewhat similar method for obtaining spectroscopic records of the stars. He also had to supplement the driving clock by manual adjustment, and keep the image of a star upon the slit of the spectroscope; but in his case the only harm which happened when the image of the star wandered from the slit was that, as no photographing went on at all, the exposure was thus increased. In Mr. Common's pictures the photographing would still continue if the image moved, and the effect would be that well known to the photographer when his camera moved during exposure—a worthless doubled image.

Then there are difficulties of varying colours in the stars, of which Mr. Common says:—"Though such pictures may differ slightly from eye observations, owing to the different colours of light not affecting the eye and the sensitive plate in the same manner, they would have the enormous advantage that they could be compared directly with other pictures taken after the lapse of any number of years under conditions that there would be no difficulty in making almost identical." Mr. Lockyer says the same thing in language, showing that colour need be no difficulty:—"It is perfectly simple to get one photographic plate and to put on it a dozen or twenty images of different stars, which will give you, in terms of a certain salt of silver, at one epoch the different radiant energy of those stars for comparison in future time."

The effects of differing exposures has been well seen in a series of Mr. Common's celebrated photographs of the nebula in Orion. When one minute's exposure was given nothing of the nebula was seen, and only a few of the brightest stars. With two and a-half minutes the brightness was increased, and a trace of the nebula shown. Four minutes gave more stars—ten minutes the nebula fairly starting into sight. Twenty minutes increases its brilliancy, and an hour shows the nebula in all its beauty.

The Rev. T. E. Espin, who has been so successful in Liverpool, points out the difficulties of—(1) the instrumental errors; (2) temporary cloudiness of one part of the field photographed; (3) unequal absorption—the latter a very difficult and complex matter. He gives a neat calculation showing the various influences of length of exposure, aperture of lens, and sensitiveness of plate as affecting these conditions. But though he is doubtless right in indicating on condition, governing the apparent amplification of stars given by photography, we think that by far the larger share of the increase in size following increase of exposure beyond a certain limit may be placed to the credit of reflection from the back of the plate, and internal dispersion.

In our next issue we propose to conclude our survey of the subject by treating further of this point on the instrumental conditions governing the various problems.

We thought the days of baby shows, barmaid shows, *et hoc genus omnes*, were over, but our Gallic neighbours do not appear to think so, as a little while ago they organised a baby show in Paris, which, however, was ruthlessly prohibited by the police. Not to be cheated out of the opportunity of rewarding the possessor of exceptional beauty, the baby show is to be replaced by an "International Beauty Show," the candidates for fame not having to appear in person, but by means of a photograph. Well aware of the fictitious beauty retouching is able to impart, the projectors of the show have made a rule that the competitors are to sit to one photographer, who is appointed for the occasion, with instructions not to touch up or improve the portrait in any way. The photographs are to be of uniform size, the sitters to have low-necked dresses, and the head to be left uncovered. A jury of distinguished artists is to award the laurel, which is to be of a very substantial character—no less than a diamond tiara—while twenty unsuccessful candidates will receive diplomas. The pictures will be publicly exhibited, and the general public offered an opportunity of registering their votes. We pity the unfortunate photographer who is to be entrusted with this task. We apprehend he will for many months following the exhibition have to be guarded by *gendarmes* to protect him from irate lovers. Our very strong advice to him is that he should wear a mask and stipulate that his name be kept an inviolable secret, otherwise he will have several bad quarters of an hour.

The action of light on selenium has formed an interesting study to electricians and others for some time past. Our readers may remember that a method of transmitting photographs by electricity was founded upon this property of the light-sensitiveness of selenium. We now read that Professor Bell states he has been successful in conveying speech five hundred feet by means of a strong ray of light acting upon a selenium cell. We suppose the turn of photography will come next.

The precipitation of gold is by no means a matter of small importance, though it is too frequently one of indifference to most photographers. Waste toning baths contain large amounts of gold, which, as a rule, are thrown away; yet nothing could well be simpler than to precipitate the valuable unused metal by adding a little sulphate of iron, which throws down metallic gold ready for immediate solution after the supernatant fluid has been decanted. The best methods for precipitating gold under various conditions have lately been under investigation by German chemists; and, according to the *Chemiker Zeitung Gœthen*, the old method of the photographers has superior advantages, and is only indicated by the presence of chlorine, bromine, nitric acid, and the hypochlorites of calcium, magnesium, and sodium—substances unlikely to cause any difficulty to photographers.

White shellac is generally difficult of solution under any circumstances, even when new and in good condition; but the difficulty can be remedied by getting rid of the included water, this admixture of water being one cause of the white appearance the lac presents. It is introduced during the process of manufacture, the lac after its precipitation by chlorine being washed and pulled into ropes under water. The best method to adopt is to break the lac into small pieces, and then spread them out to dry in a warm place. After the lapse of a short time it will be found much more soluble than before, owing to that portion of the spirit in proximity to the resin not being diluted with the contained water, strong alcohol being a necessity for the solution of lac.

Considerable attention has lately been given to the obtaining of magnesium in a pure form, the metal hitherto procurable being very impure. The well-known film which so quickly appears upon the surface of the ribbon after keeping a short time is a function of the impurity, the effect—due to the combination of the metal with the atmospheric oxygen—not being seen, it is stated, when pure magnesium is employed. New methods of purification by electro-deposition have been devised, and at a recent meeting in Berlin of the Electro-Technische Verein a pure ball of magnesium of superb brilliancy was exhibited.

Mr. Brashear writes to our contemporary, the *English Mechanic*, giving some cautions about the processes of silvering glass from silver solutions. He says—"Don't let your solutions set around;" he did so once, and almost lost his life. In making some of the silvering liquid on one occasion, as he could not dissolve the precipitate readily, he left it open to the air in a vessel on his desk, forgot it, and left the room. Fulminate of silver was thus formed, and was exploded by the mere jar of a closing door as he left the room. A terrific explosion ensued, the room was wrecked, and the open vessel was driven half-an-inch into the hard wood. When the silver surface is satisfactorily made Mr. Brashear says it will stand a considerable amount of rough usage, and he recommends it to be cleaned by rubbing gently for ten minutes with a piece of cotton wool under a stream of water from the tap, blotted off with a piece of blotting-paper, and when dry the fluff brushed off with a camel's-hair brush before polishing. He states that in making the silvering solution he prefers equal parts of silver and potash, instead of half the quantity of potash as recommended by other authorities.

According to a writer in the same journal, Mr. Gorham is to be credited with an important discovery in optics. By means of a little instrument Mr. Gorham has devised he is able to measure the pupil of the eye, and the results of his measurements, which have been made several hundreds of times, show that the pupil of the eye can be made use of as a photometer. The little instrument is made as follows:—"On a circular plate fitted on to the end of a cylinder about two inches long, and one inch bore, were marked radii—the more the better. On each radius are made two small holes, varying from ·05 to ·28 in. apart. This circular plate is covered over with another which has a slit in it, and which is capable of being twisted round the first-named disc. On looking through the cylinder at any light two holes will be seen. Twisting the outer circle round till these two holes just touch, we may read on the scale at the other side the width of the diameter of the pupil. Applying the well-known rule that the intensity of light varies inversely as the square of the distance from the luminous body, we may thus compare the intensities of any sources of light." We are rather hazy as to the exact meaning wished to be conveyed in this sentence we extract; but it is by no means unlikely that the germs of some useful photographic instrument may be found.

FIXING SILVER PRINTS WITHOUT HYPOSULPHITE.

A short article in last week's Journal by Dr. Liesegang bears the above startling title. I suppose the next thing to expect will be "sensitising paper without a silver bath." Truly, we are advancing with rapid strides! But, joking apart, any novelty that promises to eliminate the only drawback to our beautiful silver process, namely, the really wearisome, never-to-be-contemplated-without-a-shudder washing operation, is (few will deny) of the utmost interest to us. The article in question I eagerly read with beating heart and bated breath, and I felt that at length the goal had been reached, that our necessary yet treacherous friend "hypo." had received his death blow, and that the photographer's "golden age" had at last come.

I congratulated myself that henceforth there would be an end to those weary washings and changings, and tearings and ——— (it rhymes with tearings); an end, and for ever, to faded images, and ———. But my elation at this bright prospect was but momentary, for on nearing the end of the said article I realised that a cruel *ignis fatuus* had come to torment us with its lurid and unsubstantial beams, the writer informing us that "albumen prints lose their chloride in the bath, but the albumenate of silver remains and deepens in colour by light." Would that the happy dream had proved a reality, and that henceforth every household would afford us both developer and fixer—the former in our homely "washing soda," and the latter in that useful culinary compound, "common salt."

But the illusion is dispelled when we see that Dr. Liesegang is only talking of collodio-chloride prints, and as no one imagines that this process will ever supersede that on albumenised paper his communication will prove of little benefit to the majority of workers.

If I mistake not, now that mechanical have superseded manual methods of coating, *gelatino*-chloride paper can be manufactured of uniform quality and at a much lower cost than can *collodio*-chloride; and this paper has been shown to give prints almost, if not quite, equal to those on albumenised paper. Why should not such a paper be put into the market at the same price as the ordinary sensitised paper now used? Then, indeed, we might reap the benefit of our foreign *confrère's* ingenious discovery; for, there being no albumenate to "remain and deepen in colour by light," we should at length have a printing process possessing, as Dr. Liesegang has shown, the immense advantages of rapidity, economy, and permanence. Locke Macdona, B.A. (*Oxon.*).

MODERN "DARK ROOM" IMPROVEMENTS.

No. II.

A handy sink is one of the chief points in a well-fitted-up room. Plenty of space for splashing about freely without splashing over, and some well-contrived adjuncts for conducting at least the more usual operations, are absolutely necessary. Not least important is it that entire safety should be ensured against leakage and overflows, especially if the studio be situated in the upper part of a building—perhaps with other peoples' offices or shops below. Woe to the luckless photographer who, at the mercy of not too careful *employés*, has had the water left "on" with a defective outflow pipe. A peremptory message from the irate Mr. Blank demands that he will instantly go down and see the destruction his carelessness is causing. The vocabulary of expletives is turned full upon his devoted head; and, although the mischief may have arisen from something in which his commands have been directly disobeyed, it will be well for him if his neighbour after cooling down prove a reasonable man, or the annoyance has been arrested in good time. A few simple precautionary measures to prevent this nuisance arising will be far better employed than vain regrets after the occurrence. Memories of stores of cigars *galore*, "meerschaums," and similar articles taken and paid for because "spoiled," or at least said to be so, by infinitesimal damp prompt an earnest recommendation to *see to the outflow*, and over and above that have a gridded overflow, and again and beyond that a second and larger overflow. *Experientia docet.*

But to return to my sink. A leaden trough, four or five feet long and from two and a-half to three feet wide, in days of old was rather a capacious affair, and sufficiently so even when large plates had to be manipulated. But with flat dishes for developing, for fixing baths, to say nothing of a washing tank—all these being liable to spillings, more or less—the sink space requires very considerable extension nowadays. It is not at all requisite, however, that the sink itself, or what may be called its main body, need be altered. My own plan has been to add about three feet of wooden slope at each end draining into the sink, and of similar width. A board along the front of the whole comes sufficiently high to catch splashes and protect the clothes of the operator. Of course the whole must be made secure by a lining of some impervious material. Providing the sink itself is well leaded, a cheaper material serves every purpose for any sloping extensions where liquids are not retained. Willesden paper leaves nothing to be desired. It is cheap and easily cut to suit, though, of course, it wears out in time if chemicals are constantly getting to it; but its power of endurance is really marvellous. If anybody be very anxious to make it for themselves it is said that copper in small pieces (nails or filings) digested in liquor ammonia for some time and the solution applied to stout paper answers perfectly; but the Willesden Company supply it so reasonably that it is not worth while to try it.

On the "wings" described the fixing and alum baths can be conveniently placed, and another bath of gutta-percha contains Mr. M. Carey Lea's bichromate and sulphuric acid solution. Into this waste plates are thrown, and easily washed clean at leisure. The water pipe is forked, each branch having its own tap—one supplying general requirements, the other connected by a flexible pipe with the grooved washing tank standing in the sink proper. A shelf over and at the back of the sink and immediately below the window holds developing solutions, pourers, a box for soap and pumice stone, and any article very frequently required, not omitting a supply of table salt for cleaning the backs of gelatine negatives, which should always be attended to before passing them into the washing tank.

Comfort and convenience in developing and similar dark-room operations will be largely helped by combining plenty of what may be called "table" space with the sink space. Over all the sink and its side wings I have a pair of wooden rails, forming a sort of miniature tramway. On these travel—so that they can easily be brought forward for use, pushed out of the way, or even taken off and set aside altogether,—three or four conveniences, such as a good, stout table top about three feet square and *level;* another board with a slope to hold a large plate under a stream of water for washing, and an iron cross frame on which dishes can be run over an atmospheric gas burner. The sink may seem rather a queer place to have a gas burner. Its service is obvious in such a place for carbon and platinotype work. It should be of such a kind as will not be extinguished, nor the burner holes corroded by dropping water or chemical solutions. There are probably various patterns which meet the case; the "American retort stove" answers well. All this may seem rather complicated, perhaps, in recital, but is really not so; for it is time and energy saved in the long run to spend a leisure hour now and then in perfecting one's working appliances. With such an arrangement as the above work may be made a pleasure, which, if inadequately provided for, would involve worry and inconvenience. I have found it quite easy to manipulate thirty-four-inch opals, and opals may certainly be allowed to be rather awkward things when they are nearly the size of a kit-cat painting.

An *enlarging arrangement* attached to the upper part of the window, converting the dark room into a camera, needs no description. Of course in establishments having separate enlarging rooms it is not a *sine quâ non;* but the majority are, perhaps, not thus fortunate, and to them comes the consolation that nothing can be handier than the power of popping a negative or transparency into its place and securing the product without any running about or waiting. In my own case the enlarging apparatus traverses the room overhead. Indeed, I have had two side by side, and another in a separate room; but it is found that one will do a vast amount of work, and the extra ones are not needed. When much of this sort of work is going on the question naturally presents itself—Does light get diffused through the room so as to affect the gelatine plates while being changed or developed? I have never found it do so, but of course it would be foolish to have the plates filled into the slides near where the light from the lens would fall. One corner of the room, as far as possible from *all* sources of light, is best devoted to the operation of plate changing.

A *drying closet* is a useful convenience in the room, and perhaps the less it has of complications the better. So long as it is a fair size, has plenty of light, safe holes at the top, and a "hit and miss" perforated sheet-iron bottom, with a ring burner some distance below, it will meet most ordinary requirements. The drying of gelatine plates in any quantity is another matter, and needs a separate room where other operations are not going on. But short of that there are many operations for which a cupboard of this sort will be found very useful, whilst any sensitive plates about can be popped into it in a moment if it be desired to open the window to admit daylight.

Subsidiary drying shelving will be needed, especially where much enlarging is done. Nothing is more convenient than, instead of a plain board, to make the bearer of a pair of rails, and behind them fixed to the wall a "slotted" narrow board or broad lath, so that plates can be stood up perfectly straight resting on the two rails, and with one side held in the narrow slot or nick in the back lath, this being fixed so as to touch at about two-thirds the height of the plate used. There should be a series of them to take plates (say) from whole-plate to 12×10; from that to eighteen or twenty inches, and so on. Of course, being quite open, air circulates readily amongst them. These are for finished negatives of large size, glasses flowed with albumen, and other work where spontaneous drying is used. I have said "*spontaneous* drying;" but if another gas burner be permitted for boiling water and such like, and it can conveniently be placed a good distance below, the one thing is rightly fixed for helping the other by the currents of warm air passing upward.

Over this last-named stove varnishing is done in the summer when ordinary fires are out of use; and as there is a possibility of a plate just catching the flame when drying off, and also of kettles boiling over and evaporating pans breaking, I adopt the plan of setting this little stove by itself in the middle of a large metal shallow tray, which is isolated on a stone-topped platform raised a foot or so from the floor. If wet collodion be used for enlarging, as it no doubt generally is, then all collodions should be kept as far as convenient from this as well as any other flame. A good boiling pan with a copper bottom over this stove provides hot water for carbon work. Many will have the luxury of a separate room for carbon development, but where space is limited it can be very well done without. A far more important thing is a separate room for *sensitising and drying* tissue. The atmosphere of the dark room, even with the best of ventilation, seems to be most prejudicial to the keeping quality of tissue.

Whilst speaking of carbon I might mention a use for a by-product that I have not seen mentioned before. The floor of the dark room is usually of bare boards, and if it be over another room the ceiling of the latter is pretty certain to suffer from solutions spilled being partly absorbed by the boards and partly percolating between them. If the yellow backing stripped from a developing carbon picture be laid face down on the floor it adheres with great tenacity, and becomes so hard and impervious that it forms an effective protection against intruding solutions. Of course it takes some time to cover a floor; but, once done, and the stuff carried an inch or so up the skirting-board, the room floor practically forms a sort of safe tray. The only precaution needed is not to disturb it whilst wet and soft. If a pigment picture (on paper of course) prove a failure from under- or over-exposure, or any other cause, down it goes the same way. I hope nobody will suggest unpleasant comparisons with another dark abode said to be "paved with good intentions." In any case those who try it will find this sort of chromated gelatine and paper "floor-cloth" will stand being walked upon, washing when required, and that a bath of silver spilt on it would be more easily mopped up than on bare flooring-boards. BENJAMIN WYLES.

PHOTOGRAPHIC INDUSTRIES.

THE ARGENTIC BROMIDE WORKS OF MESSRS. MORGAN AND KIDD.

SEVERAL persons had spoken of the application of gelatino-bromide of silver to paper soon after it was known to have succeeded upon glass, and probably many more who kept their thoughts to themselves had indulged in surmises as to the feasibility of such application; but to Mr. Morgan, of Greenwich, was reserved the privilege of announcing to the public that he had reduced it to a commercial, practical form. Scarcely had he made public the application of "argentic bromide" to the production of positive prints upon paper than the prospective value of the process was perceived, and persons in other countries even secured it for themselves by patent. Out of this invention arose, in the country of its birth, a great industry, of which we shall now give a brief description.

The premises of Messrs. Morgan and Kidd are situated in Kew Foot-road, Richmond, being readily accessible from the various railway stations in that town. On entering the office we found ourselves in the midst of enlargements, in every style of finish, made on argentic bromide paper and opal glass. The latter in some instances were of goodly dimensions, not a few being 24×18 inches.

What appeared to be an exceptionally useful application of the process was the preparation of canvasses for the use of the painter in oils; and in the course of our visit we saw the process of preparing these canvasses. In this the great care was to have its surface in such a state, by its texture being previously impregnated with some special size, as to ensure the sensitised gelatine which is subsequently applied becoming part and parcel of the canvas, thus rendering its peeling and cracking off quite impossible. Some canvasses stretched on frames which we saw measured 50×40 inches downwards, but there seemed no difficulty in the way of preparing them of much larger dimensions whenever such should be required.

The paper is all coated by hand. Sheets of plain Saxe paper are formed into trays by having their margins turned up. They are supported below by large slabs of plate glass of the proper dimensions, loosely set in wooden frames. This ensures the paper being retained in quite a flat position. Let us follow the fortunes of one such sheet.

Upon being placed as described the frame was passed through an aperture in the partition into an adjoining room, from which all light was carefully excluded save that from gas lamps screened by red paper, aurine being the colouring medium employed. On a series of tables ranged round this dark room were placed levelled pegs at suitable intervals, on which to lay the glass plates after the paper had been coated. This latter operation was performed by the operator taking up a small vessel containing a measured quantity of emulsion, and pouring it into the paper tray. As soon as it was found to flow properly over every portion of the surface the supporting plate was then placed upon the levelled stand, and allowed to remain there until the gelatine was sufficiently set to permit of its removal. In the meantime, however, a second, third, fourth, and other sheets were being treated in like manner, and so on in succession, the number of plates being so adjusted as to ensure a succession of plates being set and ready for removal, thus keeping up the continuity of the coating and removing. When set each sheet was lifted from its glass support, attached to a light lath by one end, and suspended upon a frame which, when charged in this manner, was sent up into a drying-room overhead by the agency of an elevator or "lift." After being allowed to remain in the drying-room until quite dry—which occupied about twelve hours, more or less—the sheets, after having been examined for defects or specks, were trimmed, rolled up, and placed in the long, round cardboard boxes so familiar to those who employ argentic bromide paper. From first to last no other light had access to them than the subdued red light transmitted through the aurine paper by which the gas is carefully protected.

Recognising the impossibility of obtaining uniformity or even good quality when the emulsions are prepared with ordinary water, Messrs. Morgan and Kidd make it a strict rule to employ nothing but distilled water; and in one room we saw a large and beautiful copper boiler with its condenser, from which the distilled water was pouring continuously in a small stream.

In this room, too, we witnessed the preparation and cleaning of the opal plates. These are of the class of glass known as "pot opal," and, so far as we saw during this visit, one side was ground. This matt surface undoubtedly imparts a fine tooth for subsequent artistic work. The plates after being unpacked are laid down upon a flat slab in a sink, and subjected to smart friction with soap and water, after which they are plentifully rinsed with plain water.

Precautions are taken to ensure the temperature of the emulsifying room remaining at a uniform rate. The quantity of emulsion used daily is twelve gallons. The nitrate of silver is received in quantities of two hundred ounces every few days. Care also is taken to ensure the recovery of every particle of silver from the residues, some special means, which we are informed are to be hereafter published, being devised for this purpose. The amount recovered from residues last year netted £150.

When we visited the enlarging-room we witnessed the exposure and development of a sheet 23 × 18 inches. The enlarging cameras stand in a horizontal position, the light of the sky being thrown through the negative by a plain glass mirror erected at an angle outside; in short, the luminous sky forms the background to the negative being enlarged. At a suitable distance in front of the lens (inside of the enlarging-room) stands an easel having every adjustment and capable of taking sheets of paper of any dimensions within a reasonable range. The exposure given to the sheet referred to was thirty-four seconds, a *carte* lens being employed as the objective. At the end of this time it was placed in a dish and developed with the following:—

Saturated solution of neutral oxalate of potash... 4 ounces.
" " sulphate of iron.............. 1 ounce.
A sixty-grain solution of bromide of potassium... 6 minims.

The image came out slowly, but soon acquired great vigour and a fine colour, after which it was fixed and washed. An enlargement on a 30 × 25 sheet had just been made from a quarter-plate before we arrived, the exposure given having been a minute and a-half. But the atmosphere was thick with a brownish vapour during the day of our visit, so that the figures here given as representing the exposures must be viewed as calculated from that light.

Certain rooms upstairs are devoted to artistic work, and we there saw several lady artists engaged in finishing the enlargements under the supervision of Mr. Wake—a gentleman whose name is well known to many of our readers.

The whole of the dark rooms are lighted by gas, shielded by red paper, in preference to daylight, which has been found to be unsteady. The premises are all heated by hot-water pipes, of which there are no fewer than two thousand feet employed for this purpose. The conductors of this establishment evidently entertain the sound opinion that, in order to get the various classes of work executed in the best manner, those to whom such work is entrusted must be made to feel quite comfortable as regards temperature.

We may close by remarking that, until we were shown through the extensive and well-appointed premises of Messrs. Morgan and Kidd, we had no conception that such a large and important "industry" had been formed in connection with the sensitising of paper by the agency of argentic bromide.

A NEW DEVELOPER: FORMIC ACID IN THE DEVELOPER.

[A communication to the Glasgow and West of Scotland Amateur Photographic Association.]

There has lately been much correspondence in the photographic journals on the merits of various substances as preservers of pyro. Sodic sulphite has been well discussed, some swearing by it and others swearing at it. The truth seems to be that pure sulphite is a capital thing when you can get it, but difficult to procure and to keep when you do procure it.

For my own part I prefer formic acid. Here is a red-coloured concentrated solution of pyro. in alcohol, with the addition of formic acid. It has been kept ten weeks, yet when diluted with water for use gives a colourless solution. On the addition of ammonia and bromide, as for developing, you see it becomes a very deep ruby colour, and in a few seconds clears to the colour of very pale sherry. It will remain like this for an hour. Here is some mixed two hours and a-half ago, which is not yet dark enough to stain a plate.

In using this developer the image comes up with the same rapidity and vigour as with plain pyro. Formic acid is not in any sense a restrainer, but has itself been proposed as a developer. It, however, neutralises a small part of the ammonia, so that rather more may be used than with plain pyro. The following is a convenient stock solution:—

Pyro. .... 240 grains.
Formic acid .... 1 drachm.
Methylated alcohol .... $1\frac{1}{2}$ ounce.

Each drachm contains twenty grains of pyro. Dilute as required for the plates you use, but leave out of your formula any nitric or citric acid it may contain, as the formic acid replaces them.

W. Goodwin.

TWO POINTS AND A LITTLE PHILOSOPHY.

At various times, and from different quarters, the removal from gelatine of that abomination "grease" has formed the subject of inquiry, and articles have emanated from the pens of various gentlemen having for their object the removal of this annoying though most natural adjunct of the now indispensable stock article—the holder and recipient of the silver bromide. It was but very natural that this substance, productive as it is of the numerous opaque spots which still crop up in many makes of plates, would draw attention, and that a suitable remedy should be sought for. Even Dr. Eder had, if my memory serve me rightly, a hand in the matter, and subjected gelatine to a special treatment in view of its purification from the individual point of view now in contemplation.

Among the remedies suggested—one that I saw adopted by a professional plate-maker—was ammonia. A two-per-cent. solution of the alkali in plain water filled a jar, in which the gelatine was placed to soak for a while, the alkaline solution poured out, and the glutinous mass washed in repeated changes of water until, in fact, all smell of ammonia had disappeared. Whether this remedy was or was not fully efficient I am not prepared to say, as the answer were best elicited by actual experiment, which anyone is open to make if he choose. I believe, however, that this special mode of treatment was ultimately abandoned and some other, which I did not inquire after in that particular quarter, adopted.

As I personally object to the use of ammonia, it was in another direction I had to seek to overcome the difficulty, if possible. My plates, just the same as other people's plates, would insist now and then upon having the horrid pest—little, round, opaque spots that would have tried even Job's patience when discovered, on issuing from the laboratory, on a pet negative, promising most unprofitable labour on any proof of value it was desirable to see perfect. Ammonia is not by any means the only thing that will track out grease. There are others—spirits of turpentine, for instance, which is the inveterate enemy of oleaginous and fatty matters. It wrestles with them then and there, and has the upper hand in no time. But, then, if applied to the substance in question, with the end in view—what about its effects on sensitiveness? I confess that I did not think it advisable to try it, though it might happen that some unlooked-for results might have come forth. Such strange and unexpected things do crop up in the laboratories of even tyro experimentalists! In the golden days of the search after the philosopher's stone, quaint things sometimes came about in the alchemist's sanctum, more than one discovery of a valuable nature being made unexpectedly, and while seeking after a totally different object. Thus it might be with the search for the most suitable reagent to effect the present purpose. By the way, it is not always safe, even for those well versed in chemistry, to rashly handle chemicals and bring them in contact. A gentleman of my acquaintance (a doctor of chemistry) was much ill-used once while carrying on investigations with substances of an apparently innocent character; and in the columns of The British Journal of Photography I have at different times seen the record of possible accidents furnished by the Editors, with a view to serve as a warning to the unwary.

To return to the subject: while it was not at all unlikely that a thorough search might have led to the discovery of a better agent than ammonia, other means no less efficient might be found, and in this direction why not investigate likewise? There are more ways of killing a dog than by hanging. Why not see what might be done by various ways of filtering? I originally filtered my emulsion, to rid it of objectionable residues, with the once orthodox chamois leather

Unfortunately chamois leather, while being very useful in many ways, is heir to various disadvantages only recognised with protracted experience; and as a strainer, even under the best of conditions, it is far from being perfect. I tried swan's-down calico. One sample worked fairly so far as residues were concerned, but that was all. Another sample proved inefficacious altogether. Two, and then three, folds of muslin next had a turn, proving quite effective in checking the passage of any rather coarse particle; and, in fact, a plate coated with emulsion thus strained was free from any *grittiness* to the touch, but on the application of the developer the crop of spots came out as impudently as ever. Clearly, then, of the three kinds of strainers used there was not one that would perform the twofold duty required. The number of textile fabrics that might still have been tried would, perhaps, prove unlimited. Then there was mohair, floss silk—I was going to say wool, forgetting that it would have to be of a special kind; for ordinary wool, as most people know, is itself of a greasy nature, and might have imparted some of its own viscousness to the already-existing evil. Since animal products had that peculiar character of enhancing, in all probability, instead of destroying, the malady, it led me to lay my hand again on an old friend—a great favourite in days fast disappearing, when collodion filtering was a frequent necessity. Need I name the famed product of the Southern States of America, where, at the proper time, it is seen oozing out of the husk awaiting picking, putting into bales, and shipping to the textile manufacturer of Manchester, &c.?

I, too, had found it, and could exclaim—"Eureka!" Cotton wool (medicated) not only filtered nicely in the usual way, but it, moreover, quite effectually removed the objectionable grease from the gelatine, giving as fine and perfect an emulsion as could be desired. And why should it not, when one comes to think of it? Why? What about its fibres? Are they not so many tentacles eager to firmly lay hold of whatever they choose to forcibly retain? And this, indeed, they do with a power that would put the octopus to shame. This is at least my experience on a small scale; and, if twenty ounces of emulsion can effectually be filtered in this wise, why not more, even if one had to renew the cotton when once fully charged? It is advisable to loosen the fibres a little prior to commencing filtering operations, and it is needless to say, I presume, that the cotton ought not to be moistened if one desire to retain in the fibres the necessary elasticity. My own *modus operandi* is simply to put a plug of the cotton in the neck of the funnel—not too tightly—and to filter away.

For use on a large scale it is highly probable that layers of cotton wool, with fibres loosened as advised, placed on silver wire, mohair, or some fabric or other fixed as the wire-work is fixed in sieves, and of any desired diameter, would effect the end quite well; however, this can easily be tried. Now all this is exceedingly simple, and yet it is like the egg of Columbus—it merely wanted to be thought of and realised.

There is a point I now wish to touch upon, and which has nothing to do whatever with the one just elucidated, and that is—chrome alum: its use and its real functions. Professed chemists, many of them at least, are, I daresay, in a position to define the nature of chrome alum. There may be, for what I know, an axiom—a formula—about it. Some symbol might represent it, and all this would be very fine; but, as a simple matter of fact, I would fain ask what chrome alum is beyond the mere symbol, beyond the mere equivalents, beyond its being chrome and alum of chromated alum, if you will.

It is proved past controversy that, associated with gelatine, it gives this last an unwonted hardness, and enables it to resist that disastrous tendency—frilling. It is, in fact, usually said to tan this, as it does cognate substances. So far as I am aware the knowledge of this form of alum goes no further, photographically speaking. Now I would venture to call for a closer examination of this substance, but more especially of its effects when embodied in gelatine for photographic purposes, and when the developer is brought to bear upon the same. I would ask that two plates be coated with the identical self-same emulsion; but one prior to the addition of chrome alum, and the other after the said addition has been made. I would advise their being developed with a mild developer, so that no frilling arise with the first plate; also the two to be developed side by side in the same dish with the same solution, and, after fixing and proper washing, to be carefully examined. It will then be seen that a considerable difference exists between the two. There will be a characteristic most pronounced on the alumo-plate, and a species of harshness and strength of which the other will be *minus*. I like the alumo-plate; I much prefer it to the other, while ready to concede that it is quite possible that the plate void of alum would be appreciated for special purposes where softness would be a desideratum, as in the case of the portraits of especially delicate women and children. But for most purposes, I repeat it, I like an alumo-plate; and, what is more, I prefer it well charged with alum. Experience has shown me that it does not at all slow a properly-made plate.

I have raised this question wittingly and advisedly. I think there is much more in it than might be suspected *primâ facie*. I should like to see it examined and discussed by one of the London photographic societies, for instance. I think something useful might arise out of it. Of the secondary ingredients that find room in emulsions I scarcely think any have more sterling value; but what that exact value is remains still wrapt in a mystery which it were desirable to see dispelled.

I do not believe I am far wrong in thinking that much is yet to be learnt of the real properties of the agents in daily use in photography. Diligent as past investigators, such as the Rev. T. F. Hardwich and Mr. M. Carey Lea, for instance, have been, there is yet a wide field to explore. Some of the properties are known; others not yet as much as foreshadowed. It is when combinations take place especially that the problem becomes complex—often times manifold; and a very sagacious eye is frequently required to penetrate, determine, and fix that which had hitherto remained unperceived and unsuspected. Moreover: are we quite sure that our conception of even so simple a combination as

$$AgNO_3 + KBr + KI$$

is perfect, or, rather, complete?—that the reactions are grasped in all their bearings? This may, to say the least, be questioned. I take it that we merely have a legible formula, comprehensible as such to those versed in chemical science; but I contend that, beyond, far more lies than is apparent at the mere reading of this otherwise simple formula. The formula proper is nothing more than the various terms of a plain addition, so far requiring no interrogative note, the outcoming and usual answer to which is palpable at a glance to the initiated; but I must insist on the all-important fact that much more lies beneath than on the surface. Let us deflex two beams of light—one yellow and one blue—on a white strip of paper, and we shall certainly obtain a green strip as the result. Then on to this deflex a beam of orange and we shall obtain a deep, warm, neutral green, or, rather, olive. Now describe exactly, first of all, the absolute character of the yellow, blue, and red, characterise to a dead certainty the successive compounds, if you can, and, taking into consideration the nature of the light that passed through each coloured medium, try and find out an adequate definition. Now the chemical problem is still more intricate, still more complicated, no less abstruse. How, then, is the simple, attempted equation to give forth, and at once, all desirable answers?

Moreover, the chemical formula lacks *aqua distillata*. The respective quantities should be defined that ambient heat kept account of, and its thermometric value should be recorded as well as any change of the same during the period of contact. If artificial heat be resorted to, it likewise must be studied and registered, as each additional degree and duration of action under the individual circumstance will naturally go to influence and modify results; and while most carefully following the reactions with all known scientific instruments and knowledge, much will still wholly escape your observation which on some future day may be detected by a closer investigator. What is received currently and accepted now in science will be demonstrated some years hence as either fallacious or deficient. Such is human science happily excused by our predecessors in these curt words—*humanum est errare*.

If asked for the drift of this disquisition I shall not have to go far to seek the answer. It lies in the fact of my having sought for an inquiry into the action of chrome alum in the bromide of silver solution. I detected more in it than others have apparently done—or think I have, for one should never be too sure of anything. I think good may result from the inquiry, and that must be my apology for leading my Pegasus further and in a more disorderly manner, perhaps, than is allowable in the field of scientific speculation. A. F. Genlain.

EMULSIONS IN COLLODION.

[A communication to the Photographic Club.]

The collodio-bromide emulsion process and its various modifications for several years engaged the attention of experimentalists, but without arriving at the degree of rapidity attainable by its formidable rival, gelatine. This has been pressed into every phase of photographic practice with a kind of feverish assiduity, whilst the good features of the older forms are almost ignored. There seems, however, to be some reaction setting in, as was evinced by your favourable reception of the albumen process given recently by Mr. Ackland. In re-introducing the process, for which we are indebted to the genius of one of the members of this Club, Mr. W. B. Bolton, I shall make no apology, and in no way as a competitor with any other system; let each stand on its own merits. I would willingly have ceded the position of exponent to other hands, so now I ask your indulgence whilst I prepare the emulsion in what may be termed its incipient form.

The formula stands thus:—

Plain Collodion.

	oz.	gr.	dr.
Methylated alcohol	2	6	0
,, ether	2	2	0
Pyroxyline, H. T.	0	0	60

Bromising Solution.

Methylated alcohol	1 ounce.
Water (about)	100 minims.
Bromide ammon. (58 and 5 grs. exc.)	63 grains.

Sensitising Solution.

Nitrate of silver	100 grains.
Distilled water	60 minims.

The mixture is made.

It will be observed that there is in the above a large proportion of water, but as our purpose is to obtain a finished and washed product this is of no consequence. If it were to be used in its present form it would be quite necessary to use a bromide wholly soluble in alcohol, such as zinc or cadmium, as even the water imported into it with the silver has the effect of inducing reticulation in the film. Still, many good plates have been done by the simple emulsion process. They were coated with a mixture similar to this, washed singly, and flowed over with an organifier, such as tannin, &c. Now the washing of the whole bulk of emulsion, as afterwards proposed by the discoverer, was perfect in principle, as exemplified by the procedure with gelatine at the present day. As I cannot in the time at our disposal tonight go through the whole of the operations, I have brought examples of the different stages up to the final result. We have here our emulsion, which should be allowed to stand for a day, with an occasional shake. It should be then poured into a dish to set into the condition as found in this washing vessel. After soaking, the first water is tested to find if the bromide be really in excess, and then the washing continued till all trace of soluble nitrate of ammonia and excess of bromide has disappeared. The pellicle is now placed in a strong piece of calico, the water and remains of the solvents are squeezed out, and gathered up for drying. This may be done either in a water-bath or spontaneously. As it is now sensitive to light, care must be taken to let no white light reach it.

I showed you a dried specimen that is soluble in equal proportions of ether and alcohol—together about eight ounces—which will keep good for several years.

This is a small quantity of filtered emulsion made by the above formula. The plates are prepared by simply pouring over in the usual way with collodion, and are ready for use without further treatment. I also put in a plate to show the contrast between it and an ordinary gelatine film, a negative, and a transparency.

The reason I have given a formula divested of all the complications introduced subsequent to the first publication is that I never found any appreciable advantages resulting from their adoption, whilst many difficulties arose, such as spots, fog, thinness of image, tenderness of film, &c. There are other salts capable of emulsification in collodion, chiefly iodide, chloride, and their combinations. For the first no satisfactory developer has been discovered. I hope some day to find the iodide yielding up an image to appropriate treatment. I shall leave Mr. Doods to deal with the chlorides. J. Nesbit.

MR. NORMAN LOCKYER ON ASTRONOMICAL PHOTOGRAPHY.

[Abstract of a Cantor Lecture before the Society of Arts, May 5, 1884.]

We will begin by referring to what may be included under the term "spectrum photography." In this we have to do naturally in the day with the sun, and at night with the stars and with the nebulæ. I have not much in this present lecture to bring before you with regard to the sun, because it is not necessary that a large telescope should be used for that body, for the reason that its light is so great that the small telescope will do just as well. Parenthetically, however, it is as well that I should refer to the sun somewhat, and draw your attention to some new optical methods and arrangements, which are exquisitely beautiful in their way, with reference to that body. The light of the sun is so very overpowering, and the light of the stars is so dim, that you may easily, without my telling you, come to the conclusion that the difficulties which have to be overcome in the two classes of research are of an entirely different character; and that is so. We have to succeed in solar photography by battling with the excess of light. We have to succeed in stellar photography by battling with its defect.

I have here, by the kindness of Dr. Janssen, what in France is called a "trap," and what we call a "slide," and this instrument will give you an idea of the way in which the excess of light in the case of the sun has been dealt with, perhaps, in the most satisfactory manner. It is a complicated instrument in appearance, but really it is simple when we look at it. It is intended to deal with the excess of light of the sun by only allowing that excess of light to fall upon the plate for an excessively-minute portion of time. This apparatus, therefore, is placed in the telescope between the object-glass which collects the light and the photographic plate, and the only light which can fall on the photographic plate has to pass through an aperture. Now, in front of this aperture is arranged a sliding slit, the jaws of which can be regulated by means of a screw, so that I may bring the jaws together until they are almost in contact in case the excess of light is very great, or I may separate them still more by moving the screw in the opposite direction. Then, when I have got this slit as fine as I think it necessary to have it for that particular day, I can, by means of a trigger, allow this slit to snap very rapidly over this aperture, through which alone the light of the sun can fall on the photographic plate. There are several very beautiful contrivances in this instrument. One of them I will show you when I have again set the trigger.

Here is the point at which is the opening which allows the light to fall upon the photographic plate, and this is the spring which produces the movement. Now you will see in a moment that if this spring were acting during the whole time that the light is passing over the aperture the motion of the slit would be constantly accelerated, so that in passing through the solar image one part would be more exposed than the other, and in that way you would never get a proper photograph of the sun, because to get a perfect photograph you want the quantity of light passing through the slit to be always the same. Now, that is managed by the length of this spring. The spring ceases to act the moment the slit is in front of the aperture, so that, while the slit is passing over the aperture it only travels by means of its acquired velocity, its velocity is not being accelerated. I shall show you presently two or three photographs which Dr. Janssen has been good enough to give me, which show the magnificent results which have been obtained in this way. The most striking result is that he finds that an interval of two seconds is quite enough to change the physical distribution of the bright and dark portions of some parts of the solar surface near the spots. The instrument, in order to demonstrate that, must be so arranged that it will allow two exposures at an interval of two seconds. This is done very beautifully. I am now about to make one exposure. I have now made it, and want to make another. The slit brings with it a shield to prevent the light falling through the aperture until the trigger is again set. The instant that is done the shield flies back, and in that way it is possible to obtain photographic records over a part of the sun's surface at an interval just long enough to enable you to do this. That, then, is the way by which the excess of light is got over.

The little patches of light and dark, which on the photographs are something like half-a-second of an arc apart, have a distinct existence on the sun, and have a spectrum of their own. That we learned from Sir William Herschel, although, of course, in his time he was not able to photograph them. But what we have learned from these beautiful photographs of Dr. Janssen is that they are associated with cyclonic lines, and form part, in a great many cases, of thoroughly well-marked and developed cyclonic curves. Dr. Janssen finds, and finds alone by this means—it is not a thing visible to the eye; the eye gets too tired and strained—that these markings, such as you see here, are distributed over the whole sun's surface, and that they vary frequently in exactly the same way as the sun's spots themselves vary. That is one of the results of that method of dealing with an excess of light.

You will understand, of course, that when we have to deal with the stars—and there Dr. Huggins has been as successful in one direction as Dr. Janssen has been in another—we have no longer to deal with an excess of light, but with its defect. And here comes in another beautiful optical method. For photographing spectra of stars, of course we want a spectroscope and a slit in the ordinary way, and what we have to do in order to get the best possible result is to get it by reducing the part of the plate added on to the smallest possible extent. And while we reduce its exposure to the smallest possible extent we use as large an instrument as we can, and then see that during the whole time the instrument is pointed to the star the light at the focus shall really be entering the slit. Now, it may be a familiar fact to most of you here that if that exposure has to be (say) for an hour, and some of Dr. Huggins's were for some hours, no ordinary clock controlled by electrical influences will allow the image of any body to remain on slit or on a fine point for that time or anything like it. Dr. Huggins's method, therefore, was to use a Cassegrain reflector in an arrangement by means of which he could, with another telescope, observe the image of the star, and see whether it was the slit or not, and if it varied however little from the slit to bring it back to its proper line of duty. In that way you see the defect of light was battled with by the time of exposure. The more feeble your light the longer the exposure; and that the longer exposure might be effective he wanted a process by which the light should be compelled during the whole time to pass through the slit, and through the system of prisms on to the photographic plate. Dr. Huggins has been good enough to allow me to show you tonight some of his beautiful photographs taken by this means; and I am sure you will be none the less glad to see them when I tell you that that part of the optical method which depended on keeping the image of the star on the slit for an hour together was played—not in all cases by Dr. Huggins, but very frequently by Mrs. Huggins.

This, in sum, is what we have learned of late years in spectrum photography in the case of a defect of light, and you see it is equivalent to what we have learned from Dr. Janssen in the case of spectrum work and ordinary work—in fact, when it is a question of light.

But there are other things to do besides observing the spectra of these different heavenly bodies. We want to observe the heavenly bodies themselves. We want to see what they look like, and to know about them telescopically as well as spectroscopically. Now, in this direction I have to refer to Mr. Common's photographs, which have recently been crowned, I am glad to say, by the Royal Astronomical Society by the award of their gold medal. The photographs of nebulæ and clusters which he has recently succeeded in bringing before us are just as valuable in their way, and are fully as important as a method of optical work, as those others to which I have just referred.

When we come to inquire into Mr. Common's work we find that he is dealing, in some cases, with the very faint markings of nebulæ, and that some of his exposures have been upwards of an hour long; so that we may at once come to the conclusion that in his case also we are dealing with a defect of light. Now, how does he get over it? You see there is a very great difference between using a spectroscope, as Dr. Huggins did, and a slit, and using simply a photographic plate, as Mr. Common does, on which to receive an image. If we have our spectroscope and the slit, if the image of the star does not fall fairly on the slit it does not matter, except that you have to let the exposure go on for a longer time, because the image of the star must fall on the slit for a certain time to get a photograph. But Mr. Common's task was, so to speak, more heroic than that, because in his attempt to get images of nebulæ and clusters of stars—the nebulæ, also, of course including stars—it is a question absolutely of hit or miss. Dr. Huggins's star, if it were off the slit, did nobody any harm; but if Mr. Common wishes to take a photograph of a nebula with some stars in it, or of a cluster, if he cannot keep each star absolutely rigid on one point of the plate it is perfectly certain that we shall never get a photographic image, either of a nebula or of a star. Mr. Common, therefore, having a clock perhaps no better and no worse than Dr. Huggins, was compelled to invent a new optical method or arrangement, and this is it. He has been so kind as to bring it here in order that you may see exactly what it is. In the photographs of spectra which you have seen on the screen correction was made by altering the movement of the clock slightly, but Mr. Common, after a great deal of trial, found that would not do. You must let the clock take its course, and you must get some other means of correction. What he did was this:—On a plate which had two motions on the eyepiece of the telescope, you have separately first a photographic plate and then an eyepiece. Underneath the eyepiece is a piece of platinum supporting a system of cross wires, and then a system of rectangular screws, by which, when you have once got the image of a star on the cross wires supported by the circle of platinum, you can keep that cross wire bisecting the image of a star for as long—in fact, as long as you can. Human effort probably would break down, generally, in half-an-hour. Mr. Common's human effort, I believe, has already extended to about an hour and a-half. You have then a fine delicate star, bisected by a still finer delicate web. Your clock has to be going as well as it may, and your corrections are made by these two screws, with this important consequence—that if you can catch and keep your cross wire on your star in your eyepiece, you have kept the images of the stars absolutely rigid on the photographic plate which is beside the eyepiece.

In this way Mr. Common has obtained a photograph of the nebulæ in Orion. Of course we cannot determine the perfection of the method by the nebula, but we can determine it by the images of these smaller stars. This photograph was exposed for exactly one hour; that is to say, during sixty minutes, or sixty times sixty seconds, the eyepiece had to keep the image of some particular star (necessarily on one side of the photographic plate), by means of the two rectangular co-ordinates worked by the screws, exactly bisected by the fine cross wire, the cross wire being illuminated by a lamp.

This photograph I consider to be one of the greatest achievements of modern astronomy, and I have taken occasion elsewhere to say what I believe to be perfectly true—that if all the human efforts which have been directed, so to speak, to this group of nebulæ in Orion for two and a-half centuries were put in one scale, and this photograph were put in another, it would weigh them down; in fact, that sixty minutes of nature are worth two and a-half centuries of art. But that is not all. Not only has Mr. Common, by means of this photograph, shown us that his new method is good for taking a complete picture of that kind, but he has shown us that photography contains within itself, fortunately, the elements of its own correction. What do I mean? I mean that one of the points which now for two and a-half centuries—for the work on the nebulæ of Orion began more than two and a-half centuries ago—has occupied the minds of observers has been this—Does the nebula change or does it not? And from their drawings astronomers have not been able really to determine whether there has been any change or not. Professor Holden, in one of the most voluminous, luminous, and beautiful memoirs ever devoted to the consideration of one celestial object, a few months ago only, discussed every drawing which is extant, and his conclusion was that really you could not say from any one of those drawings whether the nebula was as it was first observed, or whether it had considerably changed. Now it will be obvious to everybody in a moment that by such photographs as these it will be quite easy to determine in one year, or one century, or a thousand years—art is long—if any change takes place. But we can do very much better than that. Mr. Common has shown that, by employing this method for different exposures, you have a perfect system of correcting the photographic record itself. If you change the salt of silver which you use, of course you may change at any given time the picture you get. You may be using different kinds of light, and you may imagine a nebula of Orion painted by every wave length, you may get an entire belt of F light, G light, A light, *a* light, H^1 light, and so on; but, without going into experiments on variation so far as wave lengths go, Mr. Common's method shows us that by a system which I have called a system of "contouring," to make things quite clear, you will be able in future times to get comparative results, quite independent, or almost independent, of the salt of silver which you employ. Let us see, for instance, how Mr. Common has beautifully built up a nebula. We have here a photograph taken in one minute's exposure, one taken in two and a-half minutes, one in four minutes, one in ten minutes, one in twenty, and then we have the one of sixty minutes' exposure.

With an exposure of one minute we have nothing of the nebula, but we have simply a few of the brightest stars. That is the beautiful trapezium which has been a test object, time out of mind, for observers with small telescopes, and that beautiful line of three stars to the right. Now, passing to the one with two and a-half minutes' exposure we get them a little brightened, and just a little bit of the nebula round the brightest region. Now the four minutes' photograph shows you some of the other stars coming out, which were not visible in the first photograph. The next brightens the nebula and also brightens the stars, and we have the nebula in full swing, so to speak. With the twenty minutes' exposure it is again increased; and now with the sixty minutes' we have the nebula in all its beauty. We have there established an absolute system of contouring, and that can go on quite independently of place—independently of everything except the salt of silver you employ.

There is one more photograph I wish to show you. You will see that this method is as good for clusters as it is for nebulæ. This is not so good a photograph—the method has not worked quite so truly—but it will show us all how important it is for science that it should work well in subsequent cases. The stars should be quite round, and as a matter of fact they are a little elongated, but you see what an immense engine Mr. Common has placed us in possession of, if you take things as you find them; for an astronomer to measure a cluster of stars like that, and give the number of them and the intensities, is a matter which would take years. The photograph I suppose took, perhaps, thirty minutes.

These beautiful photographs have been taken by Mr. Common in a mirror with a three-feet aperture. Now, if you were dealing with a mirror of eight-feet aperture of course we should be dealing with a quantity of light as 64 to 9, and as Mr. Common uses a flat, and as I have shown that a flat is not necessary we may say practically that with an eight-feet telescope we get ten times more light, and, therefore, the exposure would be one-tenth; so that you see an exposure of sixty minutes would be reduced to six minutes, and, therefore, the labour of keeping the delicate star on the delicate cross wire would be reduced in the same proportion. Further: with such a light-grasping power as that to which I have referred, we may hope that some of the stars would give us absolutely instantaneous photographs, and, if that were so, we might not only by this means get observations of spectra, but we might get observations of double stars.

With regard to observations of double stars, there is just one point which may be argued, and it is this:—Mr. Dawes, years ago, showed us that, working gradually upwards from apertures of one inch to apertures of thirty inches, we enormously increased our separating power on double stars. For instance: he held that with an aperture of one inch we could only separate a double star with a distance of 4¼″; and at ten inches we could separate stars ½″ apart; and then he calculated that for twenty inches you could separate two stars ¼″ apart; twenty-six inches, ·175″; twenty-seven inches, ·169′; and thirty inches, ·152′. But what would that ·152′ become with an aperture of ninety-six inches? We should get down to an exceedingly small fraction of a second indeed, and with a perfect mirror and Mr. Common's perfect system, I believe that the time will come when we shall get double star observations added, as a matter of course, to the observations which I have ventured to bring before you.

So that it comes to this:—First, with regard to the telescopic observations of the heavenly bodies, if we take the nebula of Orion as an example of them, we find that we have in this method certainly a better one than any eye method which the last two and a-half centuries have produced; that a system of contouring which we can apply in a few hours will replace the work of months, and give us a record on which we can absolutely rely; while the work of months, and of years, and of centuries, has turned out to be absolutely unreliable, because it is human. In doing this, then, we establish nebula photometry, but we deal with stars in the field of the nebulæ. We must, therefore, deal with the photometry of stars in the field of the nebulæ, and if we can do that why should we be limited to that field? Why should we not take the average over the whole visible heavens, and bring star after star on the same plate, in the same way as has been suggested by Dr. Huggins and myself in other fields of work? It is absolutely unnecessary, so far as stellar photometry is concerned, that we should limit ourselves to any one nebula or to any one hemisphere, and it is perfectly simple to get one photographic plate and to put on it a dozen or twenty images of different stars which will give you, in terms of a certain salt of silver at one epoch, the different radiant energy of those stars for comparison in future time. Now, it is perfectly certain that if this be so, work like that is far superior to any work which any observer, however eminent, might accomplish, because the thing would be absolutely beyond all doubt, whereas one might doubt the observer.

If we pass to spectroscopic work the spectra might be chosen from every part of the sky, and you may have, as you have hypothetically for the intensities of the luminosities of the stars, the spectra of different stars culled, so to speak, from any part of the heavens you choose; and if you can get a dozen spectra of stars, culled from near or far regions of the heavens, on one photographic plate in a single night, is not that better than any work that one observer can do with that telescope? So I would propose that, with this eight-feet telescope, the observer should be absolutely abolished, that you should not allow the telescope's time to be wasted by being employed by an eye which can only see one thing at a time, and which after all may not be quite certain what it sees, or give rise to doubt when other eyes in future years come to examine what it has seen. This eight-feet reflector I would make an instrument fitted only for such researches as those which Dr. Huggins and Mr. Common have shown us to be possible. I would then, by means of electro-magnets or what not—it is a perfectly simple thing to settle—get an arrangement by which a photographic plate could be sent up, capable of coming down again after a certain time, with ten, twenty, or thirty different images impressed upon it if you wished. If it came down with one photograph as good as those Mr. Common has enabled me to show you tonight, I, for one, should be perfectly content; but if you want quantity it is quite easy to get it by lengthening your plate. Why do I insist upon this? For this reason: that the observatory is no longer necessary. This enormous instrument, with an eight-feet aperture and sixty feet focal length, can be sheltered by a hut costing £100, instead of being rendered useless by an observatory which would cost £40,000; and I, for one, believe that if we had such an instrument as that, made on such lines as I have indicated tonight—thanks to the specimens of work which Dr. Huggins and Mr. Common have allowed me to bring before you—one year's work with it would make the year's work with more expensive instruments absolutely ridiculous.

Then, to conclude, I refer to my text, and wish to bring pointedly before the Society of Arts the fact that this dream—this beautiful dream—lacks all chance of realisation at the present time for want of glass—for want of the applications of the arts to astronomical research.

THE FINE ART SOCIETY AND THE NATIONAL GALLERY.

The following correspondence was forwarded to the daily papers one day last week:—

To the Editor.

Sir,—We take the liberty of enclosing you a copy of certain correspondence which has taken place between this Society (the Fine Art) and the Directors of the National Gallery. We venture to think that in these days when English businesses have to meet so heavy a competition from foreign countries, the balance should at all events be held evenly by those who have the care of the national property.—We beg to remain, yours obediently, THE FINE ART SOCIETY.

148, *New Bond-street, W., November* 13, 1884.

You may be aware that the iron house which has for some months disfigured the front of the National Gallery is erected by the German photographers of whom we speak in our letters.

148, *New Bond-street, October* 27, 1884.

SIR,—In the spring of last year we applied to you for permission to photograph a series of pictures in the National Gallery, with a view to their reproduction by means of photogravure and subsequent publication by us. You were so good as to give permission, but the permission was coupled with the restriction that the pictures were not to be taken down or their glasses removed—a restriction which made the permission tantamount to a refusal. We endeavoured, but without success, to obtain the removal of this restriction, although we proposed to employ any persons whom you might suggest, so as to ensure the pictures from injury, and although, as we pointed out, the restriction which was imposed upon us had not been made in the case of a French firm. We are now given to understand that these restrictions have not been enforced in the case of the German firm, Messrs. Braun and Co., who have further been permitted to erect an iron house in front of the National Gallery for the purposes of their business. It certainly seems a hardship that facilities which are afforded to foreigners should be withheld from English publishers, and we think that we have some claim to trouble you by asking for an explanation of the course followed by the trustees.—We beg to remain, yours obediently,

The Director, the National Gallery. THE FINE ART SOCIETY.

National Gallery, October 29, 1884.

SIRS,—In reply to your letter of the 27th inst., addressed to the Director of the National Gallery, I am requested to explain that the privilege of having certain pictures in this collection temporarily removed from the walls for the purpose of being photographed was accorded to M. Braun and Co. in very exceptional circumstances. That firm has been engaged for some time past in photographing pictures in the great public galleries on the continent, where also, owing to the high importance of the undertaking, unusual facilities has been afforded to them. They undertook to erect at their own cost, and with the sanction of Her Majesty's Government, a photographic *atelier* for their use, as well as to defray all expenses incurred by the removing and rehanging of the pictures. Even then, several works, the removal of which would have been hazardous, were photographed in their places on the walls. The trustees and the Director feel that to renew the special permission thus granted in favour of every application which may be made for a similar purpose would involve great risk to the pictures in this collection, and they regret, therefore, that they are unable to comply with your request.—I am, Sirs, your obedient servant, CHARLES. L. EASTLAKE.

The Fine Art Society.

148, *New Bond-street, W., October* 31, 1884.

SIR,—Our letter of the 27th inst., to which you have been so good as to reply, was not intended as a renewal of our application to photograph the pictures. We felt that to allow at one time a French firm to remove pictures from the gallery, and take away glasses—at another time a German firm to do the same—and in the interim to refuse to permit an English house to remove one single picture from its frame, is not to hold the balance fairly between all parties. It may have been, as you say, of "high importance" that English pictures should be photographed by these foreign publishers. It was without doubt a very valuable monetary concession to give them, and one that is enhanced by your refusal in the present instance; and, therefore, as the series of engravings which we propose to issue would, from an artistic standpoint, have been of equal importance with theirs, we think we are justified in complaining that privileges which were granted to them should have been withheld from,—Your obedient servants,

The Director, the National Gallery. THE FINE ART SOCIETY.

IMPROVEMENTS IN PRODUCING VIGNETTED PORTRAITS.

By HENRY VANDER WEYDE.

MY invention relates to the production of photographic negatives, particularly of portrait negatives. It has for many years been recognised by all photographers that, in printing from negatives, instead of exposing the entire surface equally to the light, and thus printing in all high lights and shadows in full strength to the very edge of the print, a more artistic and pleasing effect is produced by the process of vignetting to a half-tone by first masking off the edges or margin of the negative by means of a mask applied over the negative and leaving only the centre fully exposed, and then taking the paper from under the negative and reversing the masking process by shielding the centre of the print from the light and exposing the white margin so as to tint it or tone it down.

This vignetting is only practised, however, in printing by the evanescent silver process; and, in addition to the ordinary chemical manipulation, it requires considerable mechanical skill and artistic judgment on the part of the printer (as each negative often requires a different size and shape of mask), while it more than doubles the amount of time and labour necessary for plain printing. The increased beauty resulting from this extra mechanical manipulation is, however, so great that nearly every photographer practises it, a considerable additional charge being made for these vignettes.

The difficulties of producing vignettes by any of the permanent printing processes, such as the autotype or carbon process, the Woodburytype, the photogravure, and all other photo. printing processes, are evidently so great that those commercially engaged in them refuse to attempt it, and I am not aware that it has ever been done. Many of these permanent printing processes would long ago have superseded silver printing had it been possible to give them the additional delicacy and beauty obtained by the vignetting and printing process.

Now, by my invention I overcome all this difficulty, and am able not only to produce the most delicate vignettes in any of the permanent processes, but I produce them just as cheaply and easily as plain prints, and without any of the additional mechanical labour or skill hitherto requisite in vignetting. Moreover, by my invention the means of controlling and determining the beginning and ending of the gradations, and their depth, is placed in the hands of the artist or operator while he is focussing the image in the camera, instead of being left to the judgment of the printer.

My invention consists in the employment of a translucent or reflecting screen or screens, illuminated and interposed during exposure between the negative and the sitter or object being photographed, the shape of such screen being determined by the form of gradations desired.

Opaque screens having neither translucent or reflecting power have before been tried, and they have the power of graduating the image on the negative into utter darkness—*i.e.*, that condition of the film on the negative which will be perfectly transparent and consequently yield the deepest tone in the print.

In my improved method of vignetting the screen employed has the power, although placed in the same position as those above referred to, of replacing every ray that it obstructs by other rays which it reflects or transmits into the camera, so that instead of producing a gradation into darkness it produces a gradation into a light or half-tone of any depth desired. The negative when finished will then print only vignettes.

In order to enable one skilled in the art to use my invention, I will now describe the operation. I place my sitter and proceed to take a head and bust portrait. Having posed, lighted, and focussed the sitter, I place the screen well out of focus, either outside the camera between the sitter and the lens, or inside the camera between the lens and the negative. If I use it inside I construct the screen of a translucent material with an aperture in the centre. The material may be gauze or net or other open work fabric, or tissue paper, or opal glass or other translucent material, the aperture being sufficiently large to allow the image of the head and the top of the shoulders to be transmitted uninterruptedly to the negative. The edges of the aperture may be graduated of different thicknesses or density, or the edges of the aperture may be jagged, the effect aimed at being to obtain a soft vignette into half-tone extending to the very edges of the focussing glass. I then give the negative the ordinary exposure and develope as usual. If the screen be placed outside the camera I may use either a translucent or opaque material. If translucent I fashion it in the same manner as that just described, but on a much larger scale, as it is placed much nearer the sitter. Or I may use a reflecting instead of a translucent screen of a white or light-coloured though opaque material, such as white cardboard or white opal glass or metal. The reflecting side should face the lens, its surface being exposed to either direct illumination or to reflected light from a mirror or mirrors suitably arranged. In this case the edge of the mask nearest to the centre should be cut in the form of long V-shaped teeth.

For varying the shape and size and depth of the vignettes I employ screens of different materials and forms; and in order to obtain the desired gradation I may use two or more screens of different sizes and shapes placed in front of one another.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is:—

1st. The herein described process of producing a vignetted photographic negative, graduated off into a light or half-tone, by the interposition during exposure between the lens and the sitter or object being photographed of a translucent or reflecting screen or screens, having an aperture of suitable shape and dimensions, substantially as herein specified.

2nd. The herein described process of producing a vignetted photographic negative graduated off into a light or half-tone, by the interposition, during exposure, between the lens and the sensitive surface of a translucent screen or screens, having an aperture of suitable shape and dimensions, substantially as herein described.

3rd. As a new article of manufacture a vignetted photographic negative graduated off into a light or half-tone, substantially as herein described.

Exhibitions.

PHOTOGRAPHIC SOCIETY OF IRELAND.

THE first exhibition of this Society was opened on Tuesday last, the 18th instant, in the fine rooms of the Royal Hibernian Academy of Arts, Dublin, which, by the courtesy of that body, had been placed at the disposal of the Society.

Their Excellencies the Lord Lieutenant and the Countess Spencer had intended to be present at the opening, but were prevented by unavoidable absence in London. A large number of the members of the Society and their friends were assembled in the afternoon to do honour to the occasion, which is a novelty in Dublin. Very general surprise and satisfaction was evinced on all sides at the magnitude of the collection gathered together, and which will compare favourably with the well-known Pall Mall display.

The number of exhibits, as shown by the catalogue, is 739, contributed by 135 exhibitors, and one recognises in the list the most famous English artists, sprinkled with a few foreign friends, and the more generally-known names of our best Dublin studios; while many well-known faces and suburban views beautifully rendered are there to charm those whose limited knowledge of the differences of platinotype, Woodburytype, and other processes deprives them of the technical pleasure only experienced by a photographer. To those familiar with the displays of recent years at Pall Mall and other well-visited exhibitions, many old friends are recognised with renewed pleasure, and most of the medal pictures of this year are to be seen amongst the collection. Photographic novelties like Mr. C. V. Shadbolt's *Balloon Views* (Nos. 159 and 164), and *Lightning*, by Mr. Auty (No. 140), open up the question as to where the possibilities of photography may stop.

In walking round the rooms, with so much to admire, it is difficult to avoid omitting to notice much conspicuous merit; but No. 7, entitled *The Young Dodger*, by Mr. W. W. Winter, is a clever *genre* group; and *The Miser* (No. 10), by Mr. W. Gillard, recals the well-known scene in the *Cloches de Corneville*. A fine frame of *Yachts* (No. 14), by Messrs. West and Son, of Cowes, shows what may be done in this particular direction; and the *Chittywee*, of Pall Mall fame last year, which is amongst them, has in our opinion more than one rival. A beautiful frame of *Fans* (No. 16), by the Autotype Company, is hung too high for comfortable inspection, which is much to be regretted; and, although it is usual to abuse the hanging by those to whom its difficulties are mainly theoretical, we must say No. 240 hardly deserves a place in an art exhibition. With this and a few other trifling exceptions—which, we suppose, are unavoidable, owing to the short time usually at the disposal of the Committee—the work has been exceedingly well done, and the general effect is decidedly good, while the exigencies of the individual frames as to correct placing has not been overlooked.

Mr. W. H. L. Skeen. of Ceylon, we are pleased to see, by his contributing so largely to the Exhibition, has not forgotten his old photographic hunting grounds with incidental friendships, as shown in his pictures of tropical vegetable life (Nos. 297, 364, and 312); and, in his landscapes (Nos. 15, 64, and 18), his lines are cast in apparently pleasant places.

Mr. Booth Pearsall, in *Clouds*, on small plates (No. 24), and *Boats* (No. 269), has secured many pleasing studies which we may fairly expect to see reproduced on canvas.

Mr. George Mansfield contributes a collection of pictures in France and Spain (in all twelve frames) of high merit, and it is extremely difficult to make a choice; but Nos. 71 and 76, in our opinion, are the most worthy of praise for their technical as well as for their artistic merit. This is the best collection shown by any of the thirty-three members of the Irish society who exhibit.

Mr. McLeish (in Nos. 69 and 77) shows two of the best frames of landscapes in the room, amongst which the well-known *Misty Morning on the Wear* is certain to attract general as well as expert attention.

A Portrait of a Lady (No. 82), by Messrs. Robinson and Sons, of Dublin—a carbon enlargement—attracts and pleases very considerably, while the pose, or want of pose, leaves a sensation of something to be desired. It is, however, a fine work, and seems to command attention and praise.

Messrs. Marsh Brothers' *Study of Swans* (No. 191) and *Pigeons* (No. 195) are charming—the centre of a crowd whose attention is divided by *The Brighton Cats* of Mr. H. Pointer, who also shows in No. 98 some more of his favourites. We may mention that this latter is put down in the catalogue as a collodion plate. With the exception of some of the Glendalough pictures in 241 and 243, and a few others, wet collodion is practically unrepresented.

Mr. T. J. Dixon shows the well-known enlargements of the inhabitants in the Regent Park Gardens, and, as novelties in Dublin, are being much admired as well as for their photographic qualities. A fine enlargement (No. 112) by the Autotype Company (of whose magnificent contribution we shall have more to say hereafter) stands in a commanding position at one end of the large room, placed at just the right height for true effect.

Messrs. Chancellor, Lafayette, and Crantfield have each large portrait work, which will fully sustain the credit of Dublin studios as regards direct portraiture, and it is difficult to award the palm. Indeed, as the medals are to be given on the votes of the individual members of the Society, we think that the recording of the votes will not be such an easy matter as may have been originally intended; for in several sections, after some days' study, we are still undecided as to what is, for instance, the best portrait or instantaneous picture. We shall continue our notice next week.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

THE third Exhibition of the above Association has been confined to members' work only, its main objects being the selection of a presentation picture and displaying the views taken at the outdoor excursions. For the latter the medal has been awarded to Mr. J. P. Gibson for the best set of three pictures. Any of this artist's work, except, perhaps, his Bywell views, might have been selected. *The Blasted Oak*, and *On the Allen Starward*, are notable for the juicy tone and careful treatment of the shadows. The *Barbican, Alnwick Castle*, is a very telling instance of the good which competitions of this nature may effect. The startling light piercing through the dark sky and the brilliant illumination on the side angle of the old tower quite throw into the shade others of the same subject taken on that particular excursion. Mr. Gibson's pictures in the main are, perhaps, complete, but the introduction of figures into one or two would have been acceptable.

Mr. J. Pike has a choice collection of his summer work, full of richness and transparency. *On the Devil's Water* is greatly aided by several barelegged urchins enjoying themselves among the boulders and pools. His bromide enlargement from *A View on the North Tyne* is remarkably soft, and its peculiar greenish tint caused by the glass on which it is mounted is rather pleasing in this case than otherwise.

Mr. E. Goold has won the extra prize with his *View of Bywell Castle*—an expansive, airy picture of the ruin on the Tyne. It is much enhanced by the treatment of two figures in a boat in the foreground. The poses are excellent and of bold size, and show another instance of the value of these competitions. In other views of this subject the boat is hauled up on the shore, serving no purpose but that of overbalancing an already one-sided composition.

Mr. Auty, besides his well-known *Lightning* picture, has some interesting scenes. *Shields Harbour* shows the steam ferry and crowded shipping very ably rendered. *The Iron Gates* is a fine composition of rock and trees, full of gradation and circling ripples on the water.

Platinotype prints are abundant in the Exhibition, but Mr. J. W. Robinson's, with the clear whites, deep blacks, and fine gradation in the skies carry the palm. *A View on the Tyne*, with the dark river, the massive shipping, and the old spires of Newcastle rising into a troubled sky, is very successful. *The Old Milkmarket* is also a superior production, and also many of his old Newcastle scenes.

Mr. Pae has some good effects. One is a *Sunset on the River*.

Mr. T. G. Gibson's *English School Life* shows admirable grouping of girls busy at their desks, with their teachers overlooking. In *Quarrying* two men are seen actively engaged in hewing out the huge stones. One of these men was killed half-an-hour after the view was taken. The earth came down with a sudden rush and buried him.

Mr. A. L. Steavenson is represented by some Welsh scenes and a sparkling view *On the Conway*.

Mr. Galloway's exhibits are numerous and original. *The Return to the Village* is well chosen, showing a light trap running along the sea shore to a prettily-situated village ahead. His instantaneous farm scenes and fishing subjects will be invaluable to painters. *Looking Out* is very good. Two strong-armed young fishwives are leaning over the railings looking wistfully out to sea. They stand boldly out against a light sky.

Mr. Proctor's *Picture Without a Lens* has attracted considerable notice. It is a view of buildings, and it would be interesting, if taken again the same size with a lens, to compare the perspectives. The exposure was a-quarter of an hour with a pin-point aperture.

Mr. Templeton's exhibits must not be overlooked, for among them is a little gem of children wading and playing among the waves and rocks, entitled *Common Objects of the Sea Shore*.

Altogether the collection of exhibits has been satisfactory, but the number would have been greater if the restrictions had been less. Several members have been placed *hors de combat* in the presentation picture competition, owing to the conditions. The result of this latter has been determined by members' votes, the picture chosen being Mr. Edgar Goold's *Bywell Castle*.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
November 25 ..	Bolton Club	The Studio, Chancery-lane.
" 26 ..	Bristol Amateur	Studio, Portland-st., Kingsdown.
" 26 ..	Photographic Club	Anderton's Hotel, Fleet-street.
" 27 ..	London and Provincial	Masons' Hall, Basinghall-street.
" 27 ..	Liverpool Amateur (Ann. Meet.)	Free Library and Museum.
" 27 ..	Oldham (Annual Meeting)	The Lyceum.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society, held on the 13th inst., Mr. A. Haddon occupied the chair.

The CHAIRMAN, in opening the proceedings, observed that the special object of the meeting of the evening was to judge of the transparencies which had been produced by different methods from identical negatives. Members would be able to form an idea of the capabilities of the various processes illustrated, both for the purpose of making lantern slides and of producing enlarged or reproduced negatives.

Messrs. C. and F. DARKER provided a pair of oxyhydrogen lanterns, and the plan adopted for making comparison was to throw upon the screen the image of one transparency alternately with that from another. Any two that were thought to be similar in quality were repeatedly compared, and upon the first set (those from a negative of a steamer and shipping on the Thames) being gone through, the three which were considered to be the best, and the quality of which was considered to be equal, were handed to the Chairman, who announced that two of them had been produced by the collodio-albumen and one by the wet collodion process. The portrait series was then passed through the lantern, with the result that three were selected. One of these, which was, except as to colour, generally considered the best, was stated to have been produced by the Woodbury process, and the other two, which were very warm in tone, were by the gelatino-bromide process and the gelatino-chloride process respectively. Others showing a certain beauty of tone, which caused inquiry to be made as to the method of their production, proved to be upon bromide plates of a slow kind, expressly prepared for transparency making and developed with hydroxylamine. The formula for development being inquired for, it was stated to be—

Hydroxylamine	1 grain.
Caustic soda	2 grains.
Bromide of ammonium	4 ,,
Water	1 ounce.

After the display a hearty vote of thanks was accorded to Messrs. Darker and the members who had prepared the slides.

It was announced that at the December lecturetto night Mr. W. E. Debenham would discourse upon the subject of *Avoiding Reflections and Granularity in Copying.*

—♦—

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

On Thursday evening, the 13th inst., the Exhibition of the Photographic Society of Great Britain was open in aid of the above Association. With a charge of sixpence admission the gallery soon presented a very animated appearance, over 300 visitors passing the barrier.

At nine o'clock the Society's optical lantern was brought into use, and a series of most excellent transparencies were exhibited. Mr. W. F. Donkin, the Hon. Secretary of the Photographic Society of Great Britain, very kindly described the different scenes.

At the conclusion an admirable transparency of Mr. J. Glaisher, taken by Mr. Mayall, was put upon the screen.

Mr. H. J. Thorne, Deputy-Chairman of the Photographers' Benevolent Association, in a short speech informed the visitors that it was owing to the kindness of the President and Council of the Photographic Society of Great Britain that the Photographers' Benevolent Association were receiving the benefit from the Exhibition and the use of the lantern, and asked them to join him in thanking those gentlemen, and also those who had very willingly lent the slides which they had seen that evening. The request was most cordially responded to.

For the information of those unacquainted with the facts, the objects of the Association are to assist members, their wives and children, when in distress through sickness, death, or want of employment, by means of immediate grants of money; to grant annual pensions to aged members, and to aid the unemployed members in obtaining situations. Employers requiring assistants are requested to communicate with the Secretary. Photographers, professionals and amateurs, and assistants are eligible for membership, on their own application, subject to the approval of the Board of Management. *Subscriptions* — Members 10s., payable yearly, half-yearly, or quarterly. Donations of any amount will be received. Further particulars may be obtained upon application to W. Harland, Secretary, 181, Aldersgate-street, London, E.C.

—♦—

GLASGOW AND WEST OF SCOTLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

The usual monthly meeting of the above Association was held in their rooms, 180, West Regent-street, on Tuesday evening, the 11th instant,—Mr. Hugh Reid, President, in the chair.

The following new members were admitted:—Messrs. J. R. Reid, David McSkimming, J. Bertram, Jas. Lumsden, Wm. Gray, John Conbrough, Arch. Auld, A. Brown, G. Logan, A. McDonald, Jas. Logan, and Geo. Sheriff.

Mr. W. Goodwin then read a paper on *Isochromatic Plates,* and passed round some very interesting results, which impressed the members very favourably. He (Mr. Goodwin) also read a short paper on *A New Developer* [see page 743], and demonstrated the change of colour before the meeting.

At the request of several of the younger members of the Association,

The Chairman repeated his demonstration of the platinotype process with great success. He gave all particulars regarding license, paper, printing, &c., and developed a number of prints, which were distributed amongst the members present.

The nomination of officer-bearers for 1885 was then proceeded with, the voting for which will take place on Tuesday, December 2nd.

It was agreed that ladies be admitted members of the Association at a reduced rate Ladies joining in December will have the right of exhibiting at the forthcoming exhibition in the middle of December.

This being all the business, after the usual vote of thanks the meeting was adjourned.

—♦—

MANCHESTER PHOTOGRAPHIC SOCIETY.

The ordinary monthly meeting of this Society was held in the Society's rooms, at the Manchester Technical Schools, on Thursday, the 13th inst., —Mr. John S. Pollitt, President, in the chair.

The minutes of the previous meeting were read and confirmed. The following gentlemen were elected members of the Society: — Messrs. Thomas Parkinson, James Brown, William Oram, William Hartley, Thomas William Steventon, O. E. Taylor, Deakin, William H. Farrow, W. Linnell, J. T. Foster, George Sington, John Stephenson, Abel Heywood, Jun., J. E. Iliff, and C. T. Faulkner.

Mr. J. W. Leigh exhibited a negative in illustration of the method of effecting local reduction by means of friction with methylated alcohol, and the same mixed with Tripoli powder.

In fulfilment of a promise made some time since, Mr. A. Brothers, in a few words, described the daguerreotype process, and showed how the silvered plates were polished, sensitised, developed, and fixed. Mr. Brothers then proceeded to explain the collodion process for the benefit of those members of the Society who had joined since the discovery of the gelatine process, and to whom it was supposed the older process was almost unknown. A portrait of the President, Mr. J. Pollitt, was taken by magnesium light, and a number of photographs were shown in the lantern to illustrate the value of the process for making lantern slides. The lantern was manipulated by Mr. Greatorex, and many of the members, including the President, showed many beautiful slides—those of swans, by Mr. Pollitt, being much admired. One of the members was heard during the exhibition to exclaim—"Wet collodion has scored one this evening!" and there could be no doubt that the process is well adapted to produce the most perfect results.

The meeting terminated with the customary vote of thanks to the gentlemen who had contributed to the interest of the meeting.

—♦—

BOLTON PHOTOGRAPHIC SOCIETY.

The November meeting of this Society was held at the Baths, on Thursday, the 6th inst.,—Mr. R. Harwood in the chair.

Messrs. J. Lomax, Jun., J. A. Walker, G. W. Walker, and R. Dickinson were elected members of the Society.

Dr. Johnston exhibited a number of prints from negatives taken during a recent visit to Norway.

It is intended to hold an "open" meeting on December 4th. Members are requested to bring as many *good* slides as possible.

—♦—

PHOTOGRAPHIC SOCIETY OF IRELAND.

The annual general meeting of this Society was held on Friday last, the 14th instant, in the Royal College of Science, Dublin,—Mr. Herbert Bewley in the chair, The report of the Council was presented as follows:—

Annual Report.

In once more presenting to the members of the Photographic Society of Ireland their annual report, the Council have again to announce the increase of members of the Society, who now number seventy-three, without counting those to be elected this evening.

The following papers were laid before you during the session:—*Isochromatic Plates*, by Greenwood Pim. *Enlargements on Gelatine Argentic Paper*, by McGhie and Bolton. *A Visit to the Pall Mall Exhibition*, by A. Conan. *On the Relative Value of Stops*, by Dr. Scott. *Further Notes on Isochromatic Plates*, by Greenwood Pim. *A Retrospect of Photography*, by C. W. Watson. *On Enamelling*, by J. V. Robinson. *Willesden Paper*, by Greenwood Pim. *A Home-made Actinometer*, by Dr. Scott. *On Photographic Lenses*, by Howard Grubb. *Through Derbyshire with the Camera*, by C. W. Watson. In addition, a varied collection of apparatus and photographic novelties have been exhibited at our meetings, which, on the whole, have been fairly attended.

The Council would prefer to see the work of contributing papers for the meetings more generally distributed amongst a larger number of members, and have to express their thanks particularly to those on whom this duty has devolved.

The annual lantern exhibition, held in March last, was as usual a great success, all the pictures shown having been taken from negatives the work of members of our Society.

It having been thought advisable to hold several short excursions on Saturday afternoons instead of the annual field day, arrangements were made, and Howth, Lucan, the Valley of the Liffey, and Glen Druid were visited. We regret, however, that the attendance at the last of these meetings was not sufficient to justify their continuance to the end of the season. We consider that we may with great confidence congratulate you on having been the means of organising the photographic exhibition, which is to be opened on Tuesday, and which, in our opinion, is one of the best collections of photographs that has ever been brought together, and we feel confident that it cannot fail to elevate the standard of our art, and be of considerable service to photography in Ireland.

The annexed statement of accounts shows our financial position:—

Statement of Accounts for the year 1884.

Dr.	£	s.	d.	Cr.	£	s.	d.
To Balance from last year	£39	19	1	By New Lanterns	£18	0	0
,, Subscriptions	34	10	0	,, Lantern Slides	6	10	6
,, Entrance Fees	6	0	0	,, Lantern Exhibitions	6	13	8
,, Arrears	8	0	0	,, Stationery and Printing	3	15	5
,, Subscriptions in advance	3	10	0	,, Attendants	2	13	0
				,, Stamps	3	13	0
				,, Incidentals	0	5	6
				,, Balance	50	8	0
	£91	19	1		£91	19	1

We have examined the above account and compared it with the vouchers, and find it correct. The balance to credit of current account is £50 8s.

Samuel Baker,
Thos. H. Curtis.

14th November, 1884.

The following gentlemen were elected members of the Society:—S. Geoghegan, C.E., H. Magee, and Francis S. Hall.

Mr. John L. Robinson then read a paper entitled *A Week in Suffolk*, being an account of the trip of the British Architectural Association for the present year.

Mr. Greenwood Pim, Hon. Secretary of the Exhibition Committee, announced the particulars as to the opening of the Exhibition on the 18th inst., and the meeting was adjourned.

—◆—

SHEFFIELD PHOTOGRAPHIC SOCIETY.

The monthly meeting of the above Society was held in the Masonic Hall, on Tuesday, the 4th instant,—Mr. W. B. Hatfield, President, in the chair. After the usual business,

The Chairman preceded Mr. Foxon with a few remarks on what he thought the best way of spreading useful and practical assistance among the amateurs of the Society. He hoped the members would assist him in keeping closely to the subject selected for each evening, and bring forward in the term any experience or knowledge on the subjects they could, trying on all occasions to avoid expensive apparatus, complicated formulæ, and technical symbols. Most of these members had plodded through their homely experiments on the many subjects that would be brought before them, and the plain statement of the results would in many cases be of great use.

Mr. Foxon gave a lecture and demonstration on *Enlarging on Argentic-Bromide Paper*, and made a very careful description of the apparatus he was going to use. He spoke on the many different ones in vogue, but for simplicity and cheapness, combined with good results, it was generally admitted that his was a very good one.

Many of the members took part in the questions and discussions, among whom were Dr. Morton, Councillor Firth, Messrs. Pilley, Turner, Gilley, Bacon, and others.

Two excellent enlargements were made and finished from half-plate negatives, the light being a two-wick paraffine lamp and a six-inch condenser. A square bellows camera and a Ross's symmetrical whole-plate lens was used, the paper being pinned on an ordinary drawing board.

After the lecture a vote of thanks was proposed by Mr. Firth and seconded by Mr. I. S. Yeomans.

The subject for the December meeting was then discussed, and decided to be *An Exhibition of Photographic Lantern Slides, and How to Make Them.*

The meeting, which was the largest the Society ever had, was then adjourned.

LEEDS PHOTOGRAPHIC SOCIETY.

A meeting of this Society was held on Tuesday, the 11th instant, at the Yorkshire College. The alteration in the date of meeting was made to enable the members to spend the evening with Messrs. Bridge and Brooks, of the South London Photographic Society, who were in the town on that day.

The President (Professor Thorpe, F.R.S.) invited the members, with Messrs. Bridge and Brooks, to tea at five o'clock. There was a very large attendance. After an excellent tea a very hearty vote of thanks was passed to the President; after which the members, under the guidance of Dr. Thorpe, proceeded to view the various departments in the new college, and much admiration was expressed at the completeness of its arrangements.

At eight o'clock the ordinary business of the Society commenced, Dr. Thorpe in the chair.

Mr. J. W. Reffitt, Treasurer, then read his financial statement, from which it appeared that £21 15s. had been received as subscriptions, and £11 19s. 1d. expended in printing, postage, &c., leaving at the date of the audit £9 15s. 11d. in hand. The books having by rule to be audited in October, several items of expenditure were not included in the above, by means of which the balance will be reduced before the close of the year.

Mr. Butterworth was elected a member.

The Chairman then called upon Messrs. Bridge and Brooks to give their lantern demonstration. The lantern—a triple oxyhydrogen—was manipulated by Mr. Brooks with his usual ability. Mr. Bridge exhibited slides on gelatino-chloride plates showing the different tones to be obtained by this process; Mr. Brooks, slides prepared by his collodio-emulsion process; Mr. Pocklington, some very peculiar results obtained by toning gelatino-bromide plates with gold, uranium, &c.; Mr. Ramsden, transparencies on gelatino-bromide plates, his own preparation; Mr. J. W. Reffitt, slides on gelatino-bromide plates.

Mr. W. Teasdale showed some detached gelatine films, prepared experimentally by Mr. W. B. Woodbury some years ago, which could be produced on a large scale at a very reasonable price if there were a demand for them. He expressed regret that such a convenient means by which a lecturer could have all his illustrations consecutively arranged in one small portable roll, and so pass them panorama fashion through the lantern, had not met with such recognition and adoption as it merited.

A very hearty vote of thanks was passed to Messrs. Bridge and Brooks for their demonstration.

Votes of thanks were also passed to F. Ritson, Esq., and E. Schunck, Esq., for allowing the members of the Society the privilege of photographing in their grounds.

The technical meeting of the Society will be held on Thursday, December 4th, and the Secretary (Mr. Thomas. W. Thornton, 22, Carr Road) will be glad to receive for exhibition novelties in apparatus, &c.

Correspondence.

MAGIC LANTERN TRANSPARENCIES.

To the Editors.

Gentlemen,—In your issue of today I notice that the Rev. H. Victor Macdona gives the result of some experiments on the production of lantern transparencies on ordinary gelatino-bromide plates. I am very glad to see his letter, as every successful experiment in this direction proves that amateurs have the power in their own hands of producing beautiful slides from ordinary materials. The utmost credit I deserve in the matter is that of again reminding your readers of the real value of the two formulæ in combination. The soda developer I have to thank Mr. Genlain for, and the clearing solution is known to me as that of Mr. B. J. Edwards. The two in conjunction enable any one possessed of the necessary skill to produce admirable transparencies, and to entirely overcome the effects of over-exposure.

I may inform your readers who are interested in this question that another old formula aids materially in producing clear transparencies. Take—

Sulphite of soda (pure)	120 grains.
Water	30 drachms.
Pyro.	30 grains.

Before adding the pyro. make the sulphite of soda solution neutral to test paper with citric acid. I have tried this, using one drachm of this solution to one ounce of the soda developer. The pyro. solution is so clear that a clever friend has suggested that I have omitted the pyro. altogether. It, however, developes perfectly, and stains neither the plate nor the fingers.—I am, yours, &c., H. Norwood Atkins.

Liverpool, November 14, 1884.

LANTERN TRANSPARENCIES AT THE EXHIBITION.

To the Editors.

Gentlemen,—I have to call your attention to the extraordinary action of the Photographic Society of Great Britain in respect to the medal offered for lantern slides at the late exhibition. The medal has been awarded to Mr. Gale. I have written to the Secretary to protest against it, on the following grounds:—1. That the slides exhibited by Mr. Gale were not qualified for competition. 2. That if they were they were not worthy of the medal. 3. That they were not submitted to the whole of the jurors.

The first of these objections is founded upon the conditions under which the medal was offered—that the slides for competition should be sent in by a certain date. They do not appear either in the original uncorrected catalogue or the second corrected edition. I am also in a position to show that they were not in the possession of the Society at anyrate up to the 6th October, 1884, the day upon which the exhibition was opened to the public.

A series of slides by Mr. Gale were exhibited *on the screen* on that evening, I believe; but they were not the slides which were afterwards shown, and for which the medal was awarded.

The second objection applies, of course, still more forcibly to the first series of slides which were shown on the screen as Mr. Gale's, as they were in every respect far inferior to the final selection. I wish to give Mr. Gale every credit for the real artistic feeling which dictated these slides, but affirm that their technical defects were sufficiently great to render them unworthy of the distinction of a medal.

As to the third objection, I am in a position to prove the fact. To this the Photographic Society may reply that the medals awarded to Mr. Gale and Mr. M'Kellen were extra medals. I should also add I have no objection whatever if *the* medal had been awarded for the slides actually sent in for competition. It is absolutely impossible for any one knowing anything at all of the subject to deny that there were at least two frames of slides, which were entered strictly in accordance with the regulations, worthy of a medal. The fact is that I—and I believe all the other exhibitors without exception—feel deeply aggrieved at the want of consideration or common courtesy allotted to us by the entire management of the lantern show, both last year and this.

Professional slide makers know that the optical lantern must become the great educational instrument of the future, and sent their slides in for exhibition on the faith of the Society's prospectus, fully expecting that their merits would be fairly judged and that the public would thereby become acquainted with the progress made in so very important a branch of photography. Neither they nor the public wanted that ridiculous nightly apology for directing the Society's lantern from its special purpose (of spectrum analysis in connection with photography!) to the comparatively base use of showing photographic transparencies.

The conditions laid down—that the negatives and transparencies should be the work of the same operator—were extremely ill-advised. The proof is that the exquisite slides of Mr. Brooks from Mr. Donkin's negatives would have been thereby shut out. The complete absence of all other conditions show either consummate ignorance of, or utter indifference to, the great importance of the class. However, many excellent slides were sent in for competition, strictly in accordance with the Society's conditions, and the manner in which their claims have been ignored is an unpardonable insult to others besides.—I am, yours, &c., George Smith.

Colebrooke-row, London, N., November 17, 1884.

To the Editors.

Gentlemen,—Some time before the opening I received a prospectus of the coming Exhibition of the Photographic Society of Great Britain, and in it I saw there was a medal offered for lantern transparencies, and thereby I was induced to send. In the prospectus there was a special notice, printed in blue ink—no doubt to give it importance. *It was to this effect:*—"Special notice.—By order of the Council. The rules and regulations respecting the Exhibition are to be strictly adhered to; therefore no picture will be received after nine o'clock p.m. on Thursday, September 25th."

All this is plain and straightforward, and its meaning cannot be misunderstood. The judging and awarding of the medals were in due course, except in the department for lantern slides, and the judges did not, or would not, meet—from some unexplainable cause—to make the award, which entirely deprived all the competitors of any criticism from the outside press, which is of very great value at times to the professional photographer. Such being the case, the medal or award is almost valueless. When I found that no award had been made I communicated with the Hon. Secretary on the matter, asking whether the judging would take place, as I hoped it would not be a "sell." His reply was that the judges would meet as soon as convenient and make their award.

After a time I received another note stating that the judging would take place on Monday, November 3rd. I also received a notice in due course from the Assistant Secretary, asking me to select not more than twelve slides from my *present* exhibits in the Exhibition to go before the judges. I replied to the effect that as I had only twelve slides on exhibition I would submit the whole to the judges. Living some twenty-five miles from London it is not convenient for me to go there at a short notice, and I am not in town every day. I did manage to look in about eight o'clock in the evening, but could not get a sound as to the result of their judgment; but it was being whispered about that several others were included in the competition, including Mr. Gale. I at once asked the Assistant Secretary whether it was a fact that Mr. Gale had been admitted as a competitor, which he acknowledged. I then made the remark that he was not an exhibitor of lantern slides. His reply was "Indeed he was," *which I knew to be absolutely incorrect.* His name does not appear in the corrected edition of the catalogue as an exhibitor of lantern slides, neither could I find anything on exhibition on the tables with the other competitions. The corrected edition of the catalogue I received about three weeks after the opening of the Exhibition.

I think, in admitting parties in this way, to say the least of it, is disgraceful and unfair. I contend that all awards ought to be made before the opening of the Exhibition, *or not at all*, for the reason that the judges mix up with the general public and hear their opinion, which has an undue influence on them—I do not mean intentionally. I should like to ask, through the medium of your columns, who else was admitted to the competition in a similar manner, and why was any one admitted after reference to the special notice which I referred to, printed in blue ink? The fact is simply this: intending competitors sent in their exhibits in due time, in accordance with the prospectus, as the written law. The judging was not done at the proper time. It was open to other parties to see all that was in competition, and then bring in what they considered better, as has been done. I should also like to ask who invited Mr. Gale to send in under these unfair conditions. Some one must have been at the bottom of it.

As for myself I should scorn such an action to send things in under these conditions and accept an award; but, apparently, others are not of my way of thinking. I believe the President is morally responsible for the very unfair way in which this competition has been conducted. One of the Lantern Committee told me that the Monday evening lantern exhibitions were a paying concern, and I should suppose that that led them to offer a medal as a bait to get slides on purpose to make capital out of the exhibits at the expense of the contributors. I know for a fact that my slides have been paraded on the screen night after night. I now leave the matter in the hands of your readers for their verdict.—I am, yours, &c.,

Laurel Villa, Wray Park, Reigate, WM. BROOKS.

RECENT RESEARCHES IN STELLAR PHOTOGRAPHY, &c.

To the EDITORS.

GENTLEMEN,—On re-reading the very interesting paper *On Stellar Photography*, by the Rev. T. E. Espin, which appeared in THE BRITISH JOURNAL OF PHOTOGRAPHY of the 7th inst., it strikes me that there are several points which, for the sake of clearness, should be further explained, some of the statements appearing contradictory.

At the top line of page 715, Mr. Espin says:—"Increased sensitiveness of the plates is more important than either size of aperture or lengthened exposure;" while a few lines lower down he says:—"It is obvious that the increase of aperture is of more consequence than either increase of exposure or sensitiveness." These sentences appear to me to be so contrary and so "mixed up," as our American friends would say, that I fail to see at what the Rev. Mr. Espin is driving.

Again: he says—"But increase of aperture means increase of focal length." This does not necessarily follow, the focal length depending entirely on the quality of the glass and the curves to which its surfaces are ground. Those of your readers who take an interest in this branch of science would, I am sure, appreciate any explanation of these paradoxical statements.—I am, yours, &c., W. HORSEMAN KIRKBY.
November 18, 1884.

THE SOUTH LONDON PHOTOGRAPHIC SOCIETY.

To the EDITORS.

GENTLEMEN,—Kindly allow me space for a few lines on behalf of the above Society, because I am afraid, in my anxiety not to keep the audience waiting for Mr. Taylor's lecture on *Florida* at our last meeting, I scarcely made myself as plain as I could have wished.

What I intended to point out was that the present "scare" about the Society ceasing to exist is the result of a groundless and unauthorised report circulated some months since to the effect that the Society could not be kept on after the loss it had sustained by the death of its late President, and would cease at the end of the year; and so widespread has this idea become that, although we have held our meetings as usual, everyone seemed to consider the Society as practically dead.

As a matter of fact there is no more reason for the Society ceasing to exist now than there ever was; and if half as much exertion had been used to improve its meetings as to circulate reports of its dissolution it would never have been in such good condition as at present.

That a difficulty sometimes exists to obtain papers is, of course, true, and always will be, while those to whom we used to look years ago for help take all their interest and information to the societies meeting weekly. But there must be many who do not belong to these societies who would be willing to help, and it is to these we mainly look for assistance.

I have already received several promises and many valuable suggestions; and if our new Committee will only be unanimous in their desire to make some personal exertions for the Society's benefit, and endeavour to increase the number of really useful members, there is no reason why the Society should not yet enjoy many years of prosperous existence. It has in times past done much for the art of photography and introduced or popularised the efforts of most of our best-known men, and, if properly managed, will continue its useful work.

Trusting that as many members as possible will attend our annual meeting on the 4th December, and that we shall have a large number of pictures sent in for the artistic competition,—I am, yours, &c.,

East Lodge, Dalston, London, F. A. BRIDGE,
November 18, 1884. *Hon. Sec. and Treasurer.*

HYDROKINONE.

To the EDITORS.

GENTLEMEN,—After many experiments and meeting difficulties, which I need not specify here, but which I have overcome, I beg to offer the following formula:—

Saturated solution of carbonate of potass	4 ounces.
,, oxalate potass	1 ounce.
,, oxalic acid	10 minims.
Or,	
Liq. potass, B. P.	25 minims.
Solution of hydrokinone............................	2 drachms.
	= 2 grains.

The curious part of the above is that either alkali or acid will do to mix with the other ingredients. You can develope with carbonate of potass and hydrokinone alone, but it seems impossible to avoid "comets," and is slow. The addition of the oxalate, if it do not prevent development, takes so long that it would be useless as a practicable developer.

Hitherto the difficulty in all my experiments has been to avoid comets, or spots, and no amount of care and filtering prevented them. But with the above formula there is nothing of the kind; I get a clean, even negative. I have fixed with cyanide of potassium, fifteen to twenty grains to the ounce.

In conclusion: I think the great superiority of hydrokinone over pyro. is that, whatever density you may develope the negative to, the just and true relation between the shadow and high lights is maintained. After fixing I still find a soak in alum (saturated solution) improves the negative.—I am, yours, &c., W. T. F. M. INGALL.

Notes and Queries.

A. E. COE inquires concerning gas bottles and condensing pumps. He ought to put himself in communication with Messrs. W. H. Oakley and Co., Grange-road, Bermondsey, who are the makers, so far as we know, of appliances of this nature.

F. JOSEPHS writes for information concerning the class to which certain photographic lenses named by him belongs.——In reply: We have not the advantage of being acquainted with the lenses he specifies. A note to the maker will doubtless secure the information.

"CAN nitrate of magnesia be mixed with nitrate of silver? and is there any advantage in this admixture when employed in photographic printing?—W. D. S."——In reply: we have never heard of this mixture except in the form of "*sel clement*"—a photographic nostrum which, about fourteen or fifteen years ago, was brought to this country from France. There is no doubt that the two nitrates can be mixed, but we do not consider the magnesia addition any more useful than the nitrates of soda and potash which, twenty years ago, elicited several letters and clever articles in the pages of this Journal.

"I HAVE been making some attempts at portraiture by magnesium light, but am baffled by the light going out just when wanted. Is there any way of preventing this?—YORKS."——The magnesium lamps sold contain a small spirit lamp combined with them, which, once alight, helps to keep the magnesium always burning. There is, however, a mode of treating the magnesium ribbon (which we suppose you use) so as to cause the combustion to continue without a break. This is simply to sandpaper it on both sides till quite bright. The treatment removes the film of oxide formed, and materially assists even combustion.

M. FRASER desires us to submit the following to the readers of our *Notes and Queries*:—"I wish to know how to produce a photograph on a dry plate having the acted-on parts of a pure semi-transparent white, the marked parts being clear glass. If it can be done on a dry plate I should prefer it, as I am only a dabbler in photography, and have not the means of working collodion, nor the skill. The nearest I have seen to what I want is the collodion positive on glass, but any I have seen are not pure and translucent enough in the white. I thought of trying a white pigment in the Woodburytype, but found on trial that the colour of the acted-on gelatine completely spoiled the colour of the white, white being so easily dirtied. According to what appears in the Journal, so many different tints can be obtained with gelatine plates that I have some hope you may be able to assist me."

"WHAT remedy have I against a professional photographer who fraudulently advertised a wide-angle lens for sale, which, when I fitted it in my camera after I purchased it, I find will not take a wider angle than my old landscape lens?—VICTIM."——Are you a victim to anything but your own ignorance? You accuse a man of dishonesty because you say his wide-angle lens will not take a wide-angle view in your camera. We recommend you, before making such a strong accusation, to borrow another camera capable of taking a picture twice as large as your present camera will hold, and then to report to us. The chances are that the lens will then take a wide angle. If a man sold you a telescope capable of showing objects twenty miles away you surely would not accuse him of fraud if, upon trying it in your own billiard-room, you could not see beyond the opposite wall? Yet this is precisely what you are doing. A "wide-angle" lens means a lens that is *capable* of taking a wide angle; but you must give it a chance by using a plate sufficiently large. If your size of plate be circumscribed you must get a shorter focus lens, which may still be a "wide angle."

Geo. Smith (Dudley).—Our correspondent is thanked for th information concerning the trial of lenses.

G. G. inquires—1. What kind of quarter-plate lens is the best to use to enlarge from quarter-plate negatives?—2. I have a 12 × 10 Dallmeyer's triplet. Would that be suitable to enlarge from cabinet negatives?—3. Is it an advantage to use a diaphragm in enlarging, or not?—4. Would it be injurious to use zinc dishes in enlarging work?—5. Will you kindly tell me why the enclosed picture is yellow, and what is wrong with it?——In reply: 1. Any good quarter-plate portrait combination.—2. The triplet will answer the intended purpose, but it will be much slower than a portrait lens.—3. This is a question involving judgment. If the lens employed will not define sharply all over the picture, make use of a diaphragm.—4. Zinc dishes may be employed when working with chemical solutions which have no action upon zinc.—5. We are unable to reply to this query unless supplied with a full statement of the circumstances under which the picture was produced.

"Bromo" puts several queries concerning eyepieces for focussing, to which we shall reply as plainly as possible. He wishes the eyepiece to be sufficiently long to enable him to keep his head beyond the tailboard of the camera, and yet to transmit an image from a wide-angle lens which falls near the margin of the focussing-screen. The former of these conditions can only be secured by employing, as the glass for focussing, the eyepiece of a tolerably large terrestrial telescope of low power—such a telescope, for example, as that known as a "one-draw marine," in which there is good light but a low degree of magnifying power. If our correspondent possess mechanical ingenuity he will be able to devise and construct means whereby he can, when examining the image at the margin, be enabled to direct the eyetube towards the lens to an extent sufficient to have the image transmitted to the eye. Otherwise a single lens, such as that employed by watchmakers, will have to be employed.

Phileus inquires:—"On what does the principle of aplanatism in a lens depend?"——We reply: As popularly understood, an aplanatic lens is one in which the corrections are made in such a perfect manner as to cause the marginal rays to be brought to a focus at the same point as those transmitted through the centre. Were we inclined to be hypercritical it would not be very difficult for us to show that the term "aplanatic" (without error) is correct in only a modified and very limited sense, because, as a matter of fact, any lens may be rendered practically aplanatic if its diameter be reduced to a sufficient degree. Aplanatism ought to have relation to aperture—by which we mean that some standard proportion between diameter and focus should be determined upon as regulating the subject of aplanatism. For example: One lens—say, an object-glass of a telescope—of three inches diameter and a certain focus may be aplanatic, and to render a second lens of the same focus aplanatic its diameter would have to be reduced to two inches, while in the case of a third a still further reduction would have to be effected. And yet they may be all said to be "aplanatic," as the current phraseology goes.

"I use a lot of gold in the course of a year—more, I think, than I ought. Is there no way of recovering the gold that does not get used up? My printer says it is no use doing anything.—J. Hicks."——Your printer makes a great mistake, more particularly if your consumption of chloride of gold is, as you believe, in excess of the actual requirements of your prints. A print toned to a certain stage will only take up a given amount of gold, no matter how large or how strong or weak your toning bath. If your bath be frequently renewed or replaced by a fresh one the chances are that you throw away a residue of considerable value. For the future, though you need not save wasting water after toning, by all means save every particle of old toning bath. Pour it all into a large bottle and, if left long enough, it will precipitate without help; but it is better to expedite matters by adding some strong solution of sulphate of iron. A bluish-looking precipitate which makes its appearance is pure, or nearly pure, gold. It must be allowed to settle well (being a fine precipitate a day or two may be needed), the supernatant liquid poured off, and the precipitate collected in a filter. This precipitate may either be washed and redissolved in *aqua regia* or sent to the refiner when a sufficient quantity of it has been collected. In the former case it will be desirable to weigh the gold—which can be readily done by "tearing" the filter first—so as to know the amount held in solution when dissolving, as it is of no practical use to evaporate to dryness for the sake of finding the amount of chloride. The simplest method is to reckon two grains of chloride for every grain of gold, that being the proportion usually guaranteed in commercial samples.

Exchange Column.

I will exchange the fifth edition of Captain Abney's *Instructions in Photography* for small tin plate boxes to hold sizes up to half-plate.—Address, C. W. Clarke, 32, Market-place, Devizes.

I will exchange a *carte* rolling-press, by Cox, for a good pair of small scales, glass pans, or hand magnifying glass.—Address, J. T. Peters, E. Stephenson-street, North Shields.

I will exchange copies of my medal picture for any other medal picture exhibited in Pall Mall this year, size 12 × 10 or 24 × 18.—Address, Geo. Renwick, 20, Station-street, Burton-on-Trent.

I will exchange a Marion press, for *cartes* and cabinets, or a whole-plate portrait lens, or a 12 × 10 set of autotype apparatus, for anything useful.—Address, J. H., photographer, 1, St. Mary's-place, Castle Gate, Berwick.

I will exchange a thermometer for testing liquids up to 220, by Dring and Fage, warranted correct, for a standard scales and weights from one grain, glass pans complete.—Address, George Bunn, 26, Gensing-road, St. Leonard's-on-Sea.

I will exchange an excellent nine-foot bagatelle board, in mahogany, with panelled back and pockets, nine ivory balls, and two cues complete, worth £9, for a first-class modern portable camera and lens, whole-plate or 10 × 8 preferred.—Address, E. C., 365, Lodge-road, Hockley, Birmingham.

A pair of telephone transmitters and receivers, with batteries and bells complete, in exchange for a biunial lantern of the best make; also a Francis's photo-chromoscope, for testing stereoscopic slides, for anything useful photographic, lantern slides, &c.—Address, J. Schofield, Heaton Mersey, near Manchester.

Answers to Correspondents.

☞ Correspondents should never write on both sides of the paper.

Photographs Registered.—

William Pankhurst Marsh, Norfolk Cottage, Bognor.—*Five Photographs of Breaking Waves;* also *Photograph of Upper Bognor Road.*

Lux.—Your former letter must have miscarried. Kindly repeat the query.

T. T.—Yes, if the pictures bear your name and address, and really have been made copyright.

P. R. S.—1. No. The boiling process has superseded it.—2. The method does answer, but it is not largely practised.

Lantern Slide.—We may possibly have an article on the subject on some future occasion. We cannot do justice to it in this column.

D. W. G.—Full details of the manipulations have appeared quite recently in the Journal. You cannot do better than read them carefully.

Col. Gubbins.—The glass mentioned by you will be perfectly safe to use. We imagine you will get an ample supply of light without glazing the whole of the window with the expensive glass.

John H. Astley.—We have had no practical experience with the instrument in question. We do not know if the maker will exchange it for another. Why not write and ask the question?

Cambrian.—1. Evidently you have not properly focussed the image.—2. Possibly both lenses will fit the same flange, but we have not the instruments before us to test.—3. No doubt the picture may be improved by better printing. The printing is much at fault.

Colesweges.—The plan answers very well, but we prefer to dry the plates spontaneously. Good methylated spirit will answer very well. After use the spirit can be treated with the carbonate of potash, but this must be perfectly dry. We do not think the spirit will injure the dishes if the japan be of good quality.

Louise.—Doubtless, from what you say, the fault arises from your not timing the exposure properly. You either under- or over-expose the pictures. We do not know of anyone who will give you instruction. Better write to Messrs. Morgan and Kidd, and perhaps they may be able to assist you in the matter.

Argol.—The bee's-wax is about the best protection you can use. Its looking "smeary" is because you have not sufficiently polished it after it was applied. Try the encaustic paste, a formula for which will be found in the Almanac for the current year. The remark does apply to the citro-chloride. Methylated spirit is right. It requires very slight washing only.

J. Cowell.—Without knowing full details of the production of the prints it is next to impossible to surmise the cause for their fading so rapidly. It may proceed from the washing being insufficient. This part of the operation, as is frequently the case, may have been delegated to careless assistants; they sometimes shirk their work, and this may possibly be the cause. An acid mountant may also be the cause of the fading. The mounts also may possibly contain something deleterious, which can only be ascertained by making an analysis.

Received.—James Robb; J. Mahoney; J. Bowler. In our next.

Photographic Society of Great Britain.—The next monthly technical meeting of this Society will take place on Tuesday next, the 25th instant, at 5a, Pall Mall East, at 8 p.m.

Photographic Club.—The subject for discussion at the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 26th inst., will be—*On Forgotten Processes.*

OUR ALMANAC.—We are requested by the Publisher to state, in reply to some communications received from former advertisers, that he will endeavour to make room for such advertisements as shall reach him by Monday next.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1282. Vol. XXXI.—NOVEMBER 28, 1884.

THE BICHROMATE DISEASE AND ITS PREVENTION.

There is no doubt that, since the question of the deleterious action the bichromate of potash has upon the skin of some carbon printers has been brought prominently before the medical profession by so eminent a member of it as Dr. Richardson, with whose observations we have from time to time kept our readers *au courant*, the subject has attracted much greater attention on the part of photographers than it has done hitherto.

Since the article on *The Bichromate Disease* appeared in our issue a fortnight ago, we have been asked by several correspondents who employ the salt only to a limited extent—as in the production of lantern slides by the carbon process, and occasionally a carbon print or two, or an opal picture by the "dusting-on" process—if there be, in our opinion, any actual danger of their contracting the disease which, from the published details, they say (and rightly, too, from what we have seen) must be of an exceedingly painful nature. One correspondent—a professional photographer—who employs both the carbon and dusting-on processes in his business, says:—"I would at once relinquish them if there really be any risk of such a disease as that described and illustrated in the last number of the *Asclepiad*, either to myself or to my assistant." He adds:—"I have used these processes for several years without either of us experiencing, as yet, any inconvenience whatever therefrom."

Now, from what has been published, and from what we have been able to ascertain from other sources, it appears that in some extreme cases the sufferer who has contracted the disease in its worst form has actually had to relinquish his profession altogether and seek another avocation. This, of course, is a very serious affair for one whose livelihood is dependent upon his labours, particularly if by taking a few simple precautions at the proper time the evil might be averted. On the other hand, we are assured that some persons have practised carbon printing continually for a great number of years without ever experiencing the slightest inconvenience; hence it is clear that the disease is not necessarily a result of the employment of the bichromate.

In order to avoid any unnecessary alarm—which the published accounts of the disease might have a tendency to create in the minds of those who may occasionally employ the salt by way of experiment, or in the minds of others who use it constantly in their daily avocations in larger quantities and under different conditions—we deem it advisable to offer a few remarks on the subject, and also to point out how its injurious action may be avoided; and that, too, with the least possible inconvenience in working.

In some processes in which the bichromate is used in photography it is necessary to pulverise the salt in order to get it into solution. In doing this the finer particles are apt to be diffused through the atmosphere, and eventually to be inhaled through the nostrils. This, as many of our readers are already aware, causes a violent irritation, often resulting in an unpleasant or even a painful fit of sneezing. In the manufactories where this dust always abounds more or less its inhalation leads to far more painful consequences; but the limited quantity ever likely to be inhaled in photographic operations will, probably, never entail anything like serious inconvenience. However, while the irritation lasts it is decidedly unpleasant, and it can easily be avoided. Dr. Richardson advises that a mask should be worn to prevent the inhalation of the dust; but this is by no means necessary in the case of the small amount that may be raised from the limited quantity of the salt usually pulverised for photographic purposes. Moreover, the formation of any dust at all may be avoided by a very simple expedient. All that is necessary is to very slightly moisten the crystals with water before commencing to pound them. A few drops of water sprinkled over several ounces of bichromate will effectually prevent the formation of any such dust as would fly about, and at the same time it will not render the powder perceptibly moist.

With regard to the use of cold solutions of the bichromate, MM. Chevalier and Bécourt state that provided there be no abrasion of the skin the hand may be immersed in it with impunity. As a matter of precaution, however, we strongly recommend that if the hands or the fingers be immersed in the solution, as they often are in sensitising carbon tissues, they should, immediately such operation is finished, be well washed in water made slightly alkaline, either with a few drops of ammonia or a crystal or two of common washing soda. This should be followed by plenty of warm water and soap, and copious rinsing under the tap. In washing the hands care should be taken that the wrists also be washed, so as to ensure the entire removal of any bichromate that may accidentally have got splashed upon them. By this simple precaution not only will all risk be avoided, but the yellow stain left on the skin by the bichromate will be effectually removed.

In dealing with the solutions generally, under which head would be included the development of carbon pictures, Dr. Richardson recommends the employment of an impermeable glove. When gloves are not used our advice is that the operator should always make it a practice, immediately after developing a batch of prints, to thoroughly wash the hands and wrists (and arms, too, if they are likely to have become contaminated) with warm water and soap—oil soap by preference, as it renders the skin more supple and less likely to chap in cold weather. The skin should be well scrubbed with a stiff nail brush, and the water used should be somewhat hotter than that employed for the development of the pictures. After the hot water a final rinse with cold will be an advantage.

As we mentioned in the previous article, india-rubber gloves are now being worn by several carbon printers who have previously suffered from the disease. From what we can learn the gloves are by no means so inconvenient to work in as many might suppose. Therefore, we strongly advise all who are constantly employed in carbon printing to obtain gloves immediately the first symptoms of the disease makes its appearance if they have not been in use previously, and not to wait until it has assumed formidable proportions before remedial measures are adopted. It may be well to mention again that the first symptoms of the disease—and they are said to be unmistakable—are a violent itching on the backs of the fingers and between them, and sometimes on the inner portions of the wrists, more particularly when the hands are warm. When this occurs no time should be lost in avoiding further contact with the solutions in any form, and the prevention lies in the wearing of india-rubber gloves.

In the foregoing remarks we have principally had in our mind the use of the bichromate, as employed daily in professional photography; but the question has been put by more than one of our correspondents, namely—"How is the bichromate likely to affect the amateur who only employs it occasionally?" To this we reply, somewhat emphatically—*Not at all.* So far as we can learn it always requires several months (often years) of continual working to develope the disease. However, if there happen to be an abrasion of the skin, and a strong solution of the salt comes into contact with it, a sore is at all times liable to be produced unless the bichromate be immediately washed out. A sore so produced is, as a matter of course, totally distinct from the disease itself.

In concluding this subject we strongly recommend all who have to deal with the bichromate of potash, whether in small or large quantities, to adopt every reasonable precaution to avoid any of its unpleasant effects, and to bear in mind the maxim that in all cases "prevention is better than cure."

TELESCOPES AND PHOTOGRAPHY.

We resume our consideration of the subject opened out in our last, when we left for further treatment in the present number the instrumental conditions governing the use of photography for astronomical purposes. We described the results hitherto obtained in solar photography, the immense excess of light in which class of work was the only difficulty, while with stellar work defect of light was the main obstacle.

It is obvious from our description of the painfully laborious method, by which only Mr. Common was able to execute his world-famous picture of the nebula in Orion, that a greater rapidity of execution would facilitate such tasks in every way, and render the results, if not more perfect—that were impossible—at anyrate more easy and certain of attainment. We should, then, not alone be able to shorten the time during which the observer's attention would be required, but far greater facilities would be given, in many ways, for increasing our store of knowledge of the stars.

For some little time past the attention of astronomers has been given to the possibilities of photography for star maps—perhaps more especially so since the interesting photographs of the great comet of 1882 taken by Dr. Gill at the Cape Observatory. Many stars of small magnitude were distinctly visible in these pictures, and it was soon perceived that an extension of the same mode of procedure would place within our reach a valuable record of the whole starry vault in which possible human fallibility could have no place.

The extent to which eye observation and the record of the pencil may err is well shown in the memoir by Professor Holden, which we quoted some time ago when alluding to Mr. Common's photograph. He had examined every drawing extant of the nebula in Orion, and had come to the conclusion that they afforded no information as to whether any change whatever had taken place in the nebula, or whether it had greatly altered since the first observation. With photographs no such doubt could exist, and thus the most interesting of all problems, the genesis of a star, could, if change were taking place, be noted from age to age by the unerring certainty of the camera.

It must be remembered that for such records to be strictly comparable they would need to be executed under precisely similar conditions in the recording agent, the film, and always by the same silver salt, although by taking a series of pictures with different exposures—a method which Mr. Lockyer terms "contouring"—it will, as he points out, enable us to employ any otherwise suitable silver salt.

To obtain such series readily a considerable increase in our present lens power would be highly desirable, and in the article to which we have called attention Mr. Lockyer suggests the lines upon which it would have to be built. Telescopes are, as our readers well know, of two kinds—reflecting and refracting. In the latter the rays are collected by a large object-glass and examined by the eyepiece; but in the former a mirror is used in lieu of the object-glass. The image given by each kind of instrument differs considerably: in the reflector a star appears as a dazzlingly bright spot or point from which irregular rays shoot out—most likely due, we imagine, to the structure of the crystalline lens of the eye rather than, as Mr. Common suggests, to the effect of a bright point upon a small portion of the retina; but in a refractor the image is of sensible diameter.

We have brought before our readers from time to time the progress of the great Lick telescope—a refractor—and the difficulties attendant upon the manufacture of the mere disc of glass alone before it is worked at all have been found so great that it is doubtful if a lens much exceeding three feet in diameter will ever be made. Then, again, with a large lens increase of size means increase of light absorption through the greater thickness of glass, liability to irregularity in the glass itself, the effect of which would be to blur the image, and finally increased difficulty in correcting the lens for colour imperfection, in which would result in defective definition.

In a reflector all these difficulties would be avoided, for the larger the mirror the greater would be the light and the better the definition and separating power. Again: Mr. Common points out, an object-glass requires a focus twice as long as is necessary with a reflector of the same diameter, and this means a light reduced fourfold—another element of slowness in photographing.

As regards the possible size of a reflector, mirrors three and four feet are already in existence. The power to increase their dimensions depends only upon the power to cast glass of the required size. Its optical character may be entirely disregarded, as its surface only is needed to be ground to shape, and it is then covered over with a thin coating of silver by one of the well-known precipitating processes. Unfortunately, at present, Mr. Lockyer says, there is only one place in the world—and that place not in our own country—where a very large piece of glass can be cast, and even there the possible piece would not much exceed the dimensions of existing glass mirrors. Experiments, however, are being made to utilise porcelain.

Mr. Lockyer has made the suggestion that a telescope of proportions far beyond anything hitherto made, or even imagined, should be constructed for photographic work entirely. When officially engaged in France, he gave data to the manufacturers sufficient for founding estimates upon, and he considers that for ten thousand pounds a reflecting telescope eight feet in diameter might be constructed. From the fact that, as regards eye instruments, it would be quite possible to conceive of a telescope, not greatly exceeding in size existing instruments, that would be too large for eye observation, while every increase in size in a reflector would actually increase its photographic power, the value of such an instrument will be easily seen.

Ten thousand pounds is an immense sum for a telescope, but Mr. Lockyer points out that little further cost would be entailed, and that the actual outlay for the purpose indicated would be far less than will be involved in refracting instruments now being constructed of less than thirty inches diameter. Each will require an observatory to work it in, which will cost, perhaps, forty thousand pounds, and seriously diminish its usefulness; while this telescope of the future could be more advantageously worked from a hut costing a hundred pounds. What a wonderful prospect for scientific photography is thus opened out!

We may conclude our survey by quoting Mr. Lockyer's descriptive anticipations of the powers, and value of such a wonderful instrument for scientific research:—"This eight-feet reflector I would make an instrument fitted only for such researches as those which Dr. Huggins and Mr. Common have shown us to be possible. I would then, by means of electro-magnets or what not—it is a perfectly simple thing to settle—get an arrangement by which a photographic plate could be sent up, capable of coming down again after a certain time with ten, twenty, or thirty different images impressed upon it if you wished. If it came down with one photograph as good as those which Mr. Common has enabled me to show * * * I for one should be perfectly content. * * * This dream—this beautiful dream—lacks all chances of realisation at the present time for want of glass—for want of the application of the arts to astronomical research."

PHOTOGRAPHY FOR NEWSPAPER CORRESPONDENTS.

A field in which photography is capable of development, if facilitated by the exercise of inventive genius in a particular direction, is that of an aid to the correspondents of illustrated newspapers. At present it is used to some extent, more especially in relation to architectural subjects and landscapes, also as an auxiliary power; but representations of stirring scenes in human life are usually done by hand by good artists, and at considerable expense. In such scenes the light may not always be suitable for photography, as in interiors or gas-illuminated subjects, but even in daylight hand-drawn sketches hold their own. A chief reason for this is that the saving of time in getting off news is nearly as great an object on a good illustrated weekly journal as it is upon a morning newspaper, and it is much quicker to dash off an outline sketch in pencil, slip it into an envelope, and start it at once, than it is to get with rapidity anything in the shape of a good positive in a form fit for transmission by post.

The chief impediments to the use of photography by the field correspondent are the delay and work involved in printing the positive, as well as the fact that all his materials for printing must pack into small compass, and be light enough in weight for a good stock to be carried on his person for a day without inconvenience.

Where but moderate expedition is necessary, and the correspondent is within the area of the international parcels post, as good a method as any for starting a positive photograph with expedition is to defer the complete washing of the negative from thiosulphate of soda until another day, to dry it quickly by the aid of alcohol, to print a transparency on another gelatine plate which can be expeditiously finished and dried in the same way, and then to start it by post. All this can be done, and has sometimes been done, with but little loss of time beyond the delay by parcels post. There would be difficulty and sometimes prohibition in sending glass from the continent by letter post; moreover, customs regulations interfere with that plan. As yet, England is not connected with the international parcels post system, and any postage parcel from the South of Europe to London is usually booked to Ostend or Calais only, on arrival at which place it has to be re-booked to reach England. The late Postmaster-General recently promised that as soon as possible his department would bring this country within the international parcels postage system It might be thought that it would be quicker to send small parcels direct to England by the regular express trains, but in some foreign countries the railway officials absolutely refuse to receive small parcels, the carriage of such being a government monopoly. By continental post a small parcel started from the South of Europe is four, five, or six days in reaching London.

From this it follows that some kind of paper or other flexible surface is necessary on which to print the positive, so that it may be sent by letter post, and risk of injury to it by breakage be avoided. The pictures being sometimes obtained at exceedingly heavy cost to the proprietors of the journal—as, for instance, in representing scenes of the war in Egypt—any risk of damage is a most serious matter. All these circumstances, then, point to the fact that flexible films, capable of development by the same liquids used for the negatives, may have a future before them for newspaper purposes. The present impediments are—that when the films are of gelatine they are so thick that they take a much longer time to dry than a recently-washed gelatino-bromide negative, and that the emulsion used is usually too rapid to give the best class of transparency. When a gelatine film is coated with collodion on one side in its manufacture it curls up when placed in the developing solution, because of the unequal expansion of the two surfaces, and this is troublesome. Most positives on gelatinised paper have a sunk-in look. What, then, is wanted is a sensitised film for transparencies which can be dried with rapidity after fixing, which does not curl at any part of the operations, which gives good contrasts, which can be printed by candle-light, which is little liable to tear or stretch when handled while wet by the fingers, and which can be developed by the same solutions as those used for negatives. Concentrated sulphite of soda and pyrogallol solution is good as regards small bulk and light weight, and when properly made and properly used gives exquisitely-clean negatives and transparencies. It will even develope paper pictures without leaving a stain.

Another point in quick newspaper work is that the camera shall be one which can speedily be fixed in position ready for use, every half-minute saved in time over this being a valuable point gained. The present tourists' cameras are capable of improvement in this respect. Among other modifications they require some arrangement for changing the lens instantaneously, without screwing and unscrewing; otherwise for quick work something on the principle of the gun camera must be used without a stand, although there are objections to the employment of such a weapon when it can be avoided.

In nothing more than the inauguration of new, and the work done by old, photographic societies can the impetus that modern photography has gained by its new methods of work be seen. For one photographer half-a-dozen years ago there must be at least a score of greater or less ability at the present time, and in consequence of this increase societies must naturally be formed for mutual interchange of ideas and instruction. Nowhere more than on the banks of the Mersey can we expect to find successful photographic work, and hence we hail with pleasure the establishment of a new society at Birkenhead—a busy centre, and a convenient meeting-place for the many residents upon the Cheshire shore of the estuary. With the veteran Mr. J. A. Forrest at its head, and a number of well-known names at the Council board, we believe we may safely predict a long and useful career to this latest-born society—"The Birkenhead Photographic Association"—and we cordially wish it every success.

A foreign contemporary describes a neat little photographic view-meter, the invention of M. Rossignol, devised, it is stated, to avoid the common trouble of finding upon setting up camera and tripod that the view, pretty though it appear to the eye, is not suitable for photographing. The apparatus is like a single opera-glass fitted with a rectangular aperture in lieu of an object-glass, while the sliding tube is fitted with a plano-convex at the view end and a plano-convex at the eye end. Upon looking through the instrument the view is perceived, and, owing to the construction of the lenses, upon a reduced scale; the aperture in front forms limiting lines capable of including more or less subject according to the distance the sliding tube is withdrawn. The instrument first requires to be set by adjusting the slide for each lens of the photographic outfit; that is to say, the camera and lens being set up for use, and the amount of view embraced noticed, the meter is adjusted to include precisely the same extent of subject, and a mark then made upon the tube. This is done for each lens, and, once arranged, a glance at the instrument will always tell what portion of the landscape would be photographed upon a plate the full size the camera will take, though, of course, marks might be made on the tube to correspond for each size of plate. It is obvious, too—though the fact is not noted—that the instrument would be useful in a converse way. Given a certain view to be included upon the plate, a glance at the meter would show the particular lens that would need to be employed.

"The clock of the future"—in all probability the near future—will include no more the time-honoured A.M. and P.M. Already what may be termed the "twenty-four o'clock" question is assuming considerable importance upon the railways in America. Journeys there sometimes, as we know, occupy days rather than hours and this interlapping and intermingling of *ante* and *post* become most confusing. In all likelihood, a day beginning at one o'clock and ending at twenty-four o'clock will be the usual mode of reckoning time, and when established it will save much inconvenience. The first important step in this direction in this country is to be taken at Greenwich. For many years there has been a timepiece there counting the hours in this manner; but from the first of January next this mode will be official. January, 1885, will begin immediately after midnight, and end at twenty-four o'clock.

At the last meeting of the Royal Microscopical Society Mr. Lewis Wright exhibited a most interesting adaptation of the optical lantern in the shape of a new lantern microscope. By means of his new arrangement, used with the oxyhydrogen light, he was able, with lenses down to half-inch aperture, to exhibit a variety of interesting microscopic objects which displayed the minutest markings with a perfection little short of that given by the microscope itself. The members present were highly pleased with the demonstration, which was admitted to surpass anything of a similar nature before attempted. There can be no doubt that, if it were needed, the arrangement would be quite sufficient for the photographing of microscopic objects, the whole secret of which lies in their due illumination.

The photographing of objects beneath the surface of the water has often been discussed, but in the most recent important attempt, in Scotland, it may be remembered a failure had to be chronicled—not through want of light, but owing to the presence of mud. For some time past experiments have been made in the clear water of the Lake of Geneva, and the latest report, by MM. Fol and Tarasin, of experiments carried out a couple of months ago is that one hundred and seventy metres—or, perhaps, a little more—is the depth to which light penetrates, the luminosity at that point being about equal to that of a clear, moonless night. It is, however, to be observed that assuming Professor Tyndall's theory of the colour of the ocean to be correct—the selective filtration of the waves of light by particles decreasing in size as the water deepens—it is evident that at the depth named, although luminosity ceased, rays of the violet end of the spectrum would still gain admission, and so photography be rendered possible, if need be, at still greater depths.

A correspondent writes to the *Athenæum* that it is not only in England that "the photographers of the shed" have had exceptional privileges accorded to them, as he was informed that a photographer at Bruges had met the same fate as the Fine Art Company. There is, however, another and important aspect under which the matter has to be viewed. The bulk of these copies are of more value to students than to any other class; but where is the value to students of the highly-retouched prints which MM. Braun send out as copies of the originals? And where is the chance of the student purchasing them at the price at which they are issued—fifteen francs each the correspondent in question believes them to be?

We would ask why does not Government undertake the photography of the pictures of our National Gallery? Photographic copies of every valuable picture the nation possesses should be available at all the public art galleries and libraries in the country. It is difficult to imagine a better mode of spreading a knowledge and a love for art among the people, and the cost would be by no means great. If there is not a sufficiently large staff at South Kensington it would be no difficult matter to find skilful English photographers who would be glad to undertake the work.

A great deal seems to be made of the difficulty of copying pictures through glass; but granted a good and sufficient light and clean glass and we do not see why any trouble need be made on that score. It is our purpose to make a few practical remarks upon this subject in our next.

The weather is a subject of perennial interest to the photographer, and the present year has been most remarkable for its peculiarities. In the columns of *Nature* for last week we find a very interesting tabulated account of the weather of the year, in which, for the first time that has come under our notice, we find a complete account of the rainfall for the year as far as the end of October. With the exception of the first quarter, when there was an excess of rainfall in all directions except over the midland and south-eastern counties of England, the whole year has been unprecedentedly dry. The rainfall has been below the average in every part of England, and in consequence the water reservoirs of the kingdom are in a very low state. In Manchester the night supply has been cut off, and in Bradford a water famine has been imminent. All this is very trying to photographers, who generally like to leave their prints washing all night. Still a good-sized cistern will overcome most difficulties, and it must be remembered that a couple of hours' washing with a machine that periodically empties itself is of more value than a dozen hours' mere turning of the tap on to a vessel full of prints.

The Times of the twenty-fourth instant has an article of an unusual nature—one interesting to all photographers, amateur and professional alike—a descriptive account of photographic printing in its present aspect, including an account of a new secret process. Touching briefly upon mechanical printing, and upon autotype and platinotype, it states that, practically, there has not been for twenty years past any improvement in the process by which the vast majority of photographs are produced, that of silver printing, and the writer describes a method he has seen in operation at Messrs. Marion's which is based upon that of Mr. Morgan, of Greenwich. The article goes on to state that, though Morgan's paper has come into extensive use, its cold, greenish hue has prevented it from securing the favour of a public educated to a liking for the rich purple and chocolate hues of ordinary photographs. The new process of Messrs. Marion, however (which it states is to be worked as a secret), is said by the writer to give tones which will be admired by all. The print, made by development, is purplish when developed, but requires gold toning to enable it to pass the ordeal of the fixing bath, and when finished, though not quite so good as the best silver printing, would require an expert to tell the difference. It concludes by saying that—"Having regard to all considerations, it may be expected that the albumenised paper will still hold its own for the finest work, and for work in summer when the light is bright and abundant; but the new paper will in all probability come largely into use for winter work, and it ought to be used by all portrait photographers for sending out 'proofs' at once of their portraits."

The balloonists claim to have scored at last in the attempts on the eighth instant by MM. Rénard and Krebs in their new balloon. M. Hervé Maignon states that, though the wind was blowing eight kilometres an hour, the balloon attained an absolute speed of twenty-three kilometres an hour; and he considers the problem of aërial navigation as practically solved. M. de Bruignac believes that they failed to fulfil the important condition of the approximation of the centres of traction and resistance. We shall see.

At the last meeting of the Photographic Society of Great Britain that careful experimentalist, Mr. L. Warnerke, gave his testimony in favour of the practical value of the carbonate of potash developer when used according to his formula, which resembles that adopted upon the continent by some who are clever at research. Its theoretical value is admitted, because it enables the operator to make a developer of fixed strength, instead of a solution which is liable to variation in consequence of the volatility of ammonia. Probably the discrepancies in the testimony of many who have tried the carbonates of potash and of soda may be due to impurities in the samples used, for these salts are liable to contain impurities which interfere with development, and it is not impossible that Mr. Warnerke's abolition of a bromide as a restrainer with these salts may be necessitated by foreign matters in his samples. The mode of manufacture of the carbonates of potash and soda renders them very liable to contain sulphates and chlorides, the latter being frequently present to the extent of between four and ten per cent. Potash salts are usually obtained from land and sea plants, sea water, felspar and other silicates, and the wool of sheep. They are so plentiful in the latter case that the sheep has the inestimable privilege of being an animal which supplies itself with a kind of natural soap, so that by the aid of a little water it can get up a good lather in perfect independence of advertising soap makers. Sulphate of potash, which is a retarding agent in development, is commonly present in carbonate of potash to the extent of thirteen or fourteen per cent., and in the potash of the Vosges it has actually been found to the extent of 38·84 per cent. by the analyses of Pesier. One of the purest varieties of carbonate of potash is made from cream of tartar—the acid tartrate of potassium found in grape juice. "Familiarity breeds contempt," so care is not always taken in photographic operations to work with pure chemicals and distilled water; yet that man alone who does so is entitled to speak with authority on the photographic influences of particular salts. The binoxalate of potash is easily obtained nearly pure; it should be further purified by recrystallisation, and then ignited in a silver or platinum crucible to yield the pure carbonate. The presence of sulphate of potassium as an impurity in any sample of carbonate of potash may be detected by adding a slight excess of diluted hydrochloric acid to it, then pouring in a little solution of chloride of barium; if sulphate of potash be present a turbidity is produced by the formation of sulphate of baryta. The presence of chloride of potassium is detected by the addition of a few drops of solution of nitrate of silver to the carbonate solution, which has previously been treated with sufficient nitric acid to give an acid reaction. The nitrate of silver then produces a white turbidity of chloride of silver in the nitrate of potash. Carbonate of potash is a deliquescent salt, and in purchasing it care must be taken not to buy in error the bicarbonate of potash, which is more commonly in demand in ordinary chemists' shops.

REFRACTING AND REFLECTING TELESCOPES.

The deep interest taken of late in connection with the subject treated in a leading article last week by us was well shown in a brisk and most interesting discussion which took place on the 14th instant, at a meeting of the Royal Astronomical Society, at Burlington House. The occasion was the reading of a paper by Professor Pritchard upon *A Photometric Comparison of Reflecting and Refracting Telescopes.* The observations made in connection with the recent eclipse of the moon led him to inquire closely into the cause of certain stars being noticed which were not in Dr. Struve's list. He discovered that the De la Rue thirteen-inch reflector only gave one, while the Grubb twelve and a-half inch refractor gave three, of these faint stars. These facts caused him to direct his attention to the relative capacities of the two classes of instruments in light-transmitting power, and, instead of finding upon investigation, as he anticipated, that the subject had been well worked out already, he discovered that comparisons hitherto made had been on such insecure bases that the results were simply conjectural.

He therefore arranged a plan for discovering the true relative value of reflectors and refractors in this respect, and he utilised for the purpose the two above-named telescopes, placing them, with his instructions, in the hands of two able assistants, Messrs. Plummer and Jenkins. Not to tire our readers with details, we may say that the results obtained were decidedly in favour of the refractors, in the proportion of 1·89 to 1 with the De la Rue reflector, and 1·5 to 1 when the latter was replaced by a Wish reflector, the latter being silver upon glass and the former speculum metal.

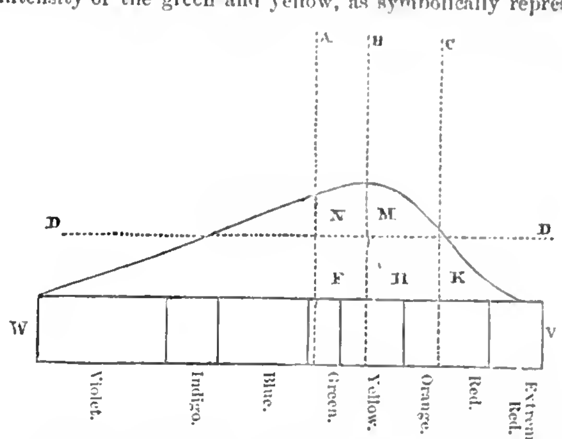
Before our readers accept these proportions as being conclusive and standard data as to the relative powers of the two classes of instruments, we would bring before them several points, including those brought into view in the discussion that followed the reading of the paper named. We have put before our readers Mr. Common's estimate of the relative capabilities of the two classes of instruments, and it must be borne in mind that in refractors increase in diameter brings increase of thickness in the glass, but no light-destroying defect in reflectors, so that the results of comparison between two twelve-inch telescopes would not hold good with larger instruments. Again: the observations recorded were eye observations, and it was pointed out by Lord Crawford that, for photographic purposes, there would be one reflection less than when the eye was employed; and Mr. De La Rue stated that speculum metal reflected more actinic rays than pure silver. Mr. Common put a question as to the positions of the wedge photometer when the comparisons were taken, and showed how the results could be made to vary according to the position of the wedge, whether in the focus or in the expanding cone of rays after passing the focus. The mirrors used were thirty-three and three years' old respectively, and it was argued that this fact would interfere with the results. Mr. De La Rue stated that his reflector was as good as new, and the Wish reflector equal to what it was when it left the maker. Silver, he said, did not tarnish when chemically deposited. Mr. Ranyard, however, said that his experience was contrary to this; for, though he kept his mirror closely covered up, he found it to deteriorate in a very few months. It will be thus seen that, though a very exactly arranged attempt has been made to compare reflectors and refractors, we are yet far from seeing an agreement come to on the subject among astronomers.

PRINCIPLES OF ILLUMINATION FOR DEVELOPING.

The great theoretical error of the past, which has for years led to the use of so much worse a light in the developing-room than is now proved to be practically necessary, seems to me to have been due to the overlooking of the fact that a reduced intensity of the yellow of the spectrum will give much more light to affect the nerves of vision than will the full-power red of the same spectrum from the same luminous source.

Fraunhöfer was the first to publish good measurements of the luminous intensity to the eye of the different parts of the spectrum. Let W V, in the accompanying diagram, represent the solar spectrum, and the curved line represent the luminous intensity of its different parts; its maximum intensity is denoted where the dotted line B crosses the curve above the yellow, a little on the blue side of the D sodium lines. Yellow glasses commonly transmit nearly all the rays between the blue-green and the extra red, and too often a portion of the blue. At all events they usually let through the light represented by N, M, F, H, K, and when they were selected with a little care they answered for the wet-plate process. When gelatine-bromide plates, with their great sensitiveness, came into use this light was found to fog them during development, so red glasses were adopted to cut off all the rays between A and C. An approximately safe light was obtained, but at the heavy cost of reducing the intensity of the light to that represented by the portion of the curve above the space K, and hence the injury to eyesight which so many photographers have found to be the practical result.

The right and alternative plan would have been to have lowered the intensity of the green and yellow, as symbolically represented



by the dotted line D D, cutting off the luminous intensity N M, and leaving for use F H K, for the benefit of the eyes. This is exactly what is done by substituting translucent lantern screens for transparent glass, combined with a source of light of low intensity, and explains why it is that all the new lights which have recently become so popular are produced by the aid of translucent instead of transparent screens. Indeed, with a thick paper giving much translucency even some feeble blue rays will pass without doing perceptible harm when the original source of light is not too strong, as exemplified in the case of "true canary medium," which is a bad screen as regards its colour, but owes its good character to its thickness.

The line D D serves to illustrate my meaning; but, as a matter of fact, a translucent white screen will not change the top of the curve into exactly a straight line. It will flatten the top of the curve, and, if the screen be of paper, linen, or other cellulose fabric, will cut off the extreme portion of the red, as I discovered by spectroscopic examination. The rest of the red it transmits liberally. Cellulose fabrics are very opaque to the luminous rays coming from a poker at a dull red heat. There is little luminosity in the extreme red rays; still, as they are comparatively safe for photography, it would theoretically, if not practically, be as well to save them by using a translucent screen containing no cellulose.

Fraunhöfer gives the following figures to represent the luminosity of the spectrum at the various chief solar lines:—Light at red extremity, 0·0; at B, 3·2; at C, 9·4; at D, 64·0. Maximum at dotted line B in my diagram, 100·0; at E, 48·0; at F, 17·0; at G, 3·1; at H, 0·56; violet extremity, 0·0. These figures of his can but be approximate, but they are near enough for the purpose of guiding experimentalists in improving the light of the developing-room. Helmholtz has proved that with care in arranging the appliances, and by placing the observer in darkness, the violet end of the spectrum can be seen far beyond the point at which it is ordinarily visible, and more of the red end of the spectrum can be seen by some persons than by others; hence all diagrams like that given herewith are not theoretically perfect, though amply good enough to serve as practical guides. Lord Rayleigh has discovered that in a spectrum taken from the light of a blue sky the different colours are not of the same relative intensity as when taken from a cloudy sky; there is more red in proportion to the green in the light from the sky when the latter is obscured by cloud. He finds that if lights from sky and cloud are of equal intensity at the line C in the red the first will be somewhere about twice as bright as the other at E in the green.

By means of alkaline albumen films stained with fluorescine great power can be exercised in regulating the kind of rays admitted into the developing-room; for, by gradually increasing the proportion of fluorescine in the solution used to coat the glass plates, the more refrangible rays are gradually cut off giving the power of cutting short the spectrum anywhere the operator chooses between A and C in the diagram. I, however, think it would be a great mistake to go farther than to cut off the bluish-green; for, if the light be then not safe enough for the purpose, the amount of general illumination should be reduced by interposing translucent colourless screens, or otherwise. If the fluorescine film be made abnormally intense in colour, it is a reddish-brown, transmitting only the red and a little orange. I prefer to obtain this effect, should it be required, by using a fluorescine film to cut off the spectrum to A only, then to superimpose a film of carmine. In fact, with separate albumenised films on glass, of fluorescine and carmine, the lower end of the spectrum may be cut short wherever desired, and the transmitted colours are pure and brilliant. Carmine is just like ruby glass in its optical properties for photography. When the film is not intense it is of a pinkish-red colour, like the ornamental articles of glass stained with suboxide of copper; when the film is more intense it is like the ruby glass in ordinary photographic use. Both let a little blue through when strained by an intense light like that direct from the sun.

A curious and little-known effect is produced when the rays of the spectrum as far as the dotted line A are admitted into the developing-room, for the green rays then slightly increase the yellow appearance of the light. In fact, if all the true yellow and a portion of the red were cut off, the room would apparently be illuminated with pure yellow light, so subject is the human eye to all kinds of illusions as to colour. Lord Rayleigh discovered this compound yellow. Mixtures of blue and yellow look green, as every mixer of colours knows; the fact is so familiar that it causes no surprise. Lord Rayleigh did not see why a mixture of pure red and green should not produce yellow, and, by using the pure red and green of the spectrum in proper proportions, he produced a yellow which fairly well matched the true colour. He made two varieties of special apparatus to do this; but the effect may be obtained in a simple way by filling a glass trough with a solution of litmus to cut off the yellow and orange rays, then adding solution of chromate of potash to cut off the blue and bluish-green. Only red and green rays then find their way through, and when the strength or thickness of the solution is so arranged that neither red nor green predominate the transmitted light appears to be yellow, although it contains no real yellow at all. He does not think it more unnatural to get a compound yellow in this way than to get a compound green by the ordinary method, and is of opinion that the bias given by constant experience is at the root of the apparent strangeness of the fact. Colour has a wonder world of its own. What is the explanation of the circumstance that a dark yellow is not generally recognised as such, but thought of and called by a new name—brown? Sir John Herschel first put this question, but where is tho answer? A dark blue is blue still.

The vertical lines separating the colour spaces in my diagram are but approximate, for no two men looking at a spectrum would select the same points as midway between each two colours, and numerous experiments in this direction, taking averages of the results, would, no doubt, reveal curious variations in the vision of different persons, not altogether ascribable to colour blindness. Robert Hunt amused himself sometimes by asking observers to note the central point between two colours, by indicating the spot with the point of a needle. Newton and Fraunhöfer each divided the length of the spectrum into 360 parts, and gave the following as the length of the space occupied by each colour:—

1. Red	45	—	56
2. Orange	27	—	27
3. Yellow	40	—	27
4. Green	60	—	46
5. Blue	60	—	48
6. Indigo	48	—	47
7. Violet	80	—	109
Total length	360		360

A common scientific error in experiments intended to relate to developing-room illumination is that of photographing coloured fabrics, under the impression that the effect they produce on the plate is a measure of their value as screens for the window of the operating-room. When this is actually the case in practice, in relation to two fabrics much alike to the eye, the result is a pure accident. The light reflected from coloured fabrics differs from that which they transmit, as readily revealed by the spectroscope. For instance: different coloured ribands reflect different amounts of unchanged white light which never enter the fabric at all. On the same principle it is a mistake to varnish the interiors of those developing-room lanterns in which reflected instead of transmitted light is used in photography. This may be proved by making a solution of a brilliant coal tar dye in albumen, coating a small glass plate with it, and, when the film is dry, allowing sunlight to fall on it so as to be reflected from the albumenised side to the ceiling. Two images will be formed on the ceiling—the one of them bright white from light reflected from the exterior surface of the albumen, and the other coloured by rays which penetrate the film and are then reflected from the back of the glass, through the film again, to the ceiling. It is not necessary even to varnish the film to obtain this effect. The inside of the Starnes's lamps should be as rough and unpolished as possible, necessitating a stronger initial light to obtain the same amount of illumination on the plate under development.

The light transmitted by fabrics also differs from the light they reflect, because of the influence of translucency, as well as because of the optical action of the colours themselves. Who can tell the colours of aniline dyes from the hues reflected by their crystals? Again: taking the common ruby glass of the photographer, samples of it are sometimes found exceptionally heavily charged with suboxide of copper, giving it a purple tint by reflected light when examined at a particular angle. The fact that such samples specially reflect some blue light is no proof that they transmit the same quantity of blue; in fact, these particular samples are the safest, because they keep out more blue than samples in other respects of the same make. Mr. Woodbury made a thick film of coloured gelatine which reflected green rays and transmitted red.

The principles laid down in this article are far-reaching. If they be true—and I think that time and experience will prove their accuracy—the theories of the past about the necessity for red light in the developing-room are false, and photographers have been blinding their eyes for years because of the erroneous ideas in their heads. These principles not alone condemn real glass utterly, but they go further, for they in a milder form condemn orange light also. They furthermore enforce that red or orange light is not the best for the manufacture of gelatine plates, over which a safe light is more necessary than for the short process of development. This point can be put to the test of experiment. It will probably be found that if the intensity of a light behind a translucent full-yellow screen of fluorescine is properly regulated, and two plates be placed respectively at such a distance from it and from the best red light as to give the same amount of fogging for the same time of exposure, the yellow light will be very much the brightest to the eye at its own fogging distance as compared with the visual intensity of the red light at its own fogging distance.

W. H. Harrison.

TRANSATLANTIC JOTTINGS.

The question of amateur photographers and the possible injury they may work to the profession is being discussed with considerable vigour on the other side of the Atlantic, and the editor of *Anthony's Bulletin* devotes some considerable space to a temperately-worded article upon the varions aspects under which the subject may be seen. He is evidently at one with us in the view we expressed some time ago that amateurs were a help rather than a hindrance to the professional photographer; but, at the same time, he points out that the conditions vary considerably between the east and the west of the States. We cannot put one view he presents better than by quoting from the journal itself, noting that the controversy has arisen through the stand taken by the gentleman whose name is mentioned:—

"Amateurs in the true sense of the word take up the art from a pure love of it, and practice without a consideration of reward. Such amateurs Mr. Melander, like all other wise and liberal-minded men, welcomes with his whole heart as valuable workers in the great photographic field. Unfortunately in the west, and especially in Chicago, there appears to be an army of so-called amateurs who from curiosity, love, the desire of gain, or some other motive have taken up the art, and who as soon as they can make a negative at once begin to canvass for *business*, proposing to make their newly-acquired art a means for increasing their income. Everyone understands, who knows anything of the universal rules governing the standing of amateurs in any branch of the arts, sciences, or of sports, knows that the moment one receives money for a performance, product, work of art, or it matters not what, that moment he ceases to be an amateur and becomes a professional."

These words are as apt as they are true; but, in our opinion, they add little weight to the argument against amateurs. Successful portraiture requires more skill, knowledge, and practice than landscape work, and there is too much vanity in human nature to allow the work of the average amateur to make any serious difference in the income of the professional photographer. It is well, however, to bear in mind the distinction between "amateur" and "professional," which is broadly stated in the above quotation.

The vast strides made by photography of late years, and the complete change that has taken place in dark-room modes, could not be better exemplified than it is in an article in the *Photographic Times*

(New York) under the title of *Ambrotypes*, which, as many of our readers will know, is the common designation in America for the collodion positive. We involuntarily referred to the cover of the journal to ascertain that the date was correct, and that we had not by accident picked up an old copy. But, no! the date was right, and there for perusal was a complete account of how to make a collodion positive, from the putting together of bath and developer to the final completion of the picture with black varnish or velvet! To old workers in photography this would seem a very useless article, but a brief consideration will show that in all probability the proportion of photographers who know nothing of wet-plate work is nowadays greatly in excess of those who are familiar with it, and that it may be useful to teach them the mode of working a process which gives really beautiful results. We do not think there is much likelihood of their taking it up, seeing that the apparatus of the day is quite unfitted for wet plates. Still, the resuscitation of the memory of an old process is interesting, and to the old hand will recal many an incident of the past. "Ah! those *were* the times!" said an old photographer to us; "no re-sits—money down!"

A suggestion is made by a writer in the same journal that "photographers would do their patrons a great favour if they would have the figures for the year printed upon the mounts in addition to name, &c. Photographs are, as a general rule, carefully preserved, and after a few years it is impossible for most people to remember just how long ago a particular photograph was taken. * * If photographers will adopt this suggestion the public will appreciate it, and everybody will wonder why it has not been done before." We can tell this gentleman why it has not been done before. It is because "it is impossible for most people to remember just how long ago a particular photograph was taken;" and when the portrait is one of a lady who once was young, and would be still, no effort of memory will enable her to date it more than two years ago. The photographer who carried out the method suggested would lose many sitters.

Professor Hough has been making experiments as to the relative rapidity of wet and dry plates. He first thought that twenty or thirty times represented the rate, but afterwards modified his notions. The conclusion he then arrived at was that they were one hundred and twenty-five times quicker, and the ground of his conclusion was, according to the President of the Chicago Photographic Association, that a picture of a landscape could be taken in the one-hundred-and-twenty-fifth of a second, while a wet plate took one second. At the same meeting where these remarks were made, Mr. Greene accounted for fog by supposing that the light which went in a straight line through a lens created the fog. When a lens was stopped down the straight rays were cut off, and only the oblique rays went through; hence the picture was sharper. These theories apparently did not gain any support, which we can scarcely say surprises us.

There is a distinctive peculiarity in American advertisements which almost enables them to be detected in a moment. When we read in a list of testimonials a letter from Mrs. ——, stating that "I value my *Photographic Times* next to my Bible," it strikes us as almost profane.

An interesting communication, by Mr. Carbutt, upon reducing the intensity of negatives, &c., is to be found in the *Photographic Times*, and in it he strongly recommends Mr. E. Howard Farmer's method with ferridcyanide of potassium and hypo.

The Photographic Section of the American Institute had an interesting conversational discussion upon founding a photographic library of reference works. The list of works suggested was rather "mixed," some of them being almost antiquated, and others only to be linked to photography by a great stretch of imagination. One of the members seemed to have noticed this, and he gravely "wished to add mention of the English Blue Book as being of great value to a library!"

We have on a previous occasion made mention of the war of tariffs which is being fought in some of the large cities of the United States, and we read that the President of the Illinois Photographers' Association recently stated that little as yet had been accomplished in the direction of fixing a "price-plank."

American photographers are more tranmelled by postal restrictions than we are in this country. "Book Post" is all that is needed here, but in America postal packages are divided into several classes; and this has led to a committee being formed to endeavour to secure a reversal of recent decisions which classified photographs as fourth class, instead of third class, as formerly. The late announcement is to the effect that "first-class postage must be paid on photographs which have been worked in *ink*, classing them as drawings." Vexatious restrictions such as these must seriously interfere with the business nature of large establishments as are are to be found in the States.

LANTERN SLIDES ON COMMERCIAL PLATES.

Part I.

In few, if any, shapes does photography play a more pleasing, interesting, or imposing part than when it takes the shape of a lantern picture on a good-sized screen. Scientific photography shows itself most valuable when it is used to throw on a screen enormously-magnified images of microscopic and often invisible objects, or objects visible only under strong powers of a good microscope. Possibly, observations on certain spectra can be made more easily, searchingly, and accurately in this manner than in any other. I am not, therefore, shooting over my mark when I say that in the optical lantern there is a power into the infinity of which man has hardly as yet more than dipped his finger; nor do I propose to dip deeply into the subject on this occasion. My remarks shall be confined to the methods of producing from ordinary photographic negatives "slides" which will give enlargements on the screen of landscape, portrait, *genre*, or marine subjects; in fact, of any subjects that can be photographed in the ordinary acceptation of the word.

Certainly one of the weak points of our art at present, as compared with the higher art of painting, is the smallness of our work. That a small work may be artistic I do not seek to deny, but a small picture in order to pass muster with the critics must be of a pitch of technical perfection most difficult to arrive at in painting; and, while I admit that technical perfection is more easily arrived at in small work by photography, I maintain that in most of our small work we lose some of the finest points that mark the work of the painter. We become "patchy" and lose breadth and vigour in our small work. That the lantern reproduces our small work in its true and original proportions of light and shade is certain, but it reproduces on such a scale that, whatever faults may be found with our work, "patchiness" is not likely to enter into the accusations against us. I know one thing as a certainty: so long as my smaller negatives can be copied as slides without losing any necessary parts of my composition which may happen to be near the edges of the negatives—so long, in fact, as my negatives can be properly squared or rounded—I have a much higher opinion of my own taste when I see my pictures as transparencies on a fifteen- or twenty-feet screen. Perfect sharpness of outline and detail is not, in my opinion, an artistic necessity—quite the reverse; and yet for some reason a small print out of focus is to me an offence, while the same picture slightly out of focus on a large screen is to me a "thing of beauty and a joy," so long as I see it. I leave it to more learned men than I am to give our readers the reason for this. It was my observation of these facts that caused me to turn my attention to lantern slide making in the first instance.

In the second place, I found very soon after I began to turn my attention to lantern slides (and that is not a year ago) that negatives absolutely or all but unprintable in silver, carbon, or platinotype yielded first-rate slides for the lantern. This discovery was the means of rescuing from the oblivion of garret and cellar many a negative that had cost me much trouble, but had to be thrown aside on account of technical imperfections. I find now that I can produce, either in the camera or by contact, a very fair slide from any negative that is not utterly ruined by thinness from over-exposure or any other cause. I also found that with perfect ease I could copy any part of a negative, so that where, for instance, I have a nice group of cattle in the centre of a large negative, I simply make a slide of the part I want, leaving out all the rest of what may perhaps be a worthless negative. This last view of the question I strongly insist upon. I have very many negatives almost perfect in one part and worthless in all the rest. And, lastly, when I have in view the illustration of some particular object or set of objects, I go in perfect happiness with a pocket camera and make small negatives in almost any weather, knowing that I shall be able to make slides from the negatives at a later period.

As an instance of this I may say that not long ago, being at Ayr, I wished to get some reminiscences of our poet Burns. There was a pretty high wind all the time, but I simply took rapid plates and "shuttered" all the views I wanted. Many of my negatives, being hard, are worthless for silver printing, but capital for slides. I do not, however, mean to assert that a bad negative makes the best slide. All I say is that a hard negative makes a very good slide. In my opinion, the perfect slide can most easily be made from a good negative rather on the hard than on the soft side; and this I apply to both contact printing and camera copying. I see that my preliminary remarks are already longer than I intended; but, as one "may as well be hanged for a sheep as for a lamb," I shall make two chapters of my subject.

There are many other points of advantage that may be claimed for slide-producing. It is not only eminently satisfactory when done but it is most interesting in process, and slide-making is the best amusement for winter that the enthusiastic amateur can find. A person, otherwise idle, can in a day produce dozens of slides by contact, or, like me, he can gloat over the production of two or three. If he copy in the camera at this season he will not produce more than two or three in a day. Contact printing can easily be done at night; but I do not intend to go into that subject, because I do not attempt such work after dark.

If ultimate success after a long series of failures give a man the right to speak with decision on any subject, I think I may safely claim that right. I dare not say how many scores of little plates I wasted before I got a slide that satisfied me. I could make slides that would "pass in a crowd"—if it were a very large franchise demonstration crowd—but I could not for a very long time make a slide that would for a moment compare with slides I had seen, not only in the market but in the collections of amateurs. In fact, I never was as nearly "licked" in anything photographic as I was in the production of good slides. I had stained skies, or general incipient fog, or, failing these, I had my shadows "bunged up;" in short, there was always something wrong. How I got over my troubles it is my object now to inform my readers.

In the first place, I have to explain that I could not make my own emulsions either of gelatine or collodion, having been expressly forbidden by my over-zealous doctor not to remain long in my operating-room. I am a tender plant, it would appear; so I had to buy my gelatine plates and my collodion emulsion, and I have to apologise once for all for having to mention commercial names, but unless I do so I shall certainly not be understood.

My first trials were with wet collodion, and in a short time I got to make sufficiently good work copying in the camera from large negatives. I made both bath and developer strongly acid with nitric acid, and used but little bromide in my collodion. Though I secured by these means fine, clear positives, I objected first to the building up of metallic silver in the shadows; and, second, to the coldness of tone, which I could not overcome with either gold or acid platinum chloride. Nor am I very fond of the wet process, but even had I succeeded with it to my complete satisfaction I should have still tried to gain the same end with some dry process. That fine slides can be made by the wet process is made certain by the fact of Mr. Gale's successes in the lantern slide line. Last year he had some grand slides by the wet process; this year he has carried off the medal for slides at Pall Mall, and I suppose he still uses the wet process. But his experience and mine seem to differ. I prefer the "stain" produced in the development of an emulsion to the building up of silver on a wet plate. I call it a "stain," because that is the appearance the reduced silver presents to the naked eye in an emulsion positive.

I now pass on to my experiments with gelatine plates. I began with some very slow bromide emulsion made by myself and in good working order. In the camera with long exposures I got results that did not satisfy me at all. I never got a thoroughly-clear sky—not even when the negative sky was blocked out—and when developing I never could tell when to stop. It is highly important in all processes of slide-making to know exactly when to stop development. Sometimes I got the whole slide blocked up, and sometimes after fixing I found only a ghost of an image. This was the case both under pyro. and ferrous oxalate development. Nor was the colour ever good with these developers, and gelatino-bromide negatives are not easy to tone. Then I tried ferrous oxalate with a citrate on some very slow bromide plates kindly given to me by Mr. G. Smith, but I had still almost the same troubles—unpleasant tone, uncertainty when to stop development, &c. Still this addition of citrate to the developer was a step in advance, as I appeared to get greater clearness in the high lights of my slides.

My first approach to success was when I took to Mr. A. Cowan's gelatino-chloride plates, and developed them with his own developer. I succeeded best with Mr. Cowan's No. 3 (or "extra-warm tone") developer. As I have already in these columns given my experience with Mr. Cowan's chloride process I need not repeat what I said before, further than in a general way. The great secret of success with any process is to expose long enough and not too long—a very wise remark on my part! But I mean that the plate must be exposed to such an extent that not the slightest forcing of development is required; in fact, the shorter the development for a lantern slide on a Cowan's plate the better, supposing always that the red colour disappears from the plate before fixing. I found that a plate fixed before the red colour left it was exceedingly easy to tone to almost any extent, but I did not find the slides when finished by any means so satisfactory as those which had *not* left the developer while still red. A plate that gains sufficient *density* while still red or reddish is almost certain to be over-exposed and want "pluck." I like plenty of half-tone in my slides, but the worst slide of all is one that is *all* half-tone, and wanting in both shadows and high lights. Therefore, the plates must not be over-exposed. As to my method and time of exposing I shall treat hereafter.

Having used a good many dozens of Mr. Cowan's plates without entirely succeeding—for which, no doubt, I alone am to blame—I tried Mr. Edwards's gelatino-chloride plates. As with Mr. Cowan's so with Mr. Edwards's: I got very near complete success; in fact, with certain kinds of negatives I consider I did attain success. Some of my slides on gelatino-chloride plates were shown in the Society's lantern in Pall Mall, and were considered, as I was told, good specimens. Many of these were copied in the camera, and others printed by contact, but it was impossible to tell "which were which." Mr. Edwards's developer is different from Mr. Cowan's, and is a little more easily made. I need not here give his formula, as he sends instructions with each box of plates. It is, however, necessary to note that the solutions should be made with distilled water, otherwise a deposit will certainly take place and frustrate the work. I think that, on the whole, I have succeeded better with Mr. Edwards's gelatino-chloride plates for lantern slides, but I prefer Mr. Cowan's for making large transparencies for window or table decorations. My experiences in the latter line are to be found in the columns of this Journal in the earlier part of the present year.

I have not a grain of doubt that very fine slides may be made with these chloride plates. But I doubt if they afford facilities for accommodation to various qualities of negatives to the same extent as either wet or dry collodion. To those who are trying, or proposing to try, gelatino-chloride plates my advice is this:—Expose so that the development is speedy but not precipitate. Develope the positive rather stronger in colour and force than you wish it to be when finished. After fixing and well washing—do not "scamp" washing because your plates are small—never omit a good dose of acid and alum; sulphuric acid is best. Expose a hard negative to a bright light, and a soft one behind ground glass. My exposures for contact printing are made beneath a thick dome of obscured glass in the roof—my room was meant for a billiard room—and my exposures with gelatino-chloride plates average about ninety seconds. In the camera I have to expose on an average negative from half-an-hour up to two hours at this abominably dull season. Referring to a remark a few lines above, I am aware that it is often recommended to expose a hard negative to a dull light for a longer time. This does not at all tally with my experience. More anon about collodion emulsion and apparatus.

Andrew Pringle.

ISOCHROMATIC PLATES.

[A communication to the Glasgow and West of Scotland Amateur Photographic Association.]

Since the introduction of gelatine as a medium for holding the sensitive silver compounds the photographic plate has made rapid strides towards perfection; yet we must admit that much remains to be done before the perfect plate is an accomplished fact. Perhaps the most prominent defect in plates as now used is their inability to reproduce different colours in the same relative intensity as they present to the eye. Let us see, then, the cause of this, and the means by which better results may be obtained.

You all know what a spectrum is, and have all seen it in the rainbow, or in a more homely form as thrown upon the wall by the prisms of a chandelier. When we examine such a spectrum we find it to consist of a band of coloured light, graduating from red at one end, through orange, yellow, green, blue, and indigo, to violet at the other; these colours blended together form the white light by which we take our photographs. Now, if we expose a plate to this spectrum and develope it we find that only some of the colours have effected reduction of the sensitive salt. Let these spaces on the board represent the various colours, and the height of this curve the intensity of their action on the plate; then pure bromide of silver will be represented by this curve, chloride by this, and iodide by this. Bromide has by far the greatest range, and when a small amount of iodide is present with it there is a slight decrease in the blue region. Such plates would, therefore, be evidently best for general landscape work, and we may be pretty sure that most commercial bromide plates do contain a trace of iodide.

It is evident that most of the work is done by the rays towards the violet end of the spectrum (a great deal is done by rays beyond the violet which are invisible to the eye), and that green has comparatively little effect. We can thus see why, in landscape work, we lose so much of the detail in shadows and foliage, the light which presents such detail to the eye being rich in green and red, but deficient in blue and violet. Could we obtain plates sensitive to green we should get negatives giving a much more natural gradation.

Leaving out of the question the actual reproduction of colour—which is as yet a far-off possibility—let us see what can be done to secure in light and shade a better rendering of the *value* of colour. The meaning of this term "value" is that bright colours should give light tones, and dark colours deep tones. We know that if we photograph blue and red on an ordinary plate they show in the print as white and black respectively, while yellow and green both appear dark; but if we can make plates sensitive to the so-called "non-actinic" colours we will then obtain prints showing a more natural gradation.

The method used to obtain such plates is the addition of some substance to the film capable of absorbing and converting into chemical energy those rays which are inactive on an ordinary plate. These substances are dyes, mostly of the aniline series, and a few natural vegetable colouring matters. They are themselves sensitive to light, as manifested by a bleaching action under its influence. The rays which effect this bleaching are those towards the red end of the spectrum—that is, the very rays which we wish to capture and divert to our plate. The immediate cause of the bleaching is oxidation of the dye, but how this effects the silver salt is a matter of dispute.

Captain Abney holds that the dye in absorbing oxygen acts as a developer, similarly to pyrogallic acid in the alkaline developer, this slight reduction forming a nucleus for a further deposit of silver during development of the plate. This theory seems to be borne out by the fact that the dye is only a colour sensitiser in presence of a chemical sensitiser—that is, a body capable of absorbing the bromine, &c., set free during exposure. Gelatine is such a sensitiser; also silver nitrate in the case of collodion plates.

Dr. Vogel's theory is that the energy absorbed in bleaching the dye is transmitted to the silver haloid, upsetting its equilibrium and rendering it capable of development. This theory seems to be proved by the fact that a dyed collodion film exposed to the spectrum will, if coated with collodio-bromide emulsion and developed without further exposure, give an image of those parts of the spectrum to which the dye is sensitive. It is very evident, however, that the invisible photographic image is still in want of a satisfactory explanation.

A large number of dyes have been found more or less effective, and I might give you a long list bearing the delightfully-simple and explicit names peculiar to the aniline and kindred series, but it will be sufficient to mention those which have been put to practical use. Amongst vegetable colouring matters, chlorophyll extracted from green leaves is a sensitiser for red, and turmeric extract for red, yellow, and green. Most of the dyes which have been tried have slowed the plates, and have been most effectual on collodio-bromide; but Dr. Vogel has recently discovered a new substance which is most effective with gelatino-bromide, and which actually increases the sensitiveness of the plate. It is, however, such a recent discovery that I can learn little about it. He has named it "azaline."

Next to azaline eosine seems to be most useful, and plates prepared with it are now disposed of commercially. Dr. Vogel has by means of eosine prepared collodion plates eight times as sensitive to yellow as to blue; but with gelatine his results have been less satisfactory, the plates being only twice as sensitive to yellow as to blue. This is a long way short of what is required, for in nature yellow is about twenty times as luminous as blue to the eye. Therefore, in using these plates for copying oil-paintings, it is found necessary to photograph them through yellow glass in order to restrain the excessive action of the more actinic colours. The above results are obtained on bromide plates, which are most affected by these colour sensitisers. Many substances which have a marked effect on bromide are inactive on chloride and iodide.

We are likely to hear a good deal about eosine, and it may interest you to know a little about what it is. Though commonly known as an analine dye it is not really so, but is a potassium compound of tetra-bromo (or iodo) fluorescein, which, in its turn, is derived from resorcin--a substance allied to pyrogallol, and, like it, a powerful developer. Pyrogallol, hydrokinone, and pyrocatetchin all yield bodies similar to fluorescin, and these produce dyes like eosine; therefore, when we buy eosine it is rather doubtful what precise substance we get. This may explain why some experimenters have met with less success than others.

True eosine exists in two forms—the iodeosine or blue shade, and bromeosine or yellow shade. It gives with silver nitrate a precipitate soluble in ammonia, which is sensitive to light. A few drops of the ammonia solution added to an emulsion is found the most effective way of preparing the colour-sensitive plates. Ordinary plates, however, may be treated with a solution of three parts of eosine in 100 parts of water containing ten per cent. of ammonia, and then dried. Here is such a plate, which you see is a faint rose colour; and here is a yellow plate stained with turmeric. I now pass round a colour scale with negatives on two such plates and on an ordinary plate. The latter shows the blue dense, and the yellow almost clear, glass. The turmeric plate shows the green denser, but on the eosine plate the difference is very striking. The yellow is nearly as dense as the blue, while both green and yellow show a notable gain in density.

It is not necessary to have a highly-coloured film, as the merest trace is sufficient. Dr. Eder prepared a stained emulsion, from which he separated the bromide by means of Plener's centrifugal machine. This he washed till the water came away colourless and re-emulsified in fresh gelatine, and the resulting plates were as colour-sensitive as the original emulsion. The washed bromide was faintly tinged, and Dr. Eder conjectures that an insoluble compound is formed between the bromide and the gelatine immediately surrounding the grains, which, being stained, is sufficient for the purpose in view.

I daresay most of you have now had enough of this subject. Still, it is one to which our attention will be often attracted during the coming season; and I trust that, when isochromatic plates become practically obtainable for landscape work, our Association will be one of the first to give them a fair trial. W. Goodwin.

ON THINGS IN GENERAL.

The cat is fairly let out of the bag about the Trafalgar-square monstrosity. The disfigurement of the finest site in Europe is not a workman's dining-room nor a place of worship. It is simply the private workshop of a foreign tradesman allowed to be set up on ground belonging to the British people to facilitate the manufacture he is engaged in, and enable it to be done at the cheapest rate. No rent, I suppose, is paid, and my readers will already have learnt that the national treasures of art have been licensed free to this foreign photographer to be taken off the walls, to have the glasses removed, and be carried about from place to place, so that he might do in the manner most convenient for his trade what has been denied to any British subject. The monopoly granted him is further enhanced in value by the authorities hastening in advance, before the request is made, to deny the like facilities to any mere Englishman. As the matter now stands in print it is nothing but an impudent slur upon our countrymen; and I hope the firm originally interested, even if their head-quarters be in the provinces, possesses sufficient influence to have the "job" brought before Parliament.

I have been interested in reading the articles on *Modern Dark-Room Improvements*, and have been able to glean some useful hints therefrom, but I should rather hesitate before adopting all. That dark room must be interesting; but to find in one room, even so well lighted as described—light enough to cure the owner of the need for the use of spectacles—and if ventilated to perfection, the operations of plate drying, negative drying, gas burners boiling, evaporating pan at work, varnishing and collodionising—all going on at the same time, and a couple of water taps only in the place, suggest that the writer, besides being able to produce photographs and pictures so well as I know he does, must also have the bump of order and system developed in the highest degree to prevent unpleasant *contretemps* occurring.

Among the new patents I see one by Mr. Vanderwyde for the production of vignettes direct in the camera by means of a screen placed either between lens and sitter, or lens and plate. His specification states that this has not been done before, except in the way of producing dead black ground, while his patent is to enable tinted grounds to be produced. Whatever the value of the translucent screen within the camera may be is not for me to say—it does not look feasible upon paper—but I can state that the idea of a vignetting screen outside the camera is very old. I distinctly remember it twenty-five years ago, and one of the most expert photographers then living used it regularly in his business, and, I believe, made an extra charge for pictures produced by its aid. It is, therefore, obvious that the patent is invalid on this ground alone unless a disclaimer be entered, and if it were I opine there would be little of value left to protect. Still, if the publication of the patent subserve no other purpose than that of drawing attention to a capital mode of vignetting which must have additional value, now that gelatine plates enable such perfect films to be produced, Mr. Vanderwyde will deserve the thanks of the photographic community.

I always like to read Mr. A. F. Genlain's articles, as he is a clever and enthusiastic photographer and an artist of skill. He will, therefore, the more readily allow me to point out an error in his last article on *A Little Philosophy*. "Let us deflect two beams of light—one yellow and one blue—on a white strip of paper and we shall certainly obtain a green strip as the result." The word "not" should be inserted after certainly. Mr. Genlain was thinking of the effect produced on his pallette when selective absorption would cause the mixture to appear green. When reflection only is called into play, blue and yellow lights will not commingle into green.

What a horrible thing to read, as I did a week or two ago in these pages, about the production of dimples by artificial means. Is it true, I wonder? What a dreadful plight the young lady would be in if, in lieu of a dimple, she found herself disfigured for life with a huge wen, or such a destruction or disorganisation of surrounding tissue as would lead to the colour entirely leaving the place, and thus the use of face powder be rendered necessary for the rest of her life! I cannot say I should think she would have cause to complain. Eyebrows made to order—not painted, but real hair—have come under my own cognisance, so that I can bear witness to the fact of the adoption of that expedient. A photographer is accustomed to see a great amount of human vanity, and hence is not surprised at any such exhibition as this. But, after all, I need not say "human" vanity, for vanity as great exists among the lower animals, as any close observer of nature knows well.

The idea of the dust of Alexander stopping a bunghole is familiar to us as an emblem of the base use to which things noble may be put, and it was forcibly brought to my mind the other day when reading of one of the uses which albumenised paper had been made to subserve—the wrapping of packets of butter. A pound of butter in a sheet of albumenised paper! The thought is too terrible to contemplate. And *such* paper as is now sold! What next? We only want to see a first-class portrait lens attached to a peepshow, a camera as a blacking box; but hold! already have we come to this latter pitch of humility: nothing is so likely to happen as the improbable. Free Lance.

THE SCENERY OF VICTORIA AND NEW SOUTH WALES.

In The British Journal of Photography for 31st August, 1883, was an article, by Mr. A. Pringle, styled a *Tour Round the World*. This I read with great interest, as I also did those which followed; and, for the benefit of such other photographers, amateur or professional, who may feel disposed to take a holiday trip in the same fashion, I thought that a short sequel might advantageously be written.

It is a pity, so far as Melbourne (and also the colony of which it is the metropolis, viz., Victoria) is concerned, that Mr. Pringle was unable to prolong his stay for a week or two, and by this means see something of the surrounding country; for, judging from his remarks, he missed some of the most striking points, though it must be admitted that in every direction, save one, in which the new arrival looks the country is flat and without the least pretension to the picturesque.

The only place of interest outside the city which Mr. Pringle mentions is Fern-tree Gully. This is certainly a pretty place, the difficulty of getting there being the one thing against it, although during the last two or three months an agitation has been got up for the purpose of trying to induce the Government to make a branch line of railway to the Gully. But this spot is only the opening scene to what, with the Blue Mountains of New South Wales—of which I shall speak shortly—is, without doubt, the grandest scenery in Australia, and which is quite different in character from the New Zealand scenery. In fact, Fern-tree Gully is considered by most of the Melbourne tourists to be old-fashioned, and other places, with more magnificent views and more easily reached, now command the attention of sightseers generally.

The most celebrated of these is the country lying between Melbourne and Wood's Point—the latter, a mining locality, in the centre of a very mountainous district. Starting from Melbourne by train, and proceeding about twenty-five miles through some picturesque suburbs and an undulating country beyond, Lilydale is reached. Here the tourist must take the coach, or, if he be fond of a few miles of stiff walking, may "tramp," *viâ* Healesville and Fernshawe, to Marysville. At Marysville, the Stevenson Falls are the show of the district. At all these places are country houses of accommodation, at which the living is good and the charges moderate. The landlords of the inns—or, as they are called, "hotels" (in Australia every place at which beer or spirits are sold is dubbed by its proprietor "hotel")—or any of the residents of the neighbourhood willingly point out subjects of interest to the traveller who is hungering and thirsting after them.

Among the scenes on this road may be mentioned the justly-celebrated "Black Spur." The scenery here is in its character unsurpassed by any in the colony—from the smallest fern tree gulleys to extensive forests of the desert growth. We can boast of some of the notorious "big trees of Victoria," which can hold their own against their world-famed brothers in California. The whole country is overflowing with grandeur. Some of the trees mentioned above are forty feet in circumference and fully four hundred feet in height. To give some idea of the timber hereabouts, it may be mentioned that one fallen tree near Healesville measured 480 feet. Another giant of the forest which had fallen across a stream running into the Watts River, and thus forming a ready-made bridge, was 435 feet from its base to the other end. The original length of the tree could not be ascertained, as its top had been consumed by a bush fire; but even at this distance from the roots it still boasted a *diameter* of three feet. It is, therefore, probable that the height of the tree when standing was about 500 feet. Sunbury, twenty-three miles from Melbourne, contains some charming "bits," situate on Jackson's creek. The landscapist may leave Melbourne by the train at midday and return the same evening with his three double-backs full of pictures, all obtained within two miles of the local railway station.

If the tourist wish to go further afield, no place will repay him more for the trouble he takes to reach it than the seaside township of Lorne, or, as it was called until recently, "Loutit Bay." The train is taken through Geelong to Winchelsea, whence Lorne is reached by coach in about seven hours from Melbourne over a rather rough road, but at the same time nothing to frighten the traveller. Here are good hotels, with all modern comforts, electric bells, gas, and other joys of civilisation, including a photographer, who reaps a fair harvest in the holiday season, the town—or rather village—being crowded. But the show of the place, so far as the picturesque is concerned, is the scene on the Erskine River, adjacent to the town. The "Erskine Fall" is one which is worth travelling almost any distance to see. The river drops over a shelf, and then, diversified by a series of breaks, reaches the basin of the stream below amid a perfect bower of ferns and other plants, the whole forming as picturesque a study for the camera as can well be imagined, its peculiar wild and romantic solemnity defying language to describe it. The only regret of the photographer who has any art feeling is that he cannot convey to others through the medium of the sensitive plate (that is, with the present power and knowledge which we possess) any but the very slightest idea of the beauty of the scene which is before him.

Another fall on this river is named the "Phantom," from the fact that, in spite of its existence having been reported by an old resident in the district, all attempts to find it again proved unavailing until three or four years ago. In addition to these there are minor points of interest all worthy of the photographer's attention, the scenery all over the district being of the wildest mountain character, and the vegetation most prolific. Daylesford—about eighty miles from Melbourne, and reached by railway—also offers ground for the tourist, who may add to rough country scenery the extra attraction of a few views of gold-mining machinery, &c.

The Australian Alps, though somewhat difficult to reach—that is to say, the road is a long and somewhat roundabout one, although good enough—amply compensate the traveller for the fatigue of the rail and coach journey. Here mountain succeeds mountain like lumps of sugar in a basin, the whole country being of the wildest nature; and, to those who look upon Australia as a land of cloudless skies all the year round, it may seem strange when they are told that it is no uncommon thing for teams of horses and waggons to be stuck for days in the snow whilst crossing these ranges.

In the northern and western districts of the colony there are also plenty of good views to be obtained. As regards the sister colony of New South Wales, the landscapist has but to sight Port Jackson (the celebrated harbour of Sydney) and he will begin immediately to wonder whether his stock of plates is sufficient to secure all the beauties he sees around him at a single glance. However, he need not feel distressed at this, as the principal makes of gelatine plates are to be obtained in both Sydney and Melbourne at London prices.

Judging from his letters, Mr. Pringle has not visited New South Wales at all. This is to be regretted, for pressed for time as he must have been he would have found a fortnight in New South Wales well spent, and the journey from Melbourne to Sydney, although taking two or three days by water, formerly occupied only twenty-four hours by rail; but since he was here the time has been reduced to eighteen hours.

As has been before mentioned, the beautiful scenery of Port Jackson and the Paramatta River will attract the first attention; then there are the Blue Mountains and the Hawkesbury River.

The Blue Mountains' scenery is as wonderful as any to be seen on the Australian continent. The mountains are reached by rail from Sydney, and to the foot of them the distance is about forty miles from the city. The ascent is made on a zigzag, and by this means an elevation of 613 feet is gained in a distance of three miles. This is sometimes called the "Little Zigzag," to distinguish it from the one by which we descend the mountains on the other side. They extend between fifty and sixty miles, and every three or four miles there is a station or platform. Within a mile or two of each of these stopping-places is situated some pretty or grand spot, the sight of which will well repay the tourist for his work in reaching it. Waterfalls—both grand and picturesque—mighty chasms and fearful precipices, rocks, and mountains meet the traveller at every turn.

The Wentworth Falls, situated at the head of an immense valley encircled for miles with lofty hills thickly covered with timber, form the first grand sight met with on the mountains. The fall of the main cataract is roughly estimated at 1,000 feet, and, as it has only a very small stream to feed it (not a Niagara by any means), the water, as a rule, breaks into spray long before it reaches the foot of the glen. About a hundred yards above this is situate a smaller fall, which is named the "Weeping Rock." It is a rock forming the bed of the stream, and stretches out, overhanging somewhat in the form of a fan, the water falling in a number of small streamlets like an artificial fountain. These falls are only two miles from the railway station, and are reached by a good country road.

About four miles further on the line is the town of Kootoomba, where there is another large fall and some smaller ones, as well as various other points, and a view of the same extensive valley which we have at the Wentworth Falls. Next we pass Blackheath Platform, which is only a mile and a-half from Govett's Leap, one of the greatest natural wonders of the world. The rent or depression is said by many (how true the statement may be must be left for each witness to judge for himself) to be the deepest chasm with perpendicular cliffs in the known world. It is almost surrounded with these cliffs. The sublimity and majestic grandeur of this scene is not realised at once. The trees in the valley below, although 100 or 200 feet high, are not recognisable in their individuality. The scenery is full of grandeur, and, to add to its beauty, two streams are precipitated into the abyss. They are changed into mist long before they reach the bottom. The depth of the principal, or Govett's Fall, to where the water first strikes the rock is 520 feet, and to the basin at the foot of the rocks immediately below, 600 feet. Standing at the basin, the cliffs forming an end to what is known as the "Horseshoe Bend" on each side rise to a height of 700 feet. The depth to the bottom of the valley, at the junction of the three falls, is 2,000 feet; and the precipices of a smaller nature round about in some cases exceed 1,000 feet.

The next station is Mount Victoria, seventy-seven miles from Sydney, and 3,422 feet above the sea level. Here are good hotels, and abundance of the same sort of scenery as that previously described. About eleven miles further on we pass through the Clarence Tunnel. The rails here are 3,658 feet above the sea level, which is the greatest altitude reached by the railway. So rough was the country at this part that the surveyors who laid out the line had to be lowered down the cliffs by ropes, and the contractor was obliged to commence the work of construction in a similar manner. The tunnel is 539 yards long; and at a further distance of two miles the descent of the mountains is commenced in a somewhat similar manner to that in which we ascended them, but on a much grander scale.

The Great Zigzag is a series of inclines made along the side of the mountain, several tunnels and viaducts being passed. The gradient for the whole distance is one in forty-two, and the distance is five miles, the line in some places traversing the brink of a precipice. The writer knows a lady who, on descending the Zigzag for the first time, fainted on looking out of the carriage window. These five miles of railway are said to have cost half-a-million sterling to construct, the whole of the lines being on the English gauge of four feet eight and a-half inches.

About a mile beyond the foot of the Zigzag is the thriving town of Lithgow, which is supported by its coal and iron mines and ironworks. At Lithgow the Blue Mountains scenery ends. The train pursues its way into the interior through the town of Bathurst, and so on towards the River Darling, to a point on which the line is in course of construction. The line is already open to a distance of over 400 miles from Sydney.

The scenery on the Hawkesbury River has been compared by many to that on the Rhine; some have, indeed, said that it excels the Rhine. Anthony Trollope has written of it in very glowing terms, and says that it surpasses both the Rhine and Mississippi. It is easy of access from Sydney. Conveyances leave in the afternoon for the mouth of the river, and next evening the tourist is landed in the city again, having had a comfortable lodging at the hotel, ascended the river to the town of Windsor, and returned by rail. The whole trip costs £2 5s—not an extravagant sum, as it includes all hotel expenses, &c.

There are various other places of interest: the Southern or Illdwarra district, and the famous Fish River Caves, which bid for the premier position against the celebrated caves of California. They are reached by conveyance from Mount Victoria.

Of course, it is impossible in a short article of this sort to give a fully-detailed account of the various places of interest in both colonies; but I think I have made it tolerably clear that the continent of Australia should not be overlooked by any traveller—be he photographer or otherwise—who wishes to make a tour "round the world."

I may mention that in the event of other photographers visiting Melbourne, any of the members of the Amateur Photographic Association of Victoria will be happy to assist them in whatever way they can, as far as obtaining views and learning the run of the country is concerned. The address of the Association is Royal Society's Hall, Melbourne; and any communication sent to the above address will be at once attended to by J. H. Harvey,

Hon. Secretary.

Changing Optical Lantern Slides with the Feet.

William Henry Duncan, Coalbrookdale, Shropshire, Engineer.

My invention has for its object changing the views, working the gas cock, and turning the limes of dissolving-view lanterns by pedals moved by the feet of the operator, so as to leave the hands and eyes free to use a book or a written lecture.

In carrying out my invention I employ two or more pedals, which are so connected to the lime cylinders, the gas cock, and to the arrangement carrying the sets of pictures that the light can be raised and lowered and the pictures fed into the lantern by pressing down the foot pedals. In my dissolving-view apparatus the views or slides to be exhibited are carried by four or more movable racks, two generally being placed on each side of the lantern. These racks are moved along guides, which keep them in the same planes as the openings in the sides of the lantern tubes intended to receive the views. One pair of the set of racks is moved forward at a time. The distance of this travel is equal to the distance from one view to another in the rack. After the rack movement has brought a picture in position opposite to a groove, fixed in line with the opening in the side of the lantern tube, a rod brought against the edge of the picture pushes it out of the rack into the groove, and at subsequent movements of the pedals other pictures are pushed out of the rack and follow each other in the conducting groove which guides them into the lantern.

After the lantern has shown the pictures on the screen the continued passing of other pictures into the groove causes those which have been exhibited to be pushed into the receiving rack on the opposite side. This rack has the same forward movement as the other, and brings an empty division in proper position to receive the slides at the time required, so that racks filled with pictures are placed on one side of the lantern. Each picture is in rotation passed through the optical systems, and after being shown on the screen is passed into a rack on the opposite side. In this manner the lanterns are served with picture slides. The lime cylinders are turned, and also raised slightly, so as to present a fresh surface continually to the flame of the combined gases at each change of the picture.

The working of the gas cock, whereby the pictures are dissolved, is done at the proper moments by the action of the apparatus, and the whole of the movements required to produce these results are given by pedals worked by the feet, or by levers worked by the knees or hands of the operator; but by preference by pedals worked by the feet, either direct or by electricity. For moving the picture racks I employ levers which act on ratchet wheels keyed on shafts fitted with toothed pinions, which latter work in toothed racks placed below the pictures. The pitch of these toothed racks is the same as the distance from picture to picture in the carrying racks, so that the set of pictures is moved forward this distance each time the catcher wheel is turned forward one tooth. By these means the pictures are moved forward through the exact space required, and at the right moments, by the action of the foot pedals. For turning the limes I use a ratchet wheel, fixed on a shaft, projecting outwards from the back of the lantern. This wheel is turned by a lever in connection with a foot pedal. For working the gas cock I use levers and a rod, which carry the motion of the pedal up the back of the lantern to the cock and turn it at the moments required. The picture pushing-rod is operated by levers and rods in connection with the pedal in the forward direction, and is drawn backward by a spring. The arrangements I have described may be used with three lanterns placed one over the other, but by preference I use them in connection with two lanterns only. The order of the various motions is as follows:—Left pedal, on commencing to descend, turns down gases from the bottom lantern and turns gases on to the middle lantern, draws back the catcher, and also lowers the ratchet lever of lime-turning arrangement during the first half of travel. Bottom lantern being now dark the next half of downward travel changes its picture. First part of pedal's return stroke draws back the picture pushing-rod, remaining part acts on catcher-wheel, moves the set of pictures forward ready for the next change; also lifts the rod for turning dissolving-cock into proper position for next dissolving with the other rod at the next change, and also turns the lime. To prevent mistake by the operator not pressing down the pedals alternately a locking device is applied, which consists of a weighted lever oscillating between the two pedals and worked by declines on the bottom portion of the lever.

What I claim is:—First, the apparatus for changing the picture slides of a dissolving-view or magic lantern by pedals moved by the feet, or by levers moved by the knees or hands of the operator; second, the apparatus for raising and lowering the light by pedals; third, the locking device for the pedals.

[Certain drawings accompanied the complete specification which it is unnecessary here to reproduce.]

Improvements in Portable Photographic Cameras.

Frederick William Hart, 8 and 9, Kingsland Green, London, Manufacturer of Scientific Apparatus.

I first construct the front framework of the camera in square or other rectangular form, such framework having a revolving flanged disc of the greatest diameter the framework will permit. Such disc has an opening through it half its width below the centre to near the circumference, the width being of such dimension as will permit the lens tube to be centrally placed and moved freely along the opening to near the circumference. On this revolving disc I place a slide diametrically over the opening, and of such length and width as will well cover the opening when the centre of the slide is brought over the opening near the circumference; on this slide the lens is to be mounted. I fix the disc and slide in any desired position by means of screws or cam clamps with my improved folding disc heads to such screws or cam clamps.

The construction:—On the shank is a disc of metal, and across the diameter is hinged a half disc of like thickness, which when raised enables the screws, cams, or racks and pinions to be actuated. When folded down the whole does not project from the body of the camera more than one-eighth of an inch, thus permitting close packing, whereas the screw heads at present in use project half- to three-quarters of an inch, thus preventing compact packing. The back framework and the flexible extending body is constructed as usual, with the exception that I employ my folding disc heads to all clamping screws and pinion heads. The advantage in using the said disc heads will now be seen in my main improvements to obtain extended range for lenses of long focus. I shut the body, as above described, up quite close, together with one or more dark slides or a magazine plate-holder included, and form around them a casing, embracing the top, front, bottom, and back, three of these rectangles being hinged and the fourth angle secured by lock, bolts or hooks. This, my improved base-board, when unfolded is made rigid by triangular bolts of metal—steel or bronze preferred—sliding in groves in opposition to the hinges, means being provided by the enclosing plate for taking up wear so as to ensure continuance of the utmost rigidity. The camera-body frames slide to and fro on this base-board, being kept parallel by side guides in the ordinary manner. On the top face of the base-board I employ two short lengths of rack, when weight is of moment, say one-sixth of the length of the base-board, the solid base of which is V or half-V on the sides, with corresponding counterparts for them to slide in the base-board. The end of each portion of rack has a spring detent pin to fix them at any part of the base-board corresponding to the focus of the lens in use at the time. Where weight is not an object the metal rack may be fixed the entire length and cut at the joints for folding.

By these recited improvements I obtain greater range for focussing than hitherto—economy of space, rigidity, and a square body throughout—thus making the camera available for lenses of short focus, including an angle of 90° to 100° of subject on the plate, as well as narrow-angle lenses of long focus for extreme distant objects. As an illustration of improvements effected: the latest tourists' cameras exhibited (say half-plate) have a range of focussing power of twelve to sixteen inches: whereas, with my recited improvements as set forth in this specification, I obtain twenty-four to twenty-six inches of focussing power, giving thereby greater facility for the production of artistic photographs from nature, also for copying.

The inventor claims:—1st. The employment of the slides for carrying the nuts.—2nd. The locking by adjustable triangular bolts on the opposite side to the hinges.—3rd. The employment of the side of the base-board on which the bolts are as the top working surface.—4th. The base-board forming a casing entirely round the camera body, with the addition of dark slides or magazine plate-holder, if desired, by which he obtains the maximum of length without the introduction of weak-extending slides as hitherto used.—5th. The cam wedge and stirrip combined, with or without screw action for clamping the parts.—6th. The folding disc head to screws, cams, and pinion spindles or axes, by the use of which much less space is occupied in the packing of photographic cameras.

[Certain drawings accompanied the complete specification, which it is unnecessary here to give.]

Exhibition.

PHOTOGRAPHIC SOCIETY OF IRELAND.

[Second Notice.]

Regarding the exhibits of portraits, Messrs. Lafayette show well to the front with three frames of large direct pictures, a few of which appear rather theatrical or over-studied in the pose, but all showing great manipulative skill and finish. The same firm have also hung several frames containing numerous cabinet-sized portraits, which are the best collection of small work in the room.

Messrs. Chancellor and Son, also of Dublin, exhibit numerous works of great merit, amongst which we have no difficulty in selecting *Il Penseroso* (No. 213) as the best, and worthy of study by all interested in this class of work; and *Fancy Ball Costumes* (No. 492), by the same firm, are exceedingly excellent.

Messrs. Robinson and Sons, of Dublin, besides the enlargement (No. 82) already noted, show several groups with their respective enlargements in carbon, but their small frame of three heads on opal, *The Sisters* (No. 454), seems to be the most superior opal plate in the room. Indeed, in the matter of this class of work, we consider there is great room for improvement, as several of the finest at first sight—notably Nos. 253 and 31—have been so much retouched with brush work as to remove them from this class of photographs pure and simple.

Mr. H. S. Mendelssohn has forwarded a charming collection of groups, which, by their unconventionality of pose and artistic treatment, are amongst the very best work in the room, and we have no hesitation in selecting Nos. 20 and 97 as being gems of their kind.

In *genre* pictures we must not omit to draw attention to *The Seven Ages of Man* (No. 136), already exhibited, and which secures a great deal of real admiration both for the results obtained and for the patience and skill which have been exercised in completing such an ambitious task. We are at a loss, however, to understand how the picture illustrating one of the ages in no way shows "the beard of formal cut," which the poet states to be one of its peculiarities.

Close to the above hangs one of the smallest of its class in the room, by C. Wyrall, and entitled *Peg in the Ring* (No. 124). It is a charming picture, having no appearance of being a made-up subject, but simply an instantaneous photograph of some boys at top-pegging. If this be so Mr. Wyrall is to be congratulated at having hit his subjects when so artistically posed. A similar picture (604) in the small room is also worthy of attention.

Mother's Love (No. 117), by J. Hubbard, whose death we regret to hear of since his pictures were hung, is a truly realistic picture of admirable composition. The same lamented artist is also represented by Nos. 12, 110, 255, 455, and 525, which are mostly all of the same character. A pretty frame of fishing boats (No. 131), by Mr. F. M. Sutcliffe, attracts and pleases; but we question the good taste of the title under the second print.

Mr. A. G. Tagliaferro exhibits a large number of interiors, all of excellent quality except for some converging lines; but still we think the medal for the best interior must go to him, or to *A Mansion in the Olden Time* (No. 494), by Mr. E. Brightman. The *Interiors* (No. 316) exhibited by the Platinotype Company are marvels of delicacy, although not quite such difficult subjects. Indeed, every praise must be accorded to the exhibits of the Platinotype Company, who, in Nos. 299 and 363, show some splendid heads, a large portion of the credit of course being due to the artist, Mr. Valentine Blanchard, from whose negative they are taken; but we cannot fail to admire the peculiar excellence that is the speciality of their process, which there is ample scope for studying in the large collection of exhibits shown either by the Company or those who are working this method of printing.

Mr. Herbert B. Berkeley, who is so intimately connected with the Platinotype Company, exhibits in his own name one of the gems of the room—a small landscape with cattle, entitled *Noon* (No. 528)—which might be overlooked, as it is not particularly well placed. Nos. 383, 430, 644, and 645 by the same gentleman are also well worthy of notice, and we have much pleasure in drawing attention to them.

The Exhibition is greatly indebted to the Autotype Company, who have hung a very large number of frames, each one of which deserves special praise. Their *Copies of Oil Paintings* (No. 193), *Dieu le Veult* (No. 197), *Come Unto These Yellow Sands* (No. 181), and *Israel in Egypt*—this latter hung too high for convenient inspection—are all marvels of good work, as are their large *Portrait of Cardinal Newman* (No. 182), *A Frame of Fans* (No. 16), and *Derwentwater* (No. 112), noticed in our last number. Mr. W. Maitland's *Sorrow on the Sea* (No. 210) and numerous others, not omitting some studies of heads in red chalk and copies of Turner's *Liber Studiorum* (Nos. 562 and 563) all show by their varied excellence that the work of the Autotype Company is as diversified in its style and character as the originals to be reproduced. For alone placing before the general public and art students true *facsimiles* of the drawings and studies from the celebrated art collections of the world the Company should receive all credit, and, we trust, more substantial reward; for, if these copies were more generally to be found in our local art schools all could learn and profit by them, and their influence become more widespread than is possible while the originals remain locked up in the Louvre, the Vatican, or in Dresden—treasures of art only visited by relatively the favoured few.

We append the list of medal awards:—

Large landscape.	227.	*Grasmere.*	Silver medal.	J. A. Greene.
,, ,,	76.	*Pas de Roland.*	Bronze ,,	Geo. Mansfield.
Small ,,	186.	*Alpine Views.*	Silver ,,	Professor Donkin.
,, ,,	528.	*Noontide.*	Bronze ,,	Herbert B. Berkeley, Platinotype.
Instantaneous.	14.	*Yachts.*	Silver ,,	G. West and Son.
,,	446.	*Shields Harbour.*	Bronze ,,	T. M. Auty.
Interior.	494.	*Olden Mansion.*	Silver ,,	E. Brightman.
,,	541.	*Church of St. John of Jerusalem, Malta.*	Bronze ,,	A. G. Tagliaferro.
Large portraits.	213.	*It Penseroso.*	Silver ,,	J. Chancellor.
,,	203.	*Large Portraits*	Bronze ,,	J. Lafayette.
Small portraits.	239.	*Cabinet Portraits.*	Silver ,,	J. Lafayette.
,,	271.	*Cabinet Portraits.*	Bronze ,,	J. Robinson and Sons.
Opals.	454.	*The Three Sisters.*	Bronze ,,	J. Robinson and Sons.
Genre picture.	450.	*Reading to Granny.*	Silver ,,	W. Gillard, Platinotype.
,,	128.	*Peg in the Ring.*	Bronze ,,	C. Wyrall.
Enlargement.	210.	*Sorrow on the Sea.*	Silver ,,	Autotype Company.
,,	82.	*Portrait.*	Bronze ,,	J. Robinson and Sons.
Transparencies.	715.	..	Bronze ,,	P. H. Fincham.
Mechanical print.	—	"*Ein Autodafé.*"	Bronze ,,	Rud. Schuster.
Animals.	108.	..	Bronze ,,	J. J. Dixon.
Microphotographs.	731.	..	Bronze ,,	Dr. R. A. Hayes.
Apparatus.	—	Improved Camera.	Bronze ,,	J. V. Robinson, Dublin.

All the above medals were awarded by the ballot votes of the members of the Photographic Society of Ireland.

Special bronze medals were awarded to Mr. E. Skeen, Ceylon, for a collection of tropical views; Mr. Geo. Renwick, for *Frost Studies* (No. 152); and Mr. H. S. Mendelssohn, for a group (No. 97).

The special prize, given by the Amateur Photographic Society for the best untouched picture by an amateur, has been awarded to Mr. George Mansfield, a member of the Photographic Society of Ireland, for *A View at Sauveterre* (No. 71).

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

At the monthly technical meeting of this Society, held on the 23rd inst., the chair was occupied by Mr. T. Sebastian Davis.

Mr. Francis Cobb showed a plate covered with fog, which was the result he obtained when using the soda developer.

The Chairman had found that with plates of his own making he could not develope with soda as the only alkali; but upon the addition of a small quantity of ammonia the image came out well.

Mr. Edwin Cocking handed round a plate developed with a mixture of soda potash and sulphite, without ammonia or restrainer. He considered the formula a very good one.

Mr. L. Warnerke found that, when using potash instead of ammonia, the restraining effect of bromide was very great.

Mr. A. Cowan agreed with this remark, and added that $\frac{1}{32}$ of a grain of bromide to the ounce of developer was too much to use when employing potash as the alkali.

Mr. Cobb remarked that when using potash, and not finding it to act with sufficient energy he had added soda to the mixture, the film had slipped from the plate.

In answer to inquiries,

Mr. Warnerke said that he was quite satisfied with the potash developer. There was less loosening of the film and less green fog than with soda. He used no restrainer unless he wanted extreme density, as in copying engravings, and then he added a few drops of a ten-per-cent. solution of bromide to the developer. The formula he employed was as follows:—

Carbonate of potash	45	grains.
Sulphite of soda	12	,,
Water	1,000	,,
Pyro.	12	grains.
Sulphite of soda	24	,,
Citric acid	2	,,
Water	1,000	,,

Mix equal parts for use.

The CHAIRMAN inquired whether any further experiments had been made with the new developer, hydroxylamine.

Mr. ARNOLD SPILLER said that since the last meeting he had found it to be advantageous to add a small proportion of alcohol to the developer. This addition lessened the liability to those little pits or spots which were formed in soft gelatine when developing with hydroxylamine; as not only was the gelatine less soluble when alcohol was present, but the gas evolved (nitrous oxide) was more soluble in an alcoholic solution than in a merely watery one.

A question was then read as to the best method of preparing hydroxylamine.

Mr. SPILLER replied that he employed the plan with nitric ether and tin. With regard to frilling when using the hydroxylamine developer, different makes of plates acted very differently; of three kinds that he had tried one frilled and two did not.

Mr. W. M. ASHMAN suggested that Mr. Spiller should give complete details of the mode of preparation of hydroxylamine in the Society's journal, and this Mr. Spiller undertook to do.

Upon being asked what advantage he found the new developer to possess over those previously in use,

Mr. SPILLER said that the image came up quite free from any stain or deposit, and that there was the same latitude in exposure as with pyro. The solution, moreover, did not change, but remained unoxidised.

The CHAIRMAN thought these advantages were very great, and that it was a thing happening very rarely that a new developing agent was discovered.

Mr. HOPKINS then showed a camera back with dark slide, similar to the one which had been shown at the late Exhibition of the Society, with this difference—that the focussing glass did not now require to be removed from the camera, but the putting in of the light-proof back shutter acted upon levers which drew the screen behind the plate to be exposed.

Mr. J. R. GOTZ showed a series of lenses by Suter, of Basle. The characteristics of them were—that the A series had, he believed, a larger aperture than any other aplanatic doublet lenses had been made with, and consequently were very rapid. The B series were somewhat slower and covered a larger field, and the C, or wide angle, included a still wider angle. They were all fitted with stops and screws according to the Society's standards, and were so arranged that several lenses would fit the same flange.

Mr. W. BEDFORD thought it would also be desirable that the equivalent focus of each lens should be indicated on the mount.

Mr. WARNERKE considered this suggestion a very important one. With regard to the choice of lenses of the A or B series: he would like to know, if they were both stopped down to the same rapidity, which lens possessed the flatter field and gave the better picture.

Mr. GOTZ believed that the B lens would have the flatter field.

The CHAIRMAN, in proposing a vote of thanks to Mr. Gotz, said that it was satisfactory to find the Society's standards adopted by lens makers.

The next technical meeting was announced for the 23rd of December, when the Chairman proposed to bring a lantern fitted with Sugg's large burner, and throw an image with it upon the screen, to illustrate the usefulness of such a convenient arrangement as the application of ordinary gas to lantern purposes.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society, held on the 20th inst., the chair was occupied by Mr. F. W. Hart.

Mr. C. H. TRINKS was introduced to the meeting by Mr. Henderson as a gentleman who had had considerable experience in photo-engraving processes, and he (Mr. Trinks) observed that the method which he ha principally followed, and which had given him the best results, was that of Mr. Fox Talbot. There was a curious action upon a sensitive surface, on which he would like to hear the views of the members. If a sensitive surface were left between the leaves of a printed book there would be found to be an impression of the letters upon it. How was that explained?

Mr. A. L. HENDERSON said that it might arise from either of two causes. The paper might act as a phosphorescent surface or the ink as a protecting one to the plate, the paper where not inked allowing the air with what impurities it might contain to have access to the sensitive surface.

The CHAIRMAN and other members thought the latter explanation more probably correct than the phosphorescence one.

A discussion then took place as to the best means of preventing the action upon gelatino-bromide, which had been stated to ensue from the nature of the material in which plates were packed, and it was suggested that the grooving of plate-boxes should be soaked in melted paraffine.

Mr. A. COWAN had kept plates in boxes with pine grooving for a period of more than two years without any injury arising therefrom.

Mr. HENDERSON thought that, as thymol had no injurious effect upon emulsion, the vapour from turpentine might be expected to be similarly innocuous. He had found, however, that when a large quantity of thymol was added to emulsion there was a mottling upon the surface of the plate.

Mr. W. E. DEBENHAM suggested that this mottling might be due to the alcohol in which the thymol had been dissolved. Mottling was characteristic of emulsion containing a large proportion of alcohol.

Mr. A. MACKIE had formerly used camphor in emulsion to preserve it. There appeared to be some chemical action, as the smell of the camphor was changed.

Mr. HENDERSON had found camphor to produce fog.

MR. MACKIE had not observed this.

A MEMBER inquired whether alcohol or any other ingredients used in forming a gelatino-citro-chloride emulsion could be traced as the cause of the gelatine being coagulated—a thing he had been troubled with.

Mr. DEBENHAM said that citrate of potash would do it if not added in the proper manner.

The CHAIRMAN remarked that bichloride of mercury was an exceedingly powerful antiseptic, so small a proportion as one in a hundred thousand being sufficient to preserve a solution. It was possible that such a minute trace would not be injurious in an emulsion.

Mr. TRINKS had found wood spirit to succeed well as an antiseptic.

Messrs. G. A. Davenport and Godefroi V. J. Porrin were elected members of the Association.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

THE first general meeting of the session was held in the Religious Institution Rooms, 177, Buchanan-street, on Thursday, the 13th inst.

The chair was occupied by Councillor ROBERTSON, who in a few remarks congratulated the meeting on such a large attendance.

The minutes of the last meeting were read by Mr. George Bell, interim Secretary, and approved of.

The first business on the list was to appoint a Secretary in room of Mr. J. Craig Annan, who has retired. Mr. GOODALL proposed Mr. Lennox, which was seconded by Mr. BELL, and unanimously agreed to.

Owing to Mr. J. Y. McLellan's departure to Russia a vacancy was made in the Council, and on the motion of Mr. BELL, seconded by Mr. Wm. LANG, Jun., Mr. Patrick Falconer was appointed to fill the vacancy.

Mr. LANG kindly offered to present members of the Association with a view of Cadzow Forest, taken at the last outdoor meeting. The offer was accepted, and a cordial vote of thanks was given to Mr. Lang for his kind offer.

Mr. FALCONER proposed that there be a discussion at the next meeting on the best medium for the dark room, which was agreed to.

The question-box contained nothing of interest.

The CHAIRMAN then called on the Treasurer, Mr. Geo. Bell, to read his annual report, which is as follows:—

TREASURER'S REPORT—SESSION 1883-84.

DR.	£	s.	d.	CR.	£	s.	d.
To Balance from last year	£15	15	3	By Secretary's Expenses	£5	2	0½
,, Members Subscriptions	22	15	0	,, Printing Account	5	14	0
,, *Conversazione* per Statement	17	15	6	,, Rent of Rooms	9	1	6
				,, Geo. Mason & Co.'s Account	2	5	0
				,, *Conversazione* Expenses	22	0	3
				,, Mr. McCall for Lantern Exhibition	1	1	0
				,, Davidson's (Gilder's) Acct.	0	13	0
				,, Treasurer's Expenses	0	6	0
				,, Mr. Paterson's Collecting Account	1	5	6
				,, Carriage of Goods	0	6	10
				,, *Citizen* Advertisement Account	0	6	6
					£48	2	4½
				,, Balance in Treasurer's hands	8	3	4½
	£56	5	9		£56	5	9

Glasgow, 13th November, 1884.

We have examined the foregoing entries of charges and discharges and found them duly vouched and correct, the balance in Treasurer's hands being £8 3s. 4½d.

(Signed), ANDREW MACTEAR, JOHN PARKER, } AUDITORS.

A vote of thanks to the Chairman brought the meeting to a close.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

THE ordinary meeting of the above Society was held in the College of Physical Science, Newcastle, on Tuesday, the 18th instant.,—Mr. J. B. Payne in the chair. The minutes of the previous meeting having been confirmed,

The CHAIRMAN said he thought they might congratulate themselves on the result of the exhibition they had held during the past week. The number of exhibitors might have been larger, but the quality of the work he considered very good. He then presented the medal, given by Mr. Borrow for the best set of three pictures taken by a member at the outdoor meetings, to Mr. J. P. Gibson, of Hexham, and the prize (a very handsome album partially filled with views), given by Mr. J. P. Gibson for the best set of two pictures taken by a member who had not previously received a medal or deploma, to Mr. Edgar Goold.

Votes of thanks were duly passed to the judges (Mr. Laws responding) and to the hanging committee.

The presentation picture for the year was announced by the scrutineers to be one by Mr. Edgar Goold, *Bywell*, No. 18 in catalogue, this picture having received the largest number of votes.

Mr. LAWS announced that Mr. Garland had promised a second medal for the transparency competition.

Mr. J. PIKE read an extract from the *Photographic Times*, which he thought might be of use to some of the members, viz.:—"Negatives showing a turbidness on parts of the plates, after removal from the alum bath, may be cleared by treating them with sulphide (?) of soda solution or weak sulphurous acid. The turbidness is caused by a separation of sulphur in the alum bath, the sulphur being retained in the film." He (Mr. Pike) said he had frequently been troubled with such a deposit on the negative, but it was always removable with a pledget of cotton wool.

The CHAIRMAN said that he had been informed recently that benzole, containing a small proportion of resin, had the effect of removing green fog.

Doubts were expressed as to the part played by the resin in this matter.

Mr. PAE remarked that he had found benzole by itself answer the purpose. He also suggested the use of benzole for reducing the density of negatives, locally or otherwise.

A question was found in the box:—"With some plates the leather (hinge) of the dark slide gives an *opaque* marking, and with others a *transparent* one; how can this be accounted for?"

Several members had experienced trouble with their dark slides, the plates of some makers being apparently more easily affected than others.

Mr. DODDS remarked that a trace of ammonia in the leather might account for the opaque marking.

The CHAIRMAN said that he had found common writing ink painted over the leather a complete cure.

Mr. PIKE had recently been working with argentic-bromide paper, and, as a consequence of manipulating large sizes of paper in a very small room, had been troubled with an occasional marking or stain of a very disagreeable colour, with metallic lustre. He had always discarded a print when marked in this way, but had found that the marking was removed by a solution of hydrochloric acid—one part of acid to twenty-five parts of water. He suggested the use of this acid in preference to sulphuric as a clearing solution.

Professor HERSCHEL said that he had also found hydrochloric acid a much superior clearing agent to the acid recommended by the makers.

Mr. JOSEPH GRAY, of Newcastle, showed some transparencies taken on chloride plates of his own make. They were developed with the ordinary pyro. and ammonia developer, and were of a very pleasing tone. He said that any of the various developers in use—sulphite of soda, washing soda, &c., &c.—were applicable, and gave a variety of tones. The transparencies shown were favourably criticised.

Mr. PIKE called attention to the very fine character of the image, and said that the emulsion had apparently been carefully filtered. Some commercial chloride plates looked as if this operation had been omitted.

A paper on and demonstration of the platinotype process was promised by Mr. H. G. Templeton, of Gateshead, for the December meeting.

NORTH STAFFORDSHIRE AMATEUR PHOTOGRAPHIC SOCIETY.

THE annual meeting of the above Society was held at the Mechanics Institute, Hanley, on Wednesday, the 19th instant,—Mr. Charles Alfieri, President, occupying the chair.

Captain West-Jones, Major Harrison, aud Mr. T. G. Keeling were elected members.

It was resolved to permanently lease a suitable laboratory in the Potteries for the Society's use.

As only photographs 8 × 6 had been sent in from two sources for selection as presentation prints, the Secretary was instructed to endeavour to procure some of a larger size for the same purpose.

It was also resolved that albums and note-books on the models of the Postal Photographic Society should be circulated among the members of the Society, who, in many instances, live some miles apart.

The financial report of the Treasurer showed a very satisfactory balance of funds in hand. The annual report of the Council was read and unanimously adopted:—

ANNUAL REPORT.

The Council, in presenting the annual report of the North Staffordshire Amateur Photographic Society, for the year 1884, congratulate the members on having passed another year of the Society's existence—a year which, although not so productive of results in outdoor work as might have been expected from the exceptionally fine summer with which we have been favoured, has still not been barren of results so far as photography is concerned.

We keep apace with the times, even our veterans having for once and for all laid aside collodion, with its baths and dippers. The artistic platinotype, and, to a large extent, the argentic-bromide paper process find favour among us, while carbon has still some votaries, the users of albumenised paper being in a minority.

Taking, first, the monthly meetings, we have not, as a rule, been favoured by the attendance of so many of our members as we would desire; but, as they live farther apart than is the case with societies in less subdivided districts, we cannot expect a large attendance when the weather proves unfavourable. Some of our meetings have been very well attended, and we are glad to see that our members are interested in any paper or demonstration announced, and arrive in force on those occasions.

The following papers have been read, and demonstrations given:—*On Enlarging upon Argentic-Bromide Paper*, by Mr. Charles Alfieri. *Lantern Slide Making upon Gelatine Plates*, by Mr. Charles Alfieri. *Artistic Composition and Pictorial Effect*, by Mr. Charles Alfieri. *Platinotype Process*, by Mr. W. B. Allison. *Printing by Artificial Light and Transparencies on Collodio-Bromide*, by Mr. W. B. Allison. *The Carbon Process*, by Mr. W. B. Allison.

The following articles of apparatus have been exhibited:—Kirkby's instantaneous shutter, and "Eclipse" shutter, from Mr. J. J. Atkinson.—Reynolds and Branson's "Phœnix" shutter, by Mr. M. Burgess.—Camera, lenses, and stands, from Mr. C. E. Elliott, London, all of which were much admired by members.—Three instantaneous shutters, and a dark slide for four plates, made by members.—A changing box for twelve plates, with camera, made by an amateur gentleman.

Outdoor meetings, as usual, were advertised monthly. Only two came off—one to Barlaston, the other into Derbyshire, and even these were but poorly attended. The gentlemen, however, who went had the satisfaction of bringing home several gems of pictorial beauty. We have been unfortunate in the weather on two occasions when excursions were arranged, and in the other instances several of our members were simultaneously absent from home. Thus, a combination of unlucky circumstances has prevented us as a Society from taking advantage of our late beautiful summer. Still, we must hope for better fortune next season.

Our Association, as originally started, was composed of photographers both amateur and professional. However, for various reasons it was, at the June meeting, after mature consideration, resolved that in future only those gentlemen or ladies who practice photography as amateurs be admitted into membership. The subsequent election as members of many well-known gentlemen of county notoriety and local influence has given to the Society a good social status; so that as the amateur practice of our art becomes more and more extended we shall doubtless have the pleasure of enumerating on our list the names of many ladies as well as gentlemen.

The meeting was then adjourned.

BIRKENHEAD PHOTOGRAPHIC ASSOCIATION.

THE preliminary meeting of the above Society was held on Thursday, the 20th instant, at Berry's Grand Restaurant, Argyle-street, Birkenhead,—Mr. John H. Day in the chair.

The undermentioned gentlemen were elected to conduct the business of the Association for the ensuing session:—*President:* Mr. J. A. Forrest.—*Vice-President:* Mr. H. N. Atkins.—*Treasurer:* Mr. J. Maurice Jones.—*Council:* Messrs. A. W. Beer, A. W. Cornish, R. W. Hill, T. Cragg James, E. Newall, and P. H. Phillips.—*Hon. Secretary:* John H. Day, 19, Milton-road, Birkenhead.

Thanks are due to Mr. Richard Hartley and Mr. C. Berry—the former of whom placed his studio in Market-street, and the latter a room in his establishment in Argyle-street, at the disposal of the members for the purpose of holding their monthly meetings, &c.

The competitive element having proved a beneficial stimulus to the production of good work in kindred societies periodical competitions were decided upon, the result of which it was proposed should be duly reported in the newspapers. It was also determined, should the funds of the Society permit, to present each subscriber annually with an enlargement, if possible, from some selected negative, the production of a member of the Association.

Arrangements are in progress for a miscellaneous concert, to conclude with a lantern exhibition, to be held on Thursday evening, the 18th of December, in connection with the above Society, on which occasion a number of original and interesting photographic pictures, the work of amateurs and others, will be thrown upon the screen.

Correspondence.

PHILADELPHIA CORRESPONDENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

THE Science Congress and the Electrical Exhibition have been held in this city, and no lecture or paper upon photography has been given at either. The Science Congress was attended by many members of the British Association, who came on by special train from Montreal for that purpose. The great assistance that photography renders to modern scientific research should have been recognised at least, if no more.

The Electrical Exhibition has been a great success in every way. The exhibition building, which is situated on the west side of the city, has been crowded every night; but whether half or quarter of the people who flocked there cared anything for electrical science is a question. It was the thing to go, and thousands went. I suppose there was very little there that you did not see in the London exhibition, and there were many exhibits which had but a remote relation to electricity. For instance: there was an artificial hatching machine, where chickens were being produced by the score, which was continually surrounded by an admiring crowd; but the only thing I could see about it connected with electricity was an instrument for registering the temperature, called the "telethermometer." This instrument was shown in other parts of the building in connection with refrigerators and store closets for fruit, meat, &c. The expansion or contraction of the mercury acts upon an arm with a pencil at one end, the point of which touches upon a sheet of paper, which is being unrolled from a roller at a stated speed. The paper is ruled horizontally for the hours and vertically for the temperature, so that the variations of temperature are registered, and also the time of the variations. This same instrument is made to give an alarm on board ship upon the approach to icebergs. When nearing icebergs the temperature of the water for a considerable distance is much lower than the normal temperature of the ocean. When the mercury in the telethermometer falls below a certain point (when hung over the side of the ship) a bell is rung by electricity in the captain's cabin or any other part of the ship to which the wire may be taken.

The exhibits connected with photography were few. Mr. W. Curtis Taylor, of 1328, Chesnut-street, had an electric light studio for taking portraits and made a large number of portraits nightly. Mr. Taylor claims to be the first photographer in this city who has used the electric light for portraiture, and shows one taken nearly fifteen years ago; but it has not been done commercially. Mr. Curtis Taylor is the only remaining partner of the well-known firm of Taylor, Wenderoth, and Brown, whose studio was situated at 914, Chesnut-street for so many years, and whose reputation was world wide. Mr. Wenderoth was well known to English readers as a most indefatigable experimentalist. He died early this year, but he had been out of the firm for some years working at his easel as an artist. Mr. Brown also left the firm, and is still working at his easel as a miniature painter, having a studio in Chesnut-street. Mr. Taylor has but lately opened his new studio at No. 1328, and has secured the sole right to photograph in the exhibition building. His studio was most simple. He says his idea was to produce a light as near as possible like his skylight in Chesnut-street. He was very much confined in space, and only exposures were made at the exhibition building, the development, printing, &c., being done in Chesnut-street. The studio was lighted by two Brush lights of 2000 candle power each, about nine feet from the floor, one being placed directly over the head of the sitter, the other about eight feet in front of it, in a direct line with it. Thus the source of light was all at the top, but below the lights and above the head of the sitter was a screen of semi-transparent paper. It is called here "onion-skin paper," and is a kind of tissue paper. This was made translucent by a coating of silicate of soda. This screen sloped towards the side of the studio but did not touch, thus leaving the side to be illuminated by the direct light from the lamp, which, being reflected, gave the side light. Mr. Taylor was very successful, the modelling in many of his negatives being exceedingly soft and delicate; but all had a very unpleasant stare in the eyes, which had to be modified in touching the prints. Vanderweyde, of London, and Kurtz, of New York, had fine exhibits of their electric light portraiture, and Mr. T. H. McCollin, of Arch-street, Philadelphia, had a fine show of enlargements made by the same light, these last being platinum prints.

The leader in the Journal upon the use of sulphite of soda has attracted considerable attention. All the journals here have reproduced it (as they do almost everthing, for there is very little of original matter in American photographic journals as a rule). It has explained the great discrepancy in the experience of many good workers who have advocated or condemned its use in the development of dry plates. I think on this side it has been used more universally and in larger quantities than in England. Take Carbutt's last formula, for instance, which stands thus:—

No. 1.

Water	10 ounces.
Citric acid	60 grains.
Crystallised sulphite of soda	2 ounces.
Pyrogallic acid	1 ounce.
Water to make up	16 ounces.

No. 2.

Water	10 ounces.
Citric acid	60 grains.
Crystallised sulphite of soda	2 ounces.
Carbonate of potash	4 ,,
Water to make up	16 ,,

His directions are for portraits on his special plates to take three-quarters to one drachm of No. 1, and from half to three-quarters of No. 2 to each ounce of water used in developing. You will note the very large proportion of sulphite of soda in this formula. It becomes a very serious item in the success or failure of those using this formula, and there should be no uncertainty as to its condition when used. In my own experience with this salt I have been most unfortunate and abandoned its use many years ago; and, in spite of the many new developers, all of which are claimed to be improvements, still develope with ammonia pyro., the formula of which I published in England some years back. All the American plates I have used here have succeeded better in my hands with ammonia than with the formulæ published by the makers of them. It may be that having had considerably more experience with the ammonia developer than any other it is only natural that I should succeed better with it. I have seen many fine negatives developed according to Carbutt's formula and other formulæ, but I have yet to see in them qualities I could not get with ammonia.

My next communication will be from the sunny south, having accepted an appointment as chief of the photographic staff of the Centennial Photographic Company at the World's Industrial and Cotton Centennial Exposition, New Orleans. This exposition is going to be one of the biggest things ever seen in this country of big things. The photographic exhibit is in the hands of a committee appointed at the Cincinnatti Convention, the chairman of which is Mr. E. L. Wilson, editor and proprietor of the *Philadelphia Photographer*, and the director-general and board of management of the exposition have made him chief and superintendent of the photographic department—a position of much responsibility and of more honour than profit. Should any English photographers wish to exhibit they could make arrangements to send together, prepaid, through Messrs. Atkinson, or other stock house, directed to Mr. Edward L. Wilson, Exposition Buildings, New Orleans, La., U.S.A. I have his authority for saying they will be received and placed to the best advantage. The space for the photographic exhibit is on the gallery of the main building—a position where light and space is everything that can be desired; and I should like to see some of the best English photographs placed in competition with those of their American cousins.

Philadelphia, U.S.A., October 9, 1884.

HYDROKINONE.

To the Editors.

Gentlemen,—Experimenting again today I have obtained as good, if not even better, results by a more simple formula than that given in my letter of last week, namely:—

Saturated solution of carbonate of potass	1 ounce.
Solution of hydrokinone (of a solution of 8 grains to the ounce of water).	2 drachms,
Water, as required	3 to 5 ounces.

Pour this on the plate and leave it on for one or two minutes. *Then*, pouring it off the plate into the developing glass, add—

Saturated solution of oxalic acid	10 minims.

Re-apply to the negative, when the image will almost directly begin to appear, and continue slowly to strengthen, resulting in a good, clean negative.

Now for a remark. Mixing the oxalic acid with the other chemicals before pouring them over the plate appears to stop the development, but on adding twenty minims of *liquor potassæ* (B. P., sp. gr. 1058) the plate then comes out as stated before. Why is this? Is development due to a process of reaction?

In this latter case the plate sometimes becomes spotty and iridescent when viewed by reflected light, but this does not show by transmitted light, except the spots on the unexposed edge that has lain on the flange of the dark slide. However, if the oxalic acid be used as directed above there is no such appearance at any time.—I am, yours, &c.,

Greenhithe, Kent, November 21, 1884. W. T. F. M. Ingall.

NORTHAMPTON MUSEUM PHOTOGRAPHIC EXHIBITION, 1884-5.

To the Editors.

Gentlemen,—May I call the attention of those of your readers who intend exhibiting at our forthcoming exhibition to the fact that the last day fixed for receiving exhibits is December 1st.

To prevent the possibility of any pictures being shut out cases should be sent in at once.—I am, yours, &c., R. Manfield, *Hon. Sec.*

Northampton, November 25, 1884.

LANTERN EVENINGS AT THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

To the Editors.

Gentlemen,—As the letters of Mr. G. Smith and Mr. W. Brooks in your last issue are bound to be seriously considered by the Council of the Photographic Society of Great Britain, I would suggest at the same time—or at anyrate between now and next season—that the whole question of lantern exhibitions should be gone into. The Society, to justify its title, should certainly be representative in all its transactions, and take care that what it essays to do should at least be as well performed as the average of undertakings of a similar nature.

On the evenings I looked in to see the transparencies shown it was pretty freely remarked that there was considerable room for improvement as regards uniformity of mounting the slides, and especially in the description of them or method of announcing the titles.

I have not the pleasure of knowing the gentleman who undertook the latter duty, and who probably is a most useful member of the Society; but one could not expect him to be able to describe subjects which he probably saw for the first time when placed on the screen. Some little previous arrangement would be an improvement, and the names of the slides should be called out in a voice that will reach to the far end of the room. Where money is received for admissions, for the credit of the Society it is necessary to give as much *entertainment* as possible.—I am, yours, &c.,

London, November 21, 1884. One of the Public.

THE RECENT ROYAL ARMS CASE.

To the Editors.

Gentlemen,—A few weeks ago I suggested by letter to you a subscription among the profession to reimburse Mr. William Turner his expenses in the law suit against Messrs. A. and G. Taylor. Has anything been done in the matter? If not, are you prepared to be treasurer of the fund?

The desire to recoup Mr. Turner is general, but it is absolutely necessary to appoint some responsible person to receive subscriptions. In the event of you having an objection to undertake this office, rather than the affair should drop through I will undertake to receive moneys and acknowledge the same (with your permission) in the Journal.

I suggest 2s. to 5s. as the amount to subscribe.—I am, yours, &c.,

12, *Clapham-road, S.W., November* 26, 1884. Geo. J. Tear.

[We should prefer to stand neutral in this matter, but publish Mr. Tear's letter in order that any intending subscribers to the proposed fund may know where to forward their contribution.—Eds.]

Notes and Queries.

A. B. says:—"What is the reason that, although the lens of the eye throws an inverted image on the retinal screen, we see objects right end uppermost and not upside down?"

"I have been much interested in your remarks upon the extraordinary conduct of the National Gallery officials. I should like to know with regard to the points raised why it is necessary to take paintings down and to remove glasses for photographing?—J. Thompson."——Our correspondent's question would require too lengthy a reply for these columns, but we may say that the subject will shortly be treated by us in a leading article. Meanwhile we may inform him that it is entirely a question of light and convenience. Neither one removal nor the other need be looked upon as an essential necessity, though in practice they may become necessary.

J. A. T. wishes to know how to make paper translucent by other methods than waxing.——In reply: Coat unsized white paper with a mixture of equal parts of Canada balsam and oil of turpentine, then hang up to dry. If more transparency be desired, take the dried paper and repeat the treatment. Another plan is to treat the paper with a mixture of equal parts of nut oil and oil of turpentine, then to rub the surface immediately with wheaten flour; next hang up for twenty-four hours to dry. The first method gives the whitest tracing paper, the latter the more flexible. After being washed with ox-gall and dried these papers may be written upon with ink.

"I HAVE bought a second-hand pair of hand-scales, but though they are quite new-looking, well made, free from rust, and, apparently, in perfect order (except that the little ornamental rod which should project above the middle of the beam was filed off by me, as it was bent), I cannot get them to weigh accurately. They don't seem to work well. Can you suggest the cause, or remedy?—INQUIRER."——Yes. The cause is the loss of the "ornament" you describe, which is not an ornament at all in the strict sense of the word. Its absence interferes with the equilibrium of the balance, altering the position of the centre of gravity, and so the scale is liable to topple over and not to recover itself properly. The scale will not work well until this pointer is replaced.

"WITH regard to the making of chloride of gold, as dwelt uponby you last week, I should be glad if you would tell me do you think there is much economy in a photographer making his own chloride?—R. TWISS."——In reply: A very simple calculation would have enabled you to discover for yourself as to there being any economy or not. If you purchase a fifteen-grain tube of chloride of gold you will usually find upon it a guarantee that the tube contains seven and a-half grains of metallic gold. In other words, you pay for gold made up as chloride at the rate of (say as an average) two shillings for every seven and a-half grains of metallic gold. There being four hundred and eighty grains in an ounce troy, it is evident that for an ounce of gold converted into chloride we pay

$$\frac{480}{7\frac{1}{2}} = 64 \times 2/\text{-} = £68\text{s. } 0\text{d.}$$

If from that we subtract £4 5s. 0d. (the actual value of the ounce of gold), we find a loss of £1 3s. 0d. per £4 5s. 0d., or about twenty-seven per cent.

"MY Bunsen burner does not act properly. I light it, see it goes all right, and watch it for a minute or two; but almost always when I leave it for a while the light goes out, or, rather, runs down and burns inside with a useless, smoky, disagreeable-smelling flame. Can I do anything to it, or shall I have to obtain a fresh one?—W. HITCHIN."——In reply: There is no need to purchase another, though it is possible you may not have the best form of burner. The running down of the flame is caused by an excess of air supply, a means of regulating which is to be found attached in the best form of Bunsen. Notice whether at the base of the instrument there be not a metal ring perforated with holes fitted to it. If there be, you have only to turn it slightly till the outer holes are not precisely opposite those in the base, and by this means you will check the egress of air to any extent you wish. Should there be no loose ring you need only slightly plug up the holes which you will find pierced in the base. We have performed this satisfactorily by breaking a wooden match into two pieces and placing them in two opposite apertures.

INQUIRER is perplexed by the conflicting testimony of skilled photographers as to the utility of sulphite of soda in the developer.——Much of these varied opinions would disappear if pure recrystallised sulphite of soda were bought in the first instance, and care then taken to give it the right degree of acidity before adding the pyrogallol to make the stock solution. A sample of sulphite of soda which looks dead white and chalky, and not in clear, bright crystals, is bad. When the salt is good, very little acid need be added to it to give it sufficient reaction before the addition of the pyrogallol; but there should be sufficient acid to give a decided reaction with litmus paper. Sulphurous acid is good for the purpose; but citric acid will do when the sulphite of soda is pure, because so little acid is then required. If much have to be added to neutralise an improper degree of alkalinity, sufficient nitrate of soda will be formed to act sensibly as a retarding agent. The method of applying the developer to the plate may have an influence. If the acid pyrogallol be applied first, and the other ingredients subsequently, the plate receives a preliminary wash of weak free acid, which probably promotes the formation of a clear negative. At all events, we have found the plan to work admirably.

Exchange Column.

*** We are compelled to leave over several Exchanges till next week.

Wanted, a biunial lantern in exchange for a 54-inch Victor bicycle; write for particulars and photograph.—Address, J. K. TOWNSEND, Kimberley, Nottingham.

I will exchange a whole-plate bellows-body camera and lens, Ross's wide-angle doublet with drop shutter, circular diaphragms, sun shade, and whole-plate plate box, all complete and in good condition, for a tricycle in good order.—Address, JAMES ROBB, 209, Dalmarnock-road, Glasgow.

I will exchange a half-plate camera and lens, with three double backs, by Lancaster, whole-plate view lens, by Grubb, and a three-wick enlarging lantern, by Hughes, all in perfect condition, for a whole-plate camera, of modern construction and by a good maker, with two or more double backs.—Address, J. MAHONEY, St. Michael's street, Malton.

I will exchange a Lancaster's improved *méritoire* camera and lens, quarter-plate, with four double backs, complete in case; also gem camera and four lenses, to take twelve on quarter-plate, all in first-class condition, for good half-plate wide-angle lens, balustrade, posing chair, or anything useful in photography. — Address, J. BOWLER, Jun., Oxford-street, Oakengates, Salop.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPHS REGISTERED.—

William Arthur Skill, 58, Bailgate, Lincoln.—*Photograph of S.S. W. Tower, Earl's Barton Church, Northant.*

ASBESTOS.—We believe the light is not yet fully in th market. When it is due notice will appear.

PYROTECHNIC.—We are sorry we have not the gentlemen's present address, or would gladly forward a letter for you.

BEGINNER.—There must be some mistake; the price of ferrous oxalate is not as many pence as you name shillings.

RAVEN.—Perhaps the best lens for your purpose would be the No. 4, or for very wide angle No. 3 of the same type as the slower one you now have.

W. F.—We shall probably have something to say on the subject in a week or two. At present, especially situated as you are, we would advise you to adhere to the old method.

W. W. EVERS.—1. We cannot refer you to any particular number of the Journal, but if you will state more definitely what you require we will do our best to help you.—2. Bigelow's *Album*—an American publication—is, we believe, out of print.

FIDUS.—The best mountant for the purpose is a thin—say ten to fifteen grains to the ounce—solution of gelatine applied warm to both glass and print, the squeegee being used in the ordinary manner.

W. G.—We cannot at present devote an article to the subject, but may refer you to past volumes of the *Almanac* and to the forthcoming one for such information as can be given without personal instruction. The pencils may be obtained from any dealer in photographic material.

NOVICE.—If you apply to any dealer in lanterns and lantern appliances you will be able to obtain such a work as you require. To ask us to give in this column "particulars as to the making and use of oxygen and hydrogen gas, and any suggestion as to the best form of apparatus jets," is too much.

C. W.—A good solution for the purpose consists of a mixture of nitrate of copper and nitrate of silver. The metal should be heated before application, and the solution re-applied until the desired colour is gained. Bichloride of platinum will also answer. You failed probably in not using heat.

E. W. R.—1. Increase the proportion of soap dissolved; the application in the dry state is no use.—2. Pretty hot, but not hot enough to injure the prints; merely warming is no use.—3. The weaker the toning bath the slower but more regular the action. The weaker the fixing the slower the action and the less the effect in lowering the tone.

GAS LIGHT.—It is more a matter of taste and convenience combined. If, after all that has been written in the past few months on the subject, you cannot make your own selection, we can only say that we still adhere to a ruby, or "ruby on orange" glass of not too pronounced a shade, while there are many who prefer Mr. W. E. Debenham's combination of green and yellow. The choice rests with yourself.

J. M.—1. The mixture should be kept at boiling temperature for a few minutes.—2. The proportions of silver to be converted and of carbonate of ammonia employed for the purpose should bear the same relation to one another as the combining equivalents of the respective salts, bearing in mind that the ammonium salt requires a double atom of the silver salt. Thus, 96 grains of $(NH_4)_2\ CO_3$ if it be pure well combine with 340 grains of $Ag\ NO_3$.—3. We do not know that there is any special "formulæ;" the silicate of potash should be diluted to a convenient strength.—4. You do not state what class of lens—whether portrait or landscape. The larger the stop employed with a single landscape lens the smaller the field it will cover sharply. Thus, your whole-plate lens may be made practically to work more rapidly for quarter-plate than for full size, but it will not bear the use of too large an aperture without entire loss of definition. If you work it with a stop not exceeding one-tenth of the focal length you will not find any cause for complaint.

RECEIVED.—Sands and Hunter; A. Rivot and Co.; J. L. Robinson; &c. In our next.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, December 3rd, the subject for discussion will be—*On Outdoor Photography.* There will also be an exhibition of photographs taken by the members during the past summer. Annual dinner on December 10th, 1884.

MARION'S ALPHA PRINTING PAPER.—We understand that a demonstration of the working of Marion's alpha printing paper will be given at Soho-square next week. This paper is introduced as a substitute for albumenised paper, and offers the advantage of rapid printing—one and a-half to four seconds in daylight and thirty seconds in gaslight.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—The annual meeting of the above Society will take place on Thursday next, the 4th December, at eight o'clock, at the House of the Society of Arts. Several important matters in connection with the welfare of the Society will be discussed, and the election of officers for the ensuing year will take place. Intending competitors for the artistic competition are reminded that their pictures must be delivered between the 1st and 4th December.

No. 1283. Vol. XXXI.—DECEMBER 5, 1884.

COLLODION EMULSION FOR TRANSPARENCIES.

Since we wrote on this subject a fortnight ago we have received several communications suggesting that we have not supplied a sufficiently definite method of working to enable any operator, hitherto inexperienced in dry collodion work, to take up the process we recommend. It had not been in our mind at the time we wrote to descant upon the general subject of collodion emulsion, but rather to confine our remarks, as we did, to the question of tone. We had for the moment lost sight of the fact that a very large number of amateurs of the present day have taken to photography since the days when collodion emulsion ceased to be a pretty regular topic in these columns, and are, therefore, perhaps, wholly ignorant of the details of the process. We may, consequently, be allowed to glance back briefly to the subject, which a few years ago was tolerably well threshed out in all its phases.

One correspondent refers us back to a formula given by Mr. G. F. Williams in 1879, of which we have spoken favourably on more than one occasion. With this he complains he has not succeeded to his satisfaction for transparency work—a complaint we can quite easily understand. The fact is that that formula was intended for rapid negative work, for which purpose it is perhaps as good a one as can be found; but, unfortunately, the requirements of rapid negative and of transparency work are not the same, and the conditions in the two cases are scarcely compatible. Besides this, it will be gathered from our article a fortnight since that an unwashed emulsion is preferable to a washed one for the purpose, if for no other reason than that it admits more readily of the use of an organifier. If the latter be added directly to the emulsion—as is necessary in the case of a washed emulsion—the organifier exerts an influence far from beneficial upon the constituents of the emulsion itself, chiefly on the pyroxyline, with the consequence that the longer the preparation is kept the more inferior is the quality of the film produced from it.

To this we may add the circumstance that, unless the conditions be of the most favourable, and the utmost care be exercised, the character of the film produced by a washed emulsion is not for transparency purposes equal to an unwashed one. It is not that there is any granularity or texture which makes itself apparent, nor is there any difficulty in making clean pictures; but the operation of washing the emulsion seems to take something out of it which deprives it of its power of giving depth, transparency, and colour in the shadows. If an emulsion be divided into parts before washing—the one used as recommended in our last article, the other "washed" and organified with the same solution as that employed with the first half—it will be found that a great difference exists in the quality of the images given by the two. The washed emulsion, though perfectly suitable for negative work, will be found to give a less "juicy" image (to use a term that has been applied for the purpose of conveying the same meaning) than the other, though probably in other respects there will be little difference between them.

Therefore we recommend decidedly, for transparency purposes, an unwashed emulsion. The preparation of the plates may be a more troublesome operation than it is with the washed preparation, which only entails the trouble of coating and drying, but the extra trouble will be fully compensated for by the greater beauty of the results. At the same time we do not mean to infer that washed emulsion is unfit for the purpose; quite the contrary. The fine examples of lantern transparencies by Mr. William Brooks, so familiar to visitors to the South London and Parent Societies, are, we believe, all produced from washed emulsion, and we have in our possession at the present time some emulsion prepared by Mr. Brooks quite two or three years ago, which yields results that it would be difficult to beat by any process. Still, however well the washed emulsion may work, we think the unwashed will work equally well with less trouble.

Another question which exercises the minds of one or two of our correspondents is as to the advisability of using a thick or a thin layer of emulsion—an opaque or a transparent film, as one puts it. This question may be considered, however, apart from the question of mere opacity, for that quality may arise from want of transparency in the layer of bromide or from the piling up of a great thickness of transparent material. Besides this, much depends upon the capability of the film to give density under development. Some of the thinnest and most transparent films in dry plates (and, for that matter, in wet plates also) have been found to be capable of yielding the densest of negatives Look back, for instance, at the old "Hill Norris" plates, and, later again, Major Russell's ordinary "tannin" plates. These, though extremely thin and transparent, yielded negatives in which the highest lights could be made absolutely opaque. On the other hand, it is possible to make an emulsion which shall give films presenting a very dense and opaque appearance before exposure, which possess in all the qualities that combine to make "body" and which yet give but the merest *shadow* of an image on development.

Thus, though transparency and "juiciness" in the shadows are the objects to be aimed at in transparency production, these qualities are dependent on other conditions than the mere thickening or thinning of the film; and we propose, in response to several requests, to give in the course of two or three articles working instructions by which anyone may successfully work the collodion emulsion process and obtain results which, if they do not surpass albumen plates in quality, will come very near them, and, at the same time, leave them far behind in the matter of convenience.

PERMANENCE OF THE GOLD-TONED COLLODION IMAGE.

It will be remembered that, a few weeks back, we devoted an article to the subject of the fading of the collodion image. In that article we alluded to the chances there were of the fading of collodion transfer pictures, more particularly when they were made by the method then described, and by which on one occasion we actually saw them produced. This method, at the time, we were assured was the one universally practised in some establishments. The reason assigned for this plan being followed was that of a great saving of time, and, also, what was of equal importance, namely, that better tones were more easily secured.

As a further example of the fading of the collodion image reference was made to the evanescent character of the once beautiful photo-crayon portraits—a style of picture introduced by the late Mr. Oliver Sarony some fifteen years or so back. So extremely fugitive did some of these pictures prove that we have heard in one case at least of an exposure of a few days only in an outside show-case being sufficient to cause their total destruction. These pictures, it need scarcely be mentioned, were toned with mercury. From this, and many other examples of their fading we could mention, it must not be assumed that *all* pictures toned with mercury will, of necessity, fade, or that all photo-crayon portraits must necessarily be fugitive; for such is not the case, as we have stated on several previous occasions.

Since writing the article to which allusion has just been made we have had an opportunity of seeing a series of half-a-dozen or so of these "photo-crayons," which were made at the time this style of enlargement was first introduced, and we must say that they are beyond question as perfect and free from all signs of deterioration as they could have been the day they were produced. The pictures are rich in tone, bold, and vigorous; and as they were in the frames —although one knew the fact—it was difficult to conceive that the image was on glass, and that the picture was not a veritable crayon drawing on paper. The gentleman who gave us the opportunity of seeing these specimens assured us that during the two years following the introduction of this particular style of enlargement he produced between one and two hundred of these pictures, and he had not been able to trace a single instance of fading or deterioration.

Now, as many are aware, the idea has got abroad that one of the principal reasons why the photo-crayon portrait had such a brief run in public favour was its alleged fugitiveness. Therefore we, very naturally, were anxious to learn the method by which these particular examples were produced. When this was ascertained we could at once see why they had stood this long test of time, and also that pictures made as these were should be theoretically amongst the most permanent photographs it is possible to produce. As the subject may be of interest to our readers we shall, with our friend's permission, here describe the method employed in their production.

The collodion used was one giving a good body, and contained about one grain per ounce more bromide than is usually employed in ordinary collodion for the wet process. The silver bath was of the usual strength of thirty grains to the ounce. It was rendered slightly acid with nitric acid, but no more of this was added than was necessary to yield absolutely clear glass in the lights. The plate was allowed to remain in the sensitising bath for a much longer period than was customary in the wet collodion process, in order to ensure the more perfect conversion of the bromide. On removal from the bath the film had a dense and creamy appearance. After draining somewhat closely the plate was then ready for the camera, and a very full exposure indeed was always given. The image was then developed with a solution of pyrogallic acid, restrained both with acetic and citric acids, and just sufficient alcohol added to cause it to flow easily over the film.

As a very full exposure was always given the image flashed out quickly after the developer was applied, the half-tones and high lights following the appearance of the shadows in rapid succession. Hence the whole of the detail was brought out before the image had time to acquire any actual density. The plate was then well washed under the tap, afterwards fixed in a very dilute solution of cyanide of potassium, and again very thoroughly washed. When the image was examined at this stage it possessed to the uninitiated, we are told, a very unpromising appearance. By transmitted light it was thin and feeble. By reflected light, when backed with a piece of white paper, the lights appeared somewhat over-exposed, and the shadows seemed little better than a buried brown mass, lacking much in detail.

The picture was now toned. This was a very simple operation, and only occupied a minute or two. A solution of chloride of gold—about two grains to the ounce of water—was poured over the plate, and after being on for a few seconds was drained off and again poured on, the effect produced by each application being carefully watched from the back of the plate. As soon as the gold had penetrated the deepest shadows, known by a change in their colour, the plate was once more thoroughly washed and then allowed to dry. It was afterwards varnished with an ordinary hard negative varnish.

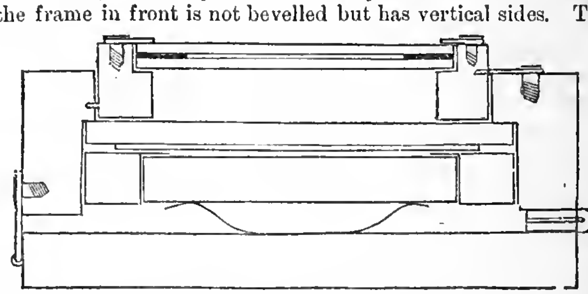
From the description of how these pictures were produced it will be seen that they should be—as undoubtedly they are, and time has proved it—as permanent as any photograph that it is possible to produce. The image is composed of metallic silver and gold—the latter metal, one of the most permanent known, predominating. The image is then hermetically sealed between the glass plate and an impervious varnish, which effectually protects it from all chances of atmospheric influence.

It will be noticed that at no stage of the operations is that alleged cause of the fugitiveness of most photographs—the hyposulphite of soda—employed at all; hence no sulphuretting action can possibly be produced. Nor is there, if the plate be washed with moderate care, any deleterious material whatever left in the film which might eventually act upon the image and lead to its destruction.

VIGNETTING.

In dealing recently [*ante* page 625] with the various methods of producing vignette effects, we proposed upon another occasion to describe a method of vignetting which we had seen practised with success, and which was especially contrived for carbon printing where, in small work at all events, a tinted margin is generally printed in, and for producing vignettes with tinted margins; in fact, for those cases in which a second printing is required that has to be in register with the first printing. This undertaking we proceed to fulfil.

The printing-frame itself is of the kind having a plate glass upon which the negative lies. It is somewhat larger than the negative itself, so as to allow for the adjustment of the latter to the opening in the vignetting form, as this form, unlike that described in our former article, is not capable of such adjustment. The inner edge of the frame in front is not bevelled but has vertical sides. These



vertical sides form a rim into which a second or vignetting-frame is dropped, secured at one end by two pins running into holes cut parallel with the glass of the printing-frame, and at the other end by a small brass button attached to the printing-frame and fitting into a groove cut in the vignetting-frame.

This upper or vignetting-frame is made of deal, and is about half-an-inch in thickness when used for small vignettes, such as the heads ordinarily printed of *carte* size. When intended for large heads or for cabinet portraits the frame is thicker—the additional thickness giving the gradation over a larger surface, which is required in such cases. On the upper surface of this frame a rabbet is cut as deep as two thicknesses of ordinary glass. Into this rabbet is dropped the vignetting form, which consists of two glasses enclosed in a sheet of opaque paper, with an opening cut on the same principle as the openings in the vignetting cards described in our former article—that is, with reference to a set of openings of definite sizes, each denoted by a certain number and letter. The glasses containing the cut paper are held together by paper binding round the edges, and the whole "form" is kept in place in the vignetting-frame by very small brass buttons.

For large heads, or when for any reason it is desired to make the vignetting very gradual, the effect is produced—in addition to the distance from the negative which the wooden frame gives—by using several thicknesses of translucent paper in place of the one thickness of opaque material, and cutting the openings in this translucent paper of sizes each a little larger than the next one. There is then, however, generally a thickness of opaque paper with the largest opening of all to preserve the whiteness of the margin. We have, however, as a variation, seen very pretty effects produced by using translucent paper only, the print in this case being strong in that part which constitutes what would otherwise be the whole picture, and the background and accessories looking as if faintly sketched in.

For printing tinted margins a set of "forms" is used, each consisting of an opaque paper enclosed, as the vignetting forms were, between two glasses, and numbered to correspond with them. Thus, if No. 18 W—signifying a vignetting form with an opening of two and a-quarter inches in length and of wide proportion—had been used in printing the vignette, a form with similar number would be employed when printing down the margin.

In order to secure the registration of the paper, or carbon tissue if that be in use, so that the margin and centre shall be printed in proper place with respect to each other, a light inner frame is employed This frame fits into the back of the pressure-frame, and its internal dimensions are only a little larger than those of the paper intended to be printed upon. This frame is put in after the negative and rests upon it. To this inner frame are hinged the flaps covered with cloth or felt, which press the paper into contact with the negative. The paper being placed close along one side and against the top of the inner frame, its position or registry is the same when the margin is being printed as when printing the picture itself in the centre. The hinged flaps are pressed against the paper by springs on a bar hinged to one side of the printing-frame itself, and fastened by a hook in the usual manner to the other side.

For carbon printing, in order to secure a white safe edge, a sheet of opaque paper is pasted over the front of the inner back frame and an opening of the requisite size cut in it. This is not required when using albumen paper, but in the establishment where we saw the whole arrangement at work it is preferred in both cases. The registration in this case is against slips of card attached to the paper mask instead of to the woodwork of the inner frame itself.

Vignetting is a device which may either add to or detract from the beauty of a photograph; and we believe that a serious consideration of the means to produce the best result and a systematic method of working cannot fail to be of advantage.

DIFFICULTIES IN COPYING OIL PAINTINGS.

The case of the Trafalgar-square monstrosity, which has recently excited so much acrid comment among photographers, has brought into strong prominence the troubles which surround the difficult task of copying oil paintings. Some of them are imaginary, but there remains a sufficiently large residuum to cause the successful production of a good copy to entail the expenditure of a considerable amount of trouble guided by skill, knowledge, and judgment. Let us follow in imagination a picture brought to the photographer's studio.

In the first case it will be encumbered with a heavy frame, which, if the picture be of large dimensions, will render the placing of the picture in a suitable position for photographing a matter of extreme difficulty; hence the removal of the canvas from the frame becomes most desirable, and may be undertaken without risk. If the picture be of moderate dimensions it may possibly have a protective sheet of glass in the manner now becoming so general. At one time engravings and pictures in water-colour and crayon, &c., were only so treated. Oil paintings were supposed not to require a glass, but modern experience proves that their surface is not a sufficient protection. The tendency of the observations made upon the Trafalgar-square case have all suggested the impossibility of photographing the oil painting without taking the glass out, but though we do not go so far as to say that such removal is no assistance, we do say that it is not necessary, and, further, that as good pictures may be obtained when the glass remains in front of the painting as when it is removed.

Two objections are urged against the presence of glass in front of an object to be copied: first, a doubled image through reflection from the two surfaces of the glass; and, secondly, the reflection of external objects. As a matter of fact this first-named reflection, with glass of ordinary thickness and near to the surface of the picture, and the camera not too close to the object, is entirely inappreciable, even in pictures of strong and sudden contrasts. We have before us a set of photographs from a number of crayon studies by Landseer, which were taken by a professional photographer, who makes no speciality of the work, for the purpose of being engraved in the *Art Journal;* yet, although he informs us they were copied through the glass, we fail upon the closest scrutiny to discover the slightest trace of the presence of any medium between picture and lens.

If such be the case with a picture where dark shadows and pure whites appear in the closest proximity, far less danger is to be apprehended when an oil painting is before the lens. Reflections from external objects, however, will stand upon another footing entirely, and will be far more likely to become impressed in the case of an oil painting than an engraving, sketch, or drawing in black and white, which, owing to the absence of varnish and the pure colours obtained through the avoidance of a resinous medium, are photographed so quickly that weakly-illuminated objects which the glass might reflect have not time to impress themselves. With the majority of oil paintings the exposure is so very long that objects so faintly illuminated as to be barely, if at all, visible upon ocular inspection will, if reflected by the glass that protects the picture, become photographed to the exclusion of faint details in the painting itself.

This, however, need not cause the condemnation of the glass, for though, as we have said, further trouble may be entailed thereby, it must be obvious that means may be adopted to obviate ill effects; and they are well worthy of being employed in such a case—for instance, as photographing the national pictures. The means are simple. They merely consist either in placing the picture in such a position that it only reflects neutral objects; or if, as would be the more likely state of things in the average studio, a suitable spot could not be found in placing dark screens in front of the painting, between it and the lens.

There are usually sufficient objects in a studio to enable this to be done—a curtain, movable background, black cloth, covered reflecting screen, or other means; but if there should not be, something would have to be found, for the simple reason—we are now coming to a fresh point—that if no glass existed to reflect objects an equal necessity would arise for screens. The picture itself would then reflect them, the only difference in the two reflections being that with glass the objects would be distinctly reflected, but with the varnished or glossy surface of the pictures the reflection would not only be indistinct, but would further spread to a greater degree on account of the surface being uneven and not, practically, plane like a piece of glass, patent plate being generally employed for the purpose.

Reflections may arise from many unthought-of causes. We have seen an apparently inexplicable stain on a plate traced to the reflection from the polished mahogany front of a camera of a portion of the picture itself that has been of an unusually bright character. Further: we have known instances where the face of the photographer, or even his shirt front, cuff, or pocket-handkerchief, as he stood cap in hand, have been reflected.

The simplest method of knowing what objects are out of the sphere of reflection is to stand in front of the lens and closely scrutinise the picture that is being copied, observing whether any glare appears to come from its surface. If there should be any such appearance it will come from some object that must be removed or covered. An imaginary line drawn from the outside of the picture through a point the width of the picture, right and left, from the lens will include all possible reflections; this the photographer can readily calculate himself. When the work is important, and many copies are made, dark cotton velvet curtains would be most convenient; they need not be large if placed in front of the camera with a narrow aperture for the lens, and they would not be costly.

We will return to the subject in our next issue, and treat of further practical difficulties that arise.

In a private letter received from our friend Mr. Frederick York, who is now in the States, we learn that he has already covered five thousand miles in his American wanderings, and has now reached Washington, where he will be engaged for some weeks in photographing what is noteworthy in the city and district. Every accommodation has been afforded to Mr. York in the photographic department at the Treasury, so that we may hope and expect to see some good things when he returns home. He has up to the present time 370 plates to develope. With the New Year he changes his quarters to New Orleans, where he will "do" the great southern exhibition.

SPEAKING on lantern matters, Mr. York says :—"The information published last year in your Journal respecting lantern slides here was misleading. I find that half-a-dollar is the price for plain photo.-slides, or forty-five dollars per hundred, and that regular piracy is not practised here. Things are sometimes copied to order to save delay in sending to England for other copies. There is a first-class manufacturer at Philadelphia who does a large trade, and his prices are about the same as ours in England. The only difference is that he has a sliding scale—8s. a dozen if twelve of a subject be taken, 12s. if six, and 15s. singly ; and his price varies with different subjects—*Yosemite Valley*, *Yellowstone Park*, &c., are more expensive than copies from engravings. I went all over his place, and he was very communicative."

MR. YORK was present at a recent optical lantern exhibition of the New York Society of Photographic Amateurs, and said that he had secured three hundred negatives of American scenery and other subjects of interest during his stay in that country.

A NEW association has just been started in Versailles, under the name of the Photographic Society of Versailles. Its president is M. Eugène Lefèbre, its secretary M. Druy, and its honorary president M. Davanne, President of the Council of Administration of the Photographic Society of France. The Versailles society will publish a journal, and its members intend, among other things, to do the useful work of photographing in general and in detail that grand monument of the pride and ambition of some of the French emperors, the palace at Versailles, also its park and museum.

AT a recent meeting of the Society of Photographic Amateurs of New York, Mr. Partridge described an easy way to convert an ordinary student-lamp into a lamp for developing purposes. He surrounded the light portion of the chimney with on ordinary ruby globe, obtained at small cost, and screened the bottom of the burner with a paste-board tube having a slit cut in to fit over the bent arm of the lamp. The chimney above the globe was protected by an ordinary ferrotype plate bent in the form of a tube, and on the top of the ferrotype tube were laid wires crosswise, on which rested a common small tin cake or biscuit-pan, which prevented the light from escaping upwards.

THE Franklin Institute of America contemplates the establishment of a School of Photography this winter.

IN Belgium there is but one photographic association, but it is in three sections—one at Brussels, one at Ghent, and the third at Liége. By this union of forces a better journal is brought out than could be done by three separate societies, each fighting on its own account. Mr. O. Campo is the new president of the Brussels section, Mr. G. De Vylder of the Ghent section, and Mr. L. De Koninck of the Liége section. The new secretary to the Brussels section is Mr. Lannoy. Mr. O. Campo, the president, is an Italian gentleman, who has long resided in Brussels, and has spent some portion of his life in India. At the first winter meeting of the Brussels section, Mr. L. Rommelaere pointed out the advantages which would result if a display of Belgian photographs were to be made, under the auspices of the Belgian Photographic Association, at the International Exhibition in Antwerp, in May next. It was resolved to consult the sections on the point, and the replies received will determine whether the Association will grant a subsidy to further the object.

THOSE who communicate with foreign journals should write proper names clearly. The *Bulletin* of the Belgian Photographic Association contains a letter from the Secretary to the Dublin Photographic Exhibition, signed "M. Greenwood Pins," also a letter from Mr. W. F. Donkin, of "Packham." Once upon a time a Parisian photographer who could not speak English interviewed an eminent man of science at his home in London. The photographer, on his return home, induced a Parisian journal to print that he had had the honour of consulting in London that "venerable" chemist "Croker Williams." Who from this French description would recognise a former editor of this Journal, Mr. William Crookes?

THE *Bulletin* of the Belgian Photographic Association is a journal of remarkably good quality, setting a good example to a portion of the other continental photographic periodicals. Its contents are intelligently selected, it is well illustrated, printed, and covered, and for years has every month printed a frontispiece illustrating the results of various methods of photo-printing for book illustration. Of late years it has confined itself to frontispieces by permanent processes. Those by Goupil et Cie., of Paris, are remarkably good

---

LIME water—that is, solution of lime in water—has been said to be the best of the many chemicals recommended for adding to solution of chloride of gold for the purpose of neutralising it for making a toning bath; but, whatever alkali or alkaline earth be added, it should always be remembered that the normal condition of pure chloride of gold is to be acid. If, therefore, the stock solution be rendered neutral to test paper, the gold in solution is not that salt of gold formerly known as "terchloride"—now more commonly termed "acid chloride"—but one possessing different qualities. It will, when so neutralised, become darker in colour, approaching a brownish-orange rather than yellow, and, what is of more importance in practice, it will not keep. It gradually decomposes and throws down metallic gold upon the sides of the bottle in which it is contained.

STILL, it is very desirable to neutralise before mixing with the acetate or other salt, as then a more definite formula can be arrived at. When unknown quantities of acid are present there cannot be uniformity in the composition of the toning bath. If lime water be used for this purpose we recommend that cold water be used in making it. Hot water dissolves less lime than cold, and it is stated that the quantity of lime dissolved is lessened by the presence of carbonate of lime. These are useful points to note; for, at the best, there is so small a quantity of lime held in solution that the amount of lime water necessary to be stored would be inconveniently great unless it were saturated.

WE should think there is scarcely a compound known which is put to so many uses as collodion. The latest we have heard of is for solidifying creosote for applying to decayed teeth, ten parts added to fifteen of the latter substance being said to combine into a plastic solid.

ANY photographer who may have had his stock of collodion rendered useless through the introduction of gelatine plates may find a pretty use for it during the winter season by converting it into balloons. We hasten to say not for outside use; we have no intention of endeavouring to rival our esteemed correspondent Mr. Shadbolt—toy balloons for ascending indoors, we mean. Collodion is superior to all other substances for this purpose, and with care and a little dexterity a small quantity of collodion will furnish a good-sized balloon. We have seen them from six inches to twenty-four inches in diameter. The mode of manufacture, which is simple, is as follows :—An ordinary glass flask—the shorter its neck the better—is carefully cleaned, rinsed out with distilled water, and perfectly dried. A quantity of collodion is then poured in and the flask turned round in all directions until it is evenly coated, when the residue can be poured out, taking care to have the inside of the neck also covered with the collodion. The flask is then placed neck downwards in a warm place till thoroughly dry; it will be well to give it two full days so as to ensure the absence of all moisture. All that remains is to withdraw this coating of collodion without breaking it—a rather delicate operation, but one that can be performed by not being over hasty and carefully humouring the film. When it is quite withdrawn it can be easily filled with gas from a gas bracket, and will then, from the lightness of the material, ascend in any room. The larger sizes are made in glass carboys, and form very effective objects.

THOSE of our readers who do not care to go to this trouble, and yet would like to have some means of an unusual kind for amusing their juvenile sitters, should make a solution for soap-bubbles, which can be inflated by hydrogen if preferred. With a properly-made solution it is quite easy to produce bubbles close upon a foot in diameter, which can without bursting be rolled along the floor, played with like a shuttlecock—using the arm as a bat; or they can be placed upon a table to be admired, and many a happy, natural pose obtained when every other means have been employed. A solution of oleic acid is better than soap with glycerine and water.

It is stated that if gum arabic be dissolved in water thrown down by strong spirit a precipitate will be obtained of great keeping powers which can readily be dissolved in water. Should this method prove to be practicable it ought to be useful, for, as is well known, gum arabic requires a long time for solution when the pieces as imported are employed; while if powdered gum be used, not to speak of the extra cost, some skill is needed to avoid the whole becoming a sticky mess difficult of solution.

When gum arabic is dissolved in the ordinary way hot water is generally employed to facilitate solution; but it is a mistake to do so, as the solution quickly turns sour. When the water is kept hot during the time the gum is becoming dissolved, no heat being used at any stage of the process, it will be found that the mucilage so formed will keep good for weeks.

Another method of preserving solution of gum has been suggested by Rother, who states that about two ounces of glycerine added to a pound of it will entirely prevent decomposition. This method is not likely to be of such use to photographers as that of Max Regensberg, which, if his recommendation be of proved success, would be a real boon. He says that four or five drops of silicate of soda for every ounce of paste, glue, or mucilage will prevent decomposition. The news seems almost too good to be true. We shall, however, give the plan a trial, when, if it possess any value, our readers will be apprised of the fact.

At a meeting of the Physical Society an interesting note was read by Mr. T. Glazebrook, M.A., F.R.S., upon the polarisation of light. He found that a film of moisture upon a plane of glass altered the angle at which the light became polarised. He also stated that blowing upon a clean plate of glass with moist air or with dry air altered the angle of the emergent polarised light, the former causing a deviation in a direction exactly contrary to that from the latter.

He also exhibited a spectro-photometer the exact details of which had been previously given by him to the Cambridge Philosophical Society. This or some similar instrument approaches what is needed to settle dark-room controversy, and put results upon a scientific basis. Given a ready means of measuring the intensity of light for each ray, it would be easy so to dull the intensities of any sets of rays as to make them uniform, and then test the chemical action. If such a result could be in practice worked out the results would be of great and lasting value.

THE CAMERA AS A METEOROLOGICAL INSTRUMENT.

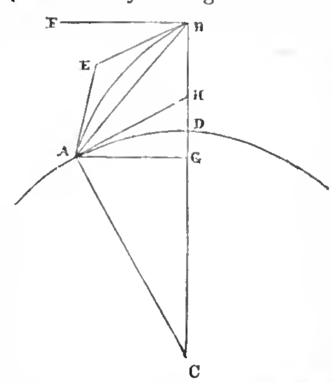
Meteorology is rapidly advancing towards the position of an exact science, and its future progress depends chiefly on the number of careful observations—not at a few isolated stations only, but at every available spot upon the earth's surface. Already a large number of private individuals have equipped themselves with the usual meteorological instruments, and are keeping accurate accounts of the temperature, pressure, and moisture of the atmosphere. Nor is it necessary here to enlarge upon the importance to the photographer of an accurate knowledge of such atmospheric conditions as these, nor upon the great influence which weather exerts on almost every detail of photographic manipulation.

But there is another condition of the atmosphere which, up to the present time, appears to have received but little attention from meteorologists, although it is of the greatest importance to the landscape photographer. It is a fact well known to those who have had much experience in target-shooting that *refraction* plays a most troublesome part in displacing the apparent position of the target, which sometimes appears elevated far above its actual place, and at other times depressed to an equal extent. Thus, the would-be marksman is at a continual loss to estimate the true elevation, and the slightest atmospheric change disturbs his most careful calculations.

In photography refraction plays an equally important part, and more especially when distant ranges of hills figure in the landscape. The actual height of a range of hills, when focussed upon the ground glass, will be found to vary considerably according to the value of the refractive index of the atmosphere.

The usual method of estimating the value of terrestrial refraction is by measuring contemporaneously the elevation of the top of a mountain above a point in the plain at its base, and the depression of that point below the top of the mountain. The distance between these two stations is the chord of the horizontal angle, and this horizontal angle, increased by the difference between the apparent elevation and the apparent depression, is equal to twice the angle of refraction. Generally speaking, the refraction is found to be about the fourteenth part of the horizontal angle.

It is usual to illustrate this by the following geometrical construction:—Let C be the earth's centre, and A an observer, with A H as his horizon; if B be some distant hill top, and the arc A B the path of a ray coming to the observer at A Now the height of D B



is so small compared with the radius of the earth C D that the angles A E B, A C B may be regarded as supplementary to one another. A C B is called the "horizontal angle." B A H is the real height of B, and E A H its apparent height. Again: the real depression of A below B is F B A, and its apparent depression is F B E. The angle F B A is equal to the sum of the angles B A H, A C B; that is, the true elevation is equal to the true depression and the horizontal angle. But the true elevation is equal to the apparent elevation diminished by the refraction, and the true depression is equal to the apparent depression increased by the refraction. Hence, twice the refraction is equal to the horizontal angle increased by the difference between the apparent elevation and the apparent depression. This process involves considerable trouble, and is not suitable for daily comparison of the relative value of the refractive power of the atmosphere.

During the past month I have taken daily observations in the following manner:—A camera, fitted with a Ross's rapid symmetrical lens of eleven inches focus, was adjusted in an upper room of my house in such a way that the landscape upon the ground glass included a garden wall in close proximity, and a range of hills (the South Downs) about 500 feet high, at a distance of a mile. Upon the ground glass I ruled carefully a number of horizontal lines, at intervals of an eighth of an inch. These lines were numbered consecutively, and the spaces between them filled up by finer lines sufficiently close together to enable the eye to discriminate distances of about ·0125 inch. I had thus a scale whereby the smallest variation in the altitude of objects focussed upon the ground glass could be accurately measured. The observations consisted simply in reading off the actual height of the line of hills upon the ground glass. It is important that the position of the camera should remain absolutely unaltered from day to day, otherwise the observations will, of course, be rendered quite worthless.

In order to check the results a photograph was taken in various states of the atmosphere, and the actual distance of the summit of the hill range from the foot of the wall in the foreground was measured with a pair of fine compass points. The following table shows some cf the figures actually obtained, with rough notes as to the general condition of the weather:—

Oct. 25.		Top line of hills reached		7.25.	Weather dull, glass falling.
,, 26.	11 a.m.	,,	,,	8.0.	Clear, no sun, after storm.
	1 p.m.	,,	,,	7.75.	Bright sunshine.
,, 27.	9 a.m.	,,	,,	7.65.	Clear, cold, sun, glass rising.
	3 p.m.	,,	,,	7.75.	,, ,, ,, ,,
,, 28.	9 a.m.	,,	,,	7.9.	Clear, warmer, no sun, rising.
	3 p.m.	,,	,,	7.6.	Dull, rain, glass falling.
,, 30.	9 a.m.	,,	,,	7.6.	Fine, clear, warm.
	4 p.m.	,,	,,	8.0.	Dull, but glass very high.
,, 31.	9 a.m.	,,	,,	8.0.	Very fine and clear, glass high
	1 p.m.	,,	,,	8.0.	,, ,, ,,
	4 p.m.	,,	,,	8.0.	,, ,, ,,
Nov. 1.	9 a.m.	,,	,,	7.5.	Fine, but slight mist.
	2 p.m.	,,	,,	8.0.	Dull, but high barometer.
,, 2.	10 a.m.	,,	,,	8.0.	Fine, clear, glass rising.
	2 p.m.	,,	,,	8.0.	,, ,, ,,
,, 3.	9 a.m.	,,	,,	8.0.	,, ,, ,,
	2 p.m.	,,	,,	8.0.	,, ,, ,,

Nov. 4.	4 a.m.	Top line of hills reached		8.0.	Fine, clear, glass rising.
	2 p.m.	,,	,,	8.2.	,, ,, ,,
,, 5.	9 a.m.	,,	,,	7.99.	Rain threatening.
	1 p.m.	,,	,,	7.80.	,, ,,
,, 6.	9 a.m.	,,	,,	7.90.	Fine, clear, after rain.
	2 p.m.	,,	,,	8.20.	,, ,, ,,
,, 7.	9 a.m.	,,	,,	8.20.	Fine, very cold, glass high.
	2 p.m.	,,	,,	8.20.	,, ,, ,,
,, 8.	9 a.m.	,,	,,	8.80.	Very fine, cold, glass very high
	2 p.m.	,,	,,	8.80.	,, ,, ,,
,, 9.	10½ a.m.	,,	,,	8.4.	Not so fine, glass high.
,, 10.	2 p.m.	,,	,,	8.2.	Dull, misty.
,, 11.	8 a.m.	,,	,,	8.0.	Glass falling.
,, 12.	8 a.m.	,,	,,	8.0.	,,
,, 13.					Too foggy for observation.
,, 14.	2 p.m.	,,	,,	7.99.	Fine, cold, glass falling.
,, 15.	2 p.m.	,,	,,	7.90.	,, ,, ,,
,, 20.	3 p.m.	,,	,,	7.90.	,, ,, ,,
,, 30.	3 p.m.	,,	,,	7.0.	Dull, wet, glass falling.

Thus it will be seen that the refractive power of the atmosphere generally increases with the height of the barometer, and diminishes with the height of the thermometer. The total difference in the actual height of the hills on the ground glass during the period of the above observations was nearly ·2 inch—an amount easily appreciable by the eye on a quarter-plate landscape. Unfortunately, during the whole of the above-mentioned time the weather was remarkably fine, cold, and dry, with an unusually high barometer. If the weather had been more variable greater differences would have been found. A series of such observations taken the whole year round would, no doubt, give valuable information respecting the several conditions upon which refraction depends.

J. Vincent Elsden, B.Sc. (Lond.), F.C.S.

COLOUR OF GELATINO-BROMIDE TRANSPARENCIES.

Gelatino-bromide, for the special work of transparency making, is perhaps as little in favour as any article so universally in use for negatives could possibly be, even for enlarging from. Its handiness has hardly compensated for its flatness and too great tendency to fog, unless used with extreme care. It has to give place largely to carbon and to other processes more or less, whilst for the lantern and decorative purposes only an operator here and there thinks of using it. Nor is the cause of this disfavour hard to seek. The very sensitiveness that is so valuable for the negative is a stumbling-block where extreme clearness of the lights and force in the shadows is desiderated.

This state of things will, however, I venture to prophecy, even in spite of the admonition not to do it "unless you know," be greatly altered should the soda developer come as generally into use as it deserves. This agent puts at once into our hands the power of making from the same gelatine plate standing ready in the stock of every dark room either the softly-gradated negative for which it was intended or the most brilliant and forcible transparency it is possible to see, by simply substituting for the pyro. ammonia developer one of soda and pyro.

A few weeks ago, in this Journal (it was November 14), the Rev. H. Victor Macdona gave a formula that answers perfectly well, namely, one ounce of washing soda and eight grains of bromide of potassium to half-a-pint of water. One grain of dry pyro. to each ounce is named, but this I look upon as entirely a variable quantity. As might be expected, the same principle holds good as when ammonia is being used; the more pyro. the more density, and the restrainer being already mixed with the alkali the power of the print is completely under control. By the addition of more pyro., or diluting the already-mixed developer with the stock soda solution, the operator can do just what he thinks well.

So far, then, there is nothing new in what I have said, and it is only advanced as an introduction to what follows on a simple means of *determining the colour* of the transparency. I think it will be pretty generally admitted that the tone or, strictly speaking, *the hue* of a gelatino-bromide transparency is anything but agreeable as it comes from the developing dish. Here are the means of altering it:—Supposing the transparency forcible and good, the operator may make it what colour he wishes—within moderate limits, of course—but with a much wider average of choice than is usually supposed. The *character of the clearing bath determines the colour.* To make sure of our ground, let us just rehearse the operations. The developing print is watched till the requisite force is slowly built up—much more slowly than with ordinary negative development—and pretty frequent racking is necessary to prevent crapy marks, though there seems no tendency to bubbles sticking to the film, as with ammonia. When developed and fixed the plate is washed, and then plunged into a bath of acid alum to remove the discoloration, which is rather greater than with ammonia.

Of course we all know that a number of acids are in general use in the formation of this clearing bath; but I am not aware that hitherto these acids have been formulated into a means of leaving the image with a series of special and definite colours. I say "definite" colour, because one would suppose that exposure and a variety of causes went to produce the tint, and that, in fact, it was more or less accidental; whereas it seems determinable in a manner reminding one of the definiteness of the rigid tints awaiting one's choice in pigment printing. It may be expected that interesting results await experiments with acids other than those named here, such as sulphuric and formic; but I content myself with naming those tried, and the tints obtainable in each case, premising that in most instances a considerable number of plates were experimented with, and that there was no variation whatever, no one of any batch running into the colour of any other batch or anything tending towards it.

1. *Warm Red.*—This is obtained by a bath of iron with tartaric acid:—

Alum	1 ounce.
Tartaric acid	1 ,,
Sulphate of iron	3 ounces.
Water	20 ,,

Rather more water may be used. There is just a danger of the salts crystallising on the film, though no harm is so done. Further dilution does not appear to affect the tint. The film is extremely non-actinic.

2. *Photographic Brown*—called thus for want of a better and more definite name.—It is describable as something similar to a good-toned brown albumenised print, or like a warm brown carbon print—very unlike the range of colours usually associated with developed pictures on glass. The formula is as before, with the omission of the iron.

3. *Yellow Green.*—This also is so called for want of any really definite term. As all artists well know, there is no talking of colour in set rigid terms; but this is wonderfully suggestive of the peculiar hue of sun-lighted foliage in the spring and early summer, running from whitish yellows through various degrees of yellow greens down to brown greens or green browns in the shade. I hope to try the effect of this on lantern slides from suitable landscape subjects. At present my experiments have been made on nothing less than whole plates:—

Saturated alum solution	1 pint.
Muriatic acid (commercial)	1 ounce.

4. *Greenish Black* was the result from the commonly-used alum and citric solution.

5. *Warm Sepia* was obtained as follows:—

Saturated solution of alum	1 pint.
Glacial acetic acid	1 ounce.

6. *Black*, slightly inclining towards warmth, but very neutral compared with the others. From Edwards's clearing solution (citric alum and iron).

7. *Cool Brown*, produced thus:—

Oxalic acid	1 ounce.
Saturated solution of alum	1 pint.

I may add that the particular brand of plates used happened to be Marion's ordinary "Britannia," though it is not probable that the results would be materially altered with other makes.

Benjamin Wyles.

GAS BAGS *VERSUS* BOTTLES.—LANTERN SLIDES.

I read with very great interest, some few weeks since, the article by Mr. Samuel Highley on *Bottles* versus *Gas Bags.* All who know Mr. Highley are aware that he is no mean authority on these matters. Being a user of the lime light I for one should be very glad to be able to do away with the gas-bags with advantage, but I fail to see how it is to be done. In the first place, good bags are indeed very expensive, and I never like to trust to common bags. I have seen several bags which were not any better than if they had been made of American cloth. If one be willing to pay a good price, good durable bags *can* be obtained. There is one advantage with bags—you can see how much gas you really have; but in a room that is packed they do take up more space than the bottles I admit, and with the latter there is no fear of any harm by being pressed or run against, which has to be guarded against when using bags.

In using bags, if there be one thing that I am more particular in than another it is to see that I have plenty of room for the bags to clear themselves as they fall, and I always insist that I have a clear half-yard from the nearest person. If I find a boy who I think inclined to be troublesome, I remove him some little distance away; but, as a rule, I never have any trouble with an audience, as they begin to know that it is not wise to play any tricks after the accounts that have appeared in the daily papers about accidents therefrom. If at any time an obstacle were put in my way, so that I could not work under my own conditions, I would not on any consideration light up until they were complied with.

Now, as for accidents occurring through weights tumbling off the bags, there need be no danger on that score; I always strap my weights on securely, so that it is not possible for them to shift as the boards go down. With bottles there are no weights to look after, but, under present conditions, the flow of the gases must be regulated at the main cocks on the bottles and not at the burners' When the operator has only one burner to attend to it is easy enough; but when he has to work a double or a triple lantern it is almost out of the question; for if the gases are regulated to keep two or more burners at their best—when, perhaps, two of them have to be turned out—the pressure will be found too great for the tubes, and something must give way. Therefore, with all their troubles and faults, bags are the best until a governor which is automatic can be adapted to the bottles, so that the cocks of the bottles can be turned full on and the lights regulated at the top of the burners themselves. Then everything will go on smoothly enough; but until such conditions can be obtained I fail to see how perfect safety from explosions can be guaranteed. I am in hopes that it will be accomplished some time.

I am alluding to the use entirely of mixed jets. No one will doubt the safety of bottles when full and both at the same pressure; the suspicion is when they are getting low and at different pressures. I am sure everyone will admit that it would not be wise to attempt to work mixed jets with a very great variation of pressure between the two bottles.

When proper regulators or governors, however perfect, are adopted I do not think they will even then drive out the use of bags, for a very important reason, namely, the cost of the gas and filling of the bottles. I think the lowest price for oxygen in bottles is about eightpence per foot. Now, when the cost is compared with the cost of gas made by myself, if much be used it means an everlasting tax. Then, again, there is the hydrogen, which has to be compressed; this is still another additional cost, and the employment of bottles would be found far more expensive than if bags were used. If this were the only obstacle to the use of bottles it might be overlooked on the score of convenience *at times*—when working near home within cab- or cart-driving distance.

There is another fact which must not be lost sight of, and that is the additional cost of railway charges. Supposing one has to go some two or three hundred miles into the country for (say) a five- or six-nights' run; in getting bottles up and down the cost would be enormous, especially if all railways charge the same as the line near which I live. Empty bottles would not come back as return empty boxes, or if they did there is no telling when they would turn up, and how many "paid-ons" there would be on the way bill; and if these were taken by passenger train there would be one farthing per pound for every thirty or forty miles, which must all be taken into consideration.

When a regulator or governor for the bottle is a fact, then manufacturers must put their wits to work to invent a simple compressor, so that the lanternist could fill his own bottles and reduce the cost. I for one should strongly object to pay eightpence per foot for all the gas I used when I could make it for nearly eighty per cent. less, according to the market rate for chlorate of potash, &c. Although I have enumerated all these drawbacks, I should be very glad to have all the gas ready to take into the lecture hall instead of having to make it when I got there; nevertheless I treat gas-making as a very simple matter, for I can fill my large bag in half-an-hour at the outside. But yet it has to be done, and every little that can be dispensed with and can be performed at home is a very great boon. I shall hail any improvement that is made in either gas bags, bottles, or other appliance appertaining to the lantern.

There is one great advantage with the bottles over the bags which, as Mr. Highley points out, must not be forgotten. Any amount of light can easily be obtained, as an enormous pressure is always at command, which is not the case with the bags, unless extra weights are loaded on, and this is not at all times desirable, especially if the bags have been in use some time. The chance of an explosion from the use of the bags never enters my calculation so long as the bags have plenty of room to work and are both under equal pressure, or nearly so. I always use the bags one on the top of the other, keeping the hydrogen at the bottom; this gives it a little more pressure, which is an advantage, as more of that gas is consumed than of the oxygen. Given good pressure and a clear gas way, I then think there is nought to fear.

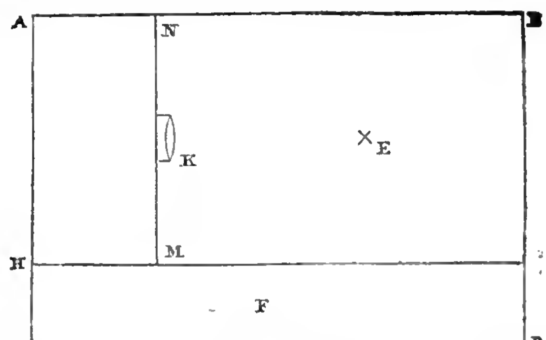
Lantern Slides.—Some time since Mr. George Smith wrote that a good slide ought to show well with any light. I think when he put that forth he was but imperfectly understood, as I have heard many argue the matter. I myself perfectly agree with him in this way. Take, for instance, a fair average slide—viz., clear in the highest lights, full of gradation to the deep shadows—and it will be found to show well on an eight- or nine-feet disc with a good oil light. The same slide will show equally well on a disc twelve to thirteen feet in diameter with a safety or blow-through jet, and equally well with a mixed jet on a disc (say) from sixteen to twenty feet in diameter. But beyond the latter size a more delicate slide is required, possessing just sufficient depth to give brilliancy. If, for the average slide before mentioned, an oil light were used for a twenty-feet disc, the light would not be expected to be sufficiently powerful; whereas with a mixed jet at its best and a nine- or ten-feet disc all the life and delicacy would be taken out of the picture by the intensity of the light. As a rule, I have noticed that amateurs generally make their slides far too dense. I make all my slides so as to be suitable for a very large disc and a powerful light.

W. Brooks.

THE CAMERA OF THE FUTURE.

After reading all that has been written of late about improvements in tourists' cameras, and having had plenty of experience at tourist photography so as to know what its requirements really are, I wish now to give some idea of the kind of camera I should like. The ideas which have been put forth by the various contributors who have written upon the subject indicate a desire for two classes of cameras for tourists, namely, box cameras and cameras which have to be used outside their packing-cases. There is much to be said in favour of each of the two classes, and both will probably find their way into the market; meanwhile I express personal preference for the box type, without asserting that the other type may not be as good.

I require a camera on the principle indicated in the accompanying diagram, in which A B C D represents the box, K the front of the closed camera, and A H the back. The end A C of the box pulls out entirely, exposing the translucent glass and the swing back; the end B D also pulls out entirely, exposing the lens K and the front N M of the camera, which have to be drawn out to E before the lens of shortest focus throws a sharp image upon the translucent screen, which should have a finer surface than



ground glass. When the front M N is not drawn out the space E is utilised to carry a light leather case, in which are packed the other lenses, the focussing-glass, and other necessaries. The space F is for six or more double dark backs—not slides, made on the American principle, to press and not slide into their places. Their shutters pull out entirely, like A C and B D; so none of them are left to flap about in the wind, thereby causing tremors. They are all stowed away for the moment in the space F while the view is being photographed. The double dark backs should be lighter, and be but about half the thickness of the wooden ones at present in use.

It is indispensable that the lenses shall be interchangeable at will in a moment, either by Mr. A. Pringle's plan or upon the rotating disc method. The latter is preferred, supposing that room can be found for the disc, and that the disc will not interfere with the action of a simple drop shutter fixed in the camera front, to be used if desired with any of the lenses. These latter points should be worked out in detail by practical camera makers. There should be some means of indicating when the swing back is absolutely parallel with the front of the camera, for at present the camera is not the instrument of scientific precision which it must become in the future. The camera should have a falling as well as a rising front, and with greater range of motion than at present.

The translucent focussing-screen, made with some better surface than that of ground glass, should not be fixed in its frame, but held "to register" by movable springs, so that when it is accidentally broken another can be substituted for it in a moment. Any thumb-screws used in the camera should be duplicated, that the operator need not be nonplussed by the loss of one. The duplicate screws for fixing the camera to the stand should each have a hole bored through its head, to permit the passage of a thick string.

The covering of the case should be of good leather, capable of resisting long exposure to rain and sunshine, and means must be provided of locking its two ends, otherwise the possessor is never happy when it is out of his sight among inquisitive persons at hotels and elsewhere. If a cheap substitute for leather be used great care must be taken in its selection, attention being given to its durability, its power of keeping out dust, and of resisting atmospheric influences. Possibly if the case were of wood, as in the old-fashioned box cameras, the weight might not be objectionable for small sizes. For larger sizes, and for all sizes when it is not desired to economise, is it not practicable to build up a skeleton framework of tough wood to give rigidity to the essential parts of the camera, and to cover it in with cork to support the outside leather skin?

The top of the stand should be a double one, so that the camera can be turned on its side instantly when desired. Means should exist to enable the camera to be taken out of its case for repairs. The power must be given of racking out either the back or the front of the camera, or both, until they project far beyond each end of the case, the object being to enable upon an emergency a lens to be used of at least three times the focal distance of the length of the largest plate the camera will take. A circular spirit level should be fixed in the case in an appropriate place.

These suggestions are not made to release "the camera maker of the future" from reading the past articles in the discussion, in which there are many suggestions that should not be overlooked by the manufacturer who intends to build up a reputation. The wide-spread interest existing in these matters is indicated by the excitement created by the appearance of Mr. McKellen's camera at the meetings of photographic societies, because of the novel points in it; but I did not see that it contained anything to remedy the chief defect of the present tourists' cameras, namely, that of unnecessarily wasting the time of the operator. W. H. Harrison.

LANTERN SLIDES ON COMMERCIAL PLATES.

Part II.

Having in my last chapter described the methods of slide-making by which I failed, or only partially and occasionally succeeded, I turn with greater pleasure to the method by which I have attained the success to which I aspired. That I may be thoroughly understood I may here state that my object was to produce, both by camera-copying and contact-printing, slides possessing the following qualities:—Perfect transparency in the highest lights, transparency in the shadows, a sufficient amount of half-tone both in lights and shadows, and a tone warm enough to suit my taste. With the process I have described I got one or other, or perhaps two, of these desiderata; but with neither wet collodion nor gelatine did I get all the qualities I insisted upon. With wet collodion I got clear lights, but lack of half-tones and a cold colour; with gelatine I got half-tone and pleasant colours, but failed in producing with certainty clear lights and transparent shadows. I think that with collodion emulsion, both "washed" and "unwashed," I can depend upon satisfying myself if I have to work upon a negative anything like making a decent print, and often with a negative too hard to make a silver print worth fixing.

I began work with a sample of washed emulsion sent to me by Mr. William Brooks. As I had never tried slide-making before in anything like a methodical way, I came to very big grief at first, and wasted a very great number of plates. My first failures were chiefly due to complete over-development. I could never remember that I was working on positives, and my first results would have been of good printing density for negatives. Then I was long perplexed by my plates refusing to fix. This was a (to me) unheard-of fault; however strong I made my cyanide there were always patches that would not fix. I blamed my india-rubber edging, but on omitting the edging the result remained as before—if I ever got the length of fixing—which, as a rule, I did not, simply because my film usually meandered down into the sink. I had had the cyanide for years, and possibly it was adulterated to begin with; but anyhow a new sample fixes the plates rapidly and thoroughly. But as I had never heard of K Cy going wrong, I was a long time before I replenished my stock, and even now I do not see why it should have fixed one part of a plate and not another. Possibly it was not the fault of the cyanide; but I do not care, as I have now no trouble in the matter.

Another vexation that for some time assailed me was the film partly slipping, even when I had edged the film previous to development. I now albumenise the plates first, edge them when the albumen is dry, and again edge them before development. No film ever slips with me now. Mr. Brooks's emulsion is a very thick one, and must be deliberately and slowly applied to the plate; nor should any attempt be made to thin it unless it becomes almost unpourable from evaporation of the solvents. I never pour the emulsion from the plate back to the bottle whence it came, but always filter it through medicated cotton wool after it leaves the plate. I am told that clean tow would be better, but the wool does quite well if not too highly rammed into the flannel. Mr. Brooks sends with his emulsion full instructions for use; but I think it will be well for my readers that I should slightly supplement and enlarge on his brief circular.

The first important point before developing is to be sure that you have pure and fresh ammonia carbonate. This salt is largely adulterated, and even when pure loses in a short time its pristine vigour. In buying the salt the purchaser must satisfy himself not only that he is getting the right article, but that the article is in a proper condition. If it have round the lumps a white powdery substance it is bad, and must be rejected; and the lumps should be not round or rounded, but irregular tablets evidently broken from a flat cake about half-an-inch thick. This, at least, is the appearance of the *good* carbonate I use (Hopkin and Williams's), while the salt I began with, and partially failed with, appeared to be broken from either a large lump or a tablet of much greater thickness. If the best carbonate be not used I prophesy failure. The ammonia carbonate is placed in a closely-stoppered bottle with a quantity of water, and for a day or two the bottle is shaken up occasionally, so that complete saturation may be obtained. Of this saturated solution two ounces are taken; to these are added acetate of soda one drachm, bromide of potassium half-a-drachm, and water four ounces. This mixture must not be heated, but kept in a bottle with an accurately-fitting cork, or a stopper smeared with vaseline. I do not dissolve my pyro. in alcohol, but keep it in its bottle, spooning it out a few grains at a time with a bone egg-spoon.

For contact printing I place my negative in a small printing-frame at the end of a long box, blackened inside. I carry box, printing-frame, and all to a position under a skylight of "obscure" glass, and I expose from half-a-minute to three minutes according to my negative. If the negative be very dense indeed I do not put it into the long box at all; if very thin I not only put it into the long box, but I cover it with a piece of ground glass. The positive must not require forcing in development, nor must it rush up red in all details as soon as the developer is poured on. *Experientia docet!* On removing the collodion plate from the negative I edge it with india-rubber solution, and let it remain about a minute. Then I pour on and off methylated spirits and water, equal parts. While the spirit is being washed off I take about three drachms of my ammonia, bromide, acetate solution, and on my egg-spoon I put about three grains, or less, of pyro. Then I pour on and off twice my ammonia solution, and add the pyro. After again applying the solution I wait for twenty or thirty seconds, and expect to see the image appearing. Some positives I develope to full density in this manner, others wanting contrast I stop short of full density, fix with cyanide, wash, flood with weak nitric acid, and intensify with water half-an-ounce, pyro. four grains, and six to eight drops of the following:—

Silver nitrate	30 grains.
Citric acid	25 ,,
Water	1 ounce.

This I pour off and on rapidly, examining the plate frequently to avoid overdoing the business. If the exposure has been about correct the resulting positive will be of a fine, warm tone; if the exposure has been too long, and the development too short, the positive will be almost a brick red; while if the brevity of exposure has entailed slight prolongation or forcing of development, the tone will be colder, but still pleasant enough. Rather than lose a plate entirely, when slightly under-exposed, I give it a drop or two of liquid ammonia and water, each one part, and bromide one part; but this must be carefully dealt with.

Before tackling the subject of camera-printing I must record a few of my mechanical troubles in this department. When I began I thought it was not of vital importance to exclude all light from the lens beyond what comes from the negative; but I am now satisfied that the best work is done when no light other than that passing through the negative reaches the lens. To obtain an arrangement by which this could be done, and adjustments of distance conveniently made, I spent a lot of time, trouble, and money. I had long boxes made to hold the camera at one end and the negative at the other, but they were all inconvenient and unsatisfactory. At last I hit upon a method that cost nothing. I took my largest camera, 10 × 8, put in the wet-plate slide with carriers for the negatives to be copied, placed the whole on a sort of studio stand, and canted the slide end up towards the sky. Removing the sliding front of the camera, I put into its place the nose of a quarter-plate camera, and closed the space at the sides of the little camera with pieces of cardboard. In the wet-plate slide I put my negative, and racked out the camera till the picture is the desired size on the ground glass of the small camera. Of course back and front of the large slide were open. Having focussed on the small ground glass, I put a piece of ground glass against the negative, closed the back of the slide, put in my small camera slide, open, covered the whole apparatus with a black cloth, raised the back of the large slide, and took note of the time. In from half-an-hour to two hours my exposure is finished. The ground glass behind the negative must not be omitted. The development for positives produced in this way is exactly the same as for those produced by contact printing, and the power of varying the process according to the kind of result required is perhaps even greater. The negatives I intend for silver printing are, as a rule, less dense than those I make with a view to making slides, and when making a slide of a thin negative in the camera I give a full exposure, stop development as soon as all details are up, and intensify the details I have after fixing. On the other hand, I have lately had to copy in the camera negatives not taken by myself, and far too dense to be good for printing. In these cases I give a long exposure, and redevelope with silver and pyro. after the first ammonia carbonate development, but before fixing. It is surprising to see what a variety of effect can be produced by such simple means if only a little sense be brought to bear upon the work.

Any positive made as above can be toned to various colours with gold, but I think preferably with platinum; yet I very seldom find my slides require toning. In fact, I have only toned them for the sake of experiment, or with a view to producing a slide in a colour similar to engraving black.

I have also had occasion to use an "unwashed" collodion emulsion supplied to me by Mr. J. M. Turnbull, of Edinburgh. In beauty of result this emulsion leaves nothing to be desired, but it requires rather more labour in coating the plates. After the emulsion is poured on the plate and allowed to set for about a minute the plate is rinsed in distilled water, and the salts washed out of the film; then the plate gets a swill of beer, and, finally, is again washed and set to dry. Mr. Turnbull's emulsion is very thin, Mr. Brooks's very thick, and Mr. Turnbull's is more rapid than Mr. Brooks's, but requires rather more development to gain density. I develope Mr. Turnbull's emulsion without bromide, merely using saturated solution of ammonium carbonate with two parts of water. I have not used sufficient of the unwashed emulsion to say whether it comes up to the washed; but I can aver that the unwashed is capable of giving slides of great beauty, particularly if soda acetate be added to the developer.

For the reproduction of engravings I have found a plan that surpasses any I ever hit upon before. I take a fully-exposed print on collodion emulsion from a small negative and develope it in the usual way, but stopping slightly short of full density. Having fixed, washed, and applied nitric acid as usual, I place the transparency in the platinum toning bath and leave it there till nothing but a ghost of an image remains. Then I wash well, and intensify to proper density with pyro. and silver. I have then a transparency in pure black and white, while, if my object be to produce a brown or sepia tone, I leave the plate for a much shorter time in the toning bath and do not intensify so much. I never saw finer "engraving-black" tones than those produced by a long toning and a brisk intensification.

I need not say anything upon varnishing and mounting the slides. I would, however, urge the use of a proper positive varnish—that is to say, a perfectly clear and not a yellow varnish; and the varnish must be filtered with the utmost care. It is a great vexation to spoil a perfect slide at the last operation, yet I have often done so from neglect of proper filtration. No care is lost upon a slide, for the smallest speck, either opaque or clear, in the slide is magnified to a monstrosity in the lantern. It will save trouble in the end if only the best patent plate be used for the slides; and for the covers the glass must be minutely inspected for bubbles, scratches, &c., before the slides are finally mounted. The binding strips ought to be broad, so as to serve for the thicker plates that sometimes turn up; and they should be at least fourteen inches long, so as to leave a bit to catch hold of in mounting. It saves a lot of money to cut one's own masks with a proper trimmer, and it is useful to have "templates" slightly varying in aperture for the various shapes. Before mounting let the gummed strips be thoroughly wet, and suit the shape of the mask as far as possible to the composition of the picture.

I do not know a more interesting, useful, or amusing pursuit for winter than lantern-slide making. ANDREW PRINGLE.

THE CAMERA OF THE FUTURE.

MOST of the cameras of the present day, however suitable they may be for studio or home work, are certainly not so portable as they should be for the tourist. They might be made considerably lighter, and with more simple adjustments without impairing their efficiency.

Being somewhat of a mechanic, I have always constructed my own photographic apparatus, lenses excepted. The last camera I made of ordinary construction was some twenty-five years ago. It was for $8\frac{1}{2} \times 6\frac{1}{2}$ plates, made of mahogany, and weighed three and a-half pounds, including a turntable, by the insertion of which I was able to dispense with a loose triangle.

I think few whole-plate cameras weigh less than this. I used it on and off up to last year, and then lent it, with a changing-box for eight plates which weighed one and a-half pound, to a novice, who has returned them to me in good condition; from this it may be gathered that they were strong enough for the ordinary work of a man's photographic lifetime. The slide and the focussing-glass each "took out;" in consequence I felt bound to cover the camera with the focussing-cloth during exposure, and sometimes to place the glass on the ground. The first was inconvenient in windy weather, and the last was objectionable when one stepped upon the glass. The latter feat I performed last year on a lone rock some twenty miles away from a plumber or glazier. I usually carry a spare glass with me, but on this occasion, of course, I did not, and so had a pleasant voyage to Inverness the next day, where I could procure only some very coarse stuff.

I might have adopted the modern plan of keeping the focussing-glass attached to the camera, but, being tired of a changing-box, and disliking the encumbrance of half-a-dozen "double backs," I resolved to construct a camera and dark slides, or, as I call them, "plate-cases," on an entirely new plan. This I completed last spring, and, having tested my invention during a ten-weeks' sojourn in Scotland with complete success, was so pleased with the result that I thought the apparatus deserved protection. I have therefore patented it, and it will, I believe, be shortly brought out by a well-known firm.

The camera itself, for whole plates, will weigh between three and a-half and four pounds. The double-plate cases weigh eight ounces each, and are little more than half-an-inch thick. The five pack in a light case three inches deep; and this case has rolled down divers braes without damage to its fragile contents. The focussing-glass, this time never having left the interior of the camera, has afforded me no opportunity of testing its friability.

The plate-cases are of a peculiar construction, on the shutter principle; and there is a contrivance within the camera which, attaching itself to the shutter of each plate-case as it is introduced, unveils the plate in perfect darkness. The facility with which these plate-cases are filled or emptied without the aid of any light is, I think, unequalled. As in my former camera a turnstile is sunk in the bottom, so that there are no loose parts. The camera is, therefore, complete in itself, and, with the tripod, which folds into a light walking staff five feet in length, can be set up or taken down—I will not say in how many seconds, but with sufficient rapidity and, which is of equal if not greater importance, with little trouble.

I do not believe in *the* camera of the future, for different uses will be better subserved by varied constructions; but the portability and simplicity of the camera described will, if I may judge by my own experience, be appreciated by many a tourist.

A few words as to things in general: One of your correspondents has most liberally suggested for an impromptu plumb-bob the use of his bunch of keys. Should I ever have the privilege of setting up my camera in his company I will gladly, if occasion demand it, avail myself of his fertility of resource—albeit totally unable to return his kindness should we ever meet again, as my own keys are of so truant a disposition that I should deem it highly improper to allow them such an excuse for slipping off and stopping behind. I should much prefer the insertion in the frame of our cameras of the small spirit level. This could easily be fitted, and would prove serviceable in many an awkward position.

What is the use of reducing the weight of cameras if the dry-plate makers do not meet us half way? It has been objected that thinner glass would be liable to fracture, and prove too expensive. In the plates I use some are double as thick as others. The gelatine covering, doubtless, strengthens the plates; of some 200 I have used this summer I have not broken the thinnest. A maker who took greater pains in the selection of his glass, or who even paid a little more for thinner sheets, would find it to his interest to be able to add to his advertisements a decrease in the weight per dozen of his dry plates. M. A.

THE OPTICAL LANTERN AND ITS MANIPULATION.

No. I.

SEVERAL useful books and articles in scientific and popular journals have been written on this subject from time to time, each giving valuable information; but it is thought by the writer that something more can yet be done, judging from the number of queries sent him from time to time, to make matters a little more clear to those who are to a certain extent uninitiated in the use of the optical lantern, and have not the opportunity to get practical instruction.

Having on several occasions started and fairly launched many gentlemen with the most complete triple lantern apparatus without one personal interview, I venture on this little matter with the hope that I may be as successful now in imparting some information to the amateur readers of the Journal that will enable them to work with confidence;

and, at the same time, there may be one or two observations worthy the attention of professionals photographers or hints worth examining.

The old title of "magic lantern" still clings to projection apparatus, no matter how costly or improved, and no doubt will do so for many years to come; for most people revere traditional names and titles, and are slow to appropriate others even if more suitable—such, as in the present case, "optical" for magic lantern. There are very few of the rising generation who think "magic" has anything to do with the entertainments now so familiar in connection with showing photographs on a screen or producing dissolving views, and why? Because the instrument has become so popular that it is to be found in almost every home—if not in an advanced state, as a toy. It is proposed to deal with it here as an instrument for imparting instruction or higher-class amusement and as a practical adjunct to photography.

The essentials of a good optical lantern are—1. Means of adequately illuminating the object to be projected.—2. Suitable lenses to project the object without distortion.

As regards the first: "adequate illumination" may be defined as that amount of light which will enable the object to be *properly* seen by the audience, or, in case of enlargement of photographs, that will produce a clear outline and detail on the sensitised paper. If the object be opaque nothing but the strongest available light at present known (the lime light) is sufficient to give a moderately-satisfactory result; but with transparent objects, such as photographs on glass or paintings on glass, a light produced by *a good oil lamp* will enable a projection to be obtained of from five to nine feet in diameter, according to the form of the burner or burners, supposing also the optical arrangements are satisfactory. This *maximum* (nine feet) can be sometimes exceeded; but, as a matter of fact, it is only under exceptionally-favourable circumstances and accompanied by drawbacks that more than counterbalance the extra size obtained. When a projection is required larger than this, the lime light in some form must be adopted, and the following may be taken as a fair average for the limit of each:—

The Oxycalcium.—Oxygen from a bag or holder forced through a flame of spirit on to a lime cylinder or ball—12 feet diameter.

The Oxyhydrogen Light (unequal pressure).—Oxygen from a bag or holder being forced through a flame of common house gas on to a lime cylinder—15 feet diameter.

The Oxyhydrogen Light (equal pressure).—Oxygen from a bag or holder being forced through a mixing chamber of carburetted or pure hydrogen (under pressure of about the same amount) from a bag or holder, and after ignition impinging on the lime—20 to 30 feet diameter (according to pressure used and form of jet).

I leave out the ethoxo light, because I think in its ordinary form it should only be used by those who have had large experience, and who understand the nature of ether and how to avoid risk.

It will be gathered from the above that the greater the amount of oxygen that can be used proportionately the better the light will be; and the difficulty in getting a very powerful oil light is the fact that as the size of wicks or the number is increased the extra supply of air to support combustion is hard to obtain. Two, three, four, and five wicks have been tried in different forms of burners and arrangements with varying success; and, although the four and five wicks have been found to give an increase of light, the excessive heat renders the manipulation of the optical lantern with them as the source of light a matter of discomfort. Thus, at the present time the three-wick lanterns may be said to carry the palm for practical work.

Another reason against too great a multiplication of wicks is the fact that, if the area of the luminant exceed half-an-inch diameter, a number of false rays pass through the optical system and result in the definition of the picture being impaired. This has been proved by the writer by employing a good average-quality front lens working at nearly full aperture (and so allowing nearly all the light to pass)—first, on a lantern illuminated by the lime light, and then by a multiplex oil lamp. In the former case the definition was all that could be desired; but in the latter the picture was blurred and hazy until a diaphragm was inserted in the objective so as to allow only those rays that were *central* to pass, and this definition was obtained at a considerable sacrifice of light.

The greater the number of wicks the more difficulty there is in regulating them for proper height and for draughtway, and some ingenious arrangements of chimneys have been devised to control the latter; but, notwithstanding all this, the four- and five-wick lamps cannot be said to have given the satisfaction originally anticipated as luminants for the optical lantern, although useful for certain special purposes. G. R. Baker.

FOREIGN NOTES AND NEWS.

Dr. Geiger on the Stability of Certain Dyestuffs.—Honour to Major Volkmer.—Wilde on the Pitting of Gelatine.—Dr. Vogel.—Transatlantic Novelties.—A Handy Cement.—A Bleaching Medium.—The Photographic Wing at the New Technical High School, Berlin.

Dr. Geiger, of the aniline manufactory, placed a series of solutions of dyestuffs in bottles and exposed them all to the light together, when he found that the bottle containing "extra phosphin" bleached much more rapidly than that containing fuchsin; while a third dye, which is a mixture of fuchsin and phosphin, and is known in commerce as "cardinal," bleached as rapidly as pure phosphin did, from which it would appear that the sensitiveness of fuchsin to light was increased by the presence of another substance sensitive to light.

Major O. Volkmer, who takes charge of the photographic department of the Imperial Military Institute at Vienna, has just been decorated by the King of the Netherlands with the Cross of Knight of the First Class of the Order of the Lion.

In the *Correspondenz* Herr F. Wilde writes:—"'Pits' in the stiffened gelatine film are popularly supposed to originate in grease in the gelatine. I have found that when grease is added to a gelatine which stiffens free from 'pits' the addition does not induce the formation of 'pits.' Gelatines having a strongly-acid reaction show a strong tendency to become pitted. The tendency of gelatine to form 'pits' is increased by the addition of acetic or citric acid. The formation of 'pits' also depends greatly on the temperature at which the gelatine film stiffens. If the film stiffen slowly the 'pits' formed are both more numerous and deeper than when the stiffening takes place rapidly. The proportion of gelatine to water also exercises an influence upon that point. The proper proportion of water varies according to the quality of the gelatine. It is not *always* possible to prevent pitting during the stiffening of films, even of the best kinds of gelatine; and these 'pits' are of consequence, as they often cause spots in the developed negative."

The same gentleman says, also, that gelatino-bromide of silver stored in alcohol is popularly supposed to ripen and become more sensitive. He has, of course, found that the alcohol acts as a preservative, but has not discovered that it otherwise improved the gelatino-bromide of silver. Indeed, the alcohol in which gelatino-bromide of silver has been preserved for some time becomes dark in colour when standing exposed to the light, and gives off flakes of glue—a proof that the alcohol does not always act as a pure preservative, but may sometimes act injuriously. Films prepared from gelatino-bromide of silver which had been preserved in alcohol gave glossy negatives, or, at least, negatives the shadow parts of which were glossy. His experience as a daguerreotypist had made him acquainted with the action of chloride of iodide, and for some time back he has been in the habit of adding a little chloro-iodide of silver to the gelatino-bromide of silver. He found that it secured films upon which the negatives covered well and gave thoroughly-worked-out details, with well-worked-out gradations of tints for the different colours.

Dr. Vogel, of the *Mittheilungen*, has been travelling through Germany and Austria on purpose to visit and observe the different photomechanical establishments and the processes worked in them, and will probably publish an account of his observations.

Our transatlantic friends are always on the *qui vive* for something new; they must have the latest invention in photography as in everything else. They have floured their faces and hair, draped themselves in Greek costumes, and been taken as statues; they have replaced the President's head by their own in postage-stamp portraits; they have had themselves caricatured as "out on a fly" or "on a ride" by having their own heads photographed on a large scale, while in front of them a picture of a large goose or a donkey, with a diminutive, headless man on its back, is fitted so that the head of the real sitter seems to belong to and complete the headless one. They have collected portraits of hands, babies, and dogs. Now they go in for portraits of cats; and American photographers, on the principle of "making hay while the sun shines," have raised their prices for cat portraits to double what they charge for their human sitters. Another contemporary has a piece of news from Saratoga, which, if true, strikes a death-blow at the business of the retoucher:—Freckles have become fashionable amongst the *belles* of that resort of the *beau monde!* But if there be no more employment in removing freckles from negatives for the unfortunate retoucher, his case is not altogether without its consolations. The same journal says those ladies whom the sun does not spot naturally in the coveted manner have the desired freckles painted on, and pay at the handsome rate of two shillings per freckle!—one painting warranted to last, with care, for three days. Perhaps removers of freckles (retouchers) thus thrown out of work may find employment as painters of freckles!

The *Archiv* recommends the following almost colourless cement as a very handy thing to have in the laboratory:—Dissolve seventy parts of finely-divided, unvulcanised caoutchouc in one hundred parts of chloroform, and then add fifteen parts of mastic. The mastic will require a few days before it becomes perfectly dissolved. The cement should be kept in a well-corked bottle.

The *Polytechisches Notizblatt* says that experiments in bleaching bones and objects prepared from them (does that include gelatine?) have been carried out lately in the laboratory of the Bavarian Industrial Museum, in which phosphorus acid has been found a useful bleaching medium. Bones, after having all fat removed by means of benzine or ether, are dried, then laid for a long time in a one-per-cent. aqueous solution of phosphorus, and washed and dried again, when they will have assumed the appearance of ivory.

For a number of years back the Technical High School at Berlin has been very much cramped for room, and the photographic department was not the smallest sufferer; indeed, the *Photo. Notizen*, from which we get this information, says that photography was the Cinderella of the sciences taught there. In its treatment, with regard to accommodation, there was a fairly-sized glass house, but the other apartments were mere closets in which four persons could hardly turn themselves at once. In this place Dr. Vogel had often to teach eight persons at a time; and the state of the ventilation may be imagined when it is stated that the height of the zinc roof was only seven and a-half feet. All these drawbacks are about to be remedied; for a splendid new Technical High School, half as large again as the Imperial Palace at Berlin, has just been finished, and adjoining it is another large building devoted to laboratories. One wing of this latter building is devoted to photography and spectral analysis, both of which departments are under the charge of Dr. H. W. Vogel. In the lowest storey there are the work-rooms, which require to be cool, and also a machine house, in which a five-horse-power gas engine drives a lighting machine, by Siemens and Halske, capable of feeding six arc lamps, each giving a light equal to 1,200 candles. A conducting wire reaches from this room to the glass house in the third or uppermost storey, where these lamps, giving collectively a light equal to 7,200 candles, should surely render the photographers independent of weather and of sunshine. A wide and easy staircase leads to the corridor of the second storey. A number of rooms open from both sides of it, while the wall spaces between the doors are used for the exhibition of the large collection of landscape, technical, historical, artistic, and scientific photographs, and to specimens of old and new processes collected by Professor Vogel during the last twenty years. On this floor are three rooms devoted to the positive process—to silver, carbon, and platinum printing. One large room is assigned to printing and washing, a smaller one to the dark room, and the third (a large one of the same size as the first) is where the prints are trimmed, mounted, retouched, and pressed. On the other side of the corridor are the teacher's *bureau* and work-room, and two rooms for lichtdruck adjoining the class-room. There is also, further to the west, an enlarging room, where phototypes (or light relief prints) and *heliogravures* (or photo.-zinc prints) are made. The negative process is carried on in the third or uppermost storey, which, like the second, is furnished with a lift for raising heavy apparatus, &c. The glass house is thirty-five feet long and twenty-two feet wide, and faces the north. Near it are the room for cleaning plates, &c., the laboratory, and dark room No. 4, which is specially devoted to wet plates. Dark rooms Nos. 1, 2, and 3 are for dry plates, and there is a special laboratory for the preparation of dry plates, fitted up with digesting apparatus, ice-box, levelled stands, &c. There are also a number of smaller work-rooms, which are intended to be placed at the disposal of artists or scientists who may be conducting independent investigations. The whole building is properly ventilated, and is heated by means of hot-water pipes. The dark rooms are lighted by Edison lamps. The adjoining photometric and spectral analysis laboratories and work-rooms are all fitted up with the latest improvements and inventions, the whole of the arrangements being calculated to excite the envy and admiration of all other cities. Vienna has long been desirous of having a similar establishment, but has been put off with the excuse of want of space and funds. However, if it should now obtain the desired grant it will be able to profit largely by the examination of the new building at Berlin. That we should have one in this country, also, is improbable, and perhaps not so very desirable, as State endowment of specific technical studies does not seem to be so much in accord with the idiosyncracies of our national character as it is with those countries that are governed on the "paternal system."

FORGOTTEN PROCESSES.

[Abstract of a paper read before the Photographic Club.]

PHOTOGRAPHY seems to me only as a rare and valuable amusement, in which I enter into the result of the labours of others, without in any way contributing to them. It is open, however, to me to think over and to marvel at the progress that photography has made. Men are not now old—in the modern use of the word—who saw its birth as a science, but it had prior to this a long record of forgotten processes. It did not spring full-armed from the head of any inventor, like the block-making machinery at Portsmouth, which is probably unique, as no improvement in it has been found possible since it was first designed.

There were heroes before Agamemnon, but they had, we are told, no Homer to record their deeds; so it is possible that others may have seen visions and dreamed dreams before Fabricius in the early part of the 16th century, when seeking the elixir we should all be so glad to find to confer perpetual youth, threw some sea salt into a solution of nitrate of silver. He noted that the precipitated chloride of silver, which he found as white as milk, became black by exposure to the sunlight. He recorded the fact in his "Book of Metals" published in 1536, but did no more. What bearing could such a thing have on the elixir of youth? Schule, in 1777, re-discovered the fact; and in 1780, Professor Charles, the inventor of the hydrogen gas balloon, turned it to practical use by spreading a solution on paper. He then projected on it a strong beam of sunlight, with the head of one of his pupils interposed, and found that the part exposed became rapidly darkened; and, following the outline of the head, the first *silhouette* was produced—the parent of those fearful and wonderful objects in black paper which are still occasionally to be met with, and were supposed to represent the grandfathers of the present generation.

It is a long leap from Professor Charles to Isidore Niépce and Daguerre. The former, as an independent worker from 1817 to 1826, and afterwards in conjunction with Daguerre, discovered that bitumen of Judea, if spread thin on metal plates and exposed to sunlight under a print or similar object, became white in the exposed parts, and insoluble in essence of lavender. Subsequently, he etched the bare metal with acid, and named the process "heliography." Meanwhile Daguerre had been working out his own idea—still with bitumen; but, by one of those happy accidents—which only genius appropriates—he chanced, it is said, to lay a silver spoon on a metal plate which had been treated with iodine, and lifting it afterwards he discovered an image of the spoon on the metal. From that time bitumen was abandoned. Silver plates were exposed to iodine vapours and heated at first with petroleum and afterwards with mercury for a developer; and on the 10th August, 1839, Daguerre demonstrated his process before the Institute of France, and photography became a fact. Paul Delaroche, who was present, is said to have exclaimed—"Painting is dead from today;" but still it lives, and will never be killed by photography, for this deals only with the objective. The imagination in it has no place. It cannot give to airy nothing a local "habitation and a name;" and while poets dream and ideal beauty beckons the painter will interpret them as best he may. It detracts nothing from the title of Daguerre to a place on the scroll of fame that the daguerreotype must be classed with forgotten processes. So beautiful were its results that they will always be regarded with interest, and it is possible that even now curiosity may here and there still cause it to find votaries; but from this begins the era of forgotten processes, for where are now the amphitype and authotype of Herschel, the calotype of Talbot, the hiergyatype of Hunt, the coffee process, the tobacco process, the Beechy process, and hosts of others—dear to their discoverers, but to few besides? Where are last winter's snows?

But the world owes a large debt of gratitude to men like Robert Hunt, who gave time and thought and money to the advance of this beautiful art. A few names stand out with especial prominence. Claudet, who, in 1841, discovered the use of bromine as an accelerator for daguerreotype plates, and made portraiture possible; Talbot, who invented the calotype process; Herschel, the astronomer, who discovered the use of hyposulphite of soda as a fixing agent; and, greatest of all results, Scott Archer, who, in 1851, with the generosity of a noble mind, gave to the world, free and unfettered, the collodion process. But although this latter, too, has been superseded by the gelatine process, the subjugation has not been complete; the two Richmonds remain in the field, and if the former is vanquished it still retires with strife. And now what shall be said of the future? Has perfection been attained, or are there still worlds to conquer? If we look at the work of the masters of the art, some of whom are present and whose blushes I will spare by not naming them, we might think that the last page was written, and that nothing more remained to be done. But it is those whose work is the best who see room for improvement, and who still go on and strive for perfection yet unobtained. Still remains the dream of photographing in colours—more a wish than an expectation; but the constantly-advancing uses of photography are no dream. The Woodburytype process enables portraits to be multiplied to any extent without fear of fading. The photogravure of Goupil makes collections of engravings despair, for the various "states" of a plate can be so exactly reproduced that no specimen can now be looked upon as unique if it has been in their possession. And its latest application, stellar photography, is perhaps to some the most interesting of all. The mind reels in contemplating the awful depth of space where worlds in myriads spangle the darkness like golden sands: or nebulæ in fantastic forms, the raw material of unformed systems, perplex the astronomer.

Photography is finding its way into book illustration, and it may be that, before many years are past, wood engraving may be driven from the field by its newest rival, and become a forgotten process, which is ever seeking new worlds to conquer. If, as it says in "Locksley Hall,"

"Science moves but slowly, slowly,
Creeping on from point to point,"

so far as photography is concerned it makes good advances.

Improvements in Photographic Cameras.

Alexander Crawford Lamb, Reform-street, Dundee.

The object of this invention is to enable photographic cameras to be carried conveniently in the pocket, while being readily opened up and adapted for use at any time.

The invention consists in connecting the front part of the camera in which is fitted the lens, and the back part or frame which carries the dark slide, by means of springs or spring bars which admit of the front and back parts being brought close together to close the camera, or opened out and rigidly held when it is to be used.

According to one modification of the invention the front and back frames of the camera are connected together by four jointed spring stays or bars similar to those used in collapsible opera hats, and fitted at each corner. Each spring stay is made in two lengths or bars, and jointed in the middle, so that it can fold inwards to close the camera. Between the parts of the stay bar a bearing shoulder is formed, and the bars are held in their distended position by means of helical or other springs which are attached to hooks or catches formed on the bars. When fully distended the two parts of each bar bear on each other at mid-length, and form a rigid stay. The stays thus formed at each corner suffice to hold out the camera in its open position. The usual bellows or dark cloth is connected to the end pieces to form the box-like body of the camera.

The inventor claims—first, the improved collapsible photographic camera; second, connecting the front and back parts of photographic cameras by means of spring stays.

Exhibition.

PHOTOGRAPHIC SOCIETY OF IRELAND.

[Final Notice.]

We have not up to the present mentioned the exhibits of the School of Military Engineering (Nos. 6, 266, and 493), all of which are remarkably well-selected views. We much admire the frame printed in platinotype.

We must not omit to draw the attention of visitors to *Views in the English Lake District* (No. 196), by Mr. Cecil V. Shadbolt, whose balloon views have already excited such wonder. We confess, however, that we would much prefer working *our* camera in the beautiful places which are depicted in this frame, in preference to the higher regions.

The two frames of racing or sailing yachts (Nos. 212 and 196), by H. Symonds, are very fine. We think it would have been better not to have vignetted some of them so much, unless there were substantial reasons for doing so, as it gives a too airy idea and takes away from the reality of the scene.

The Ploughman's Baggin' (No. 214) by Mr. L. Berry.—This title is not understood in Dublin, but adds the charm of a conundrum for the many admirers of the fine pair of horses, which are fully appreciated.

Some large direct pictures by Mr. G. Nesbitt are well worthy of study. No. 206 (a child looking through a frame which she holds on her knees) is rather stinted in idea and strained for effects; nevertheless it pleases the public, but we prefer any of the others shown by this gentleman. *Returning Home* (No. 222) depicts a girl crossing a stream on stepping stones.

Close by hangs *Instantaneous Sea Studies* (No. 242), by Mr. W. P. Marsh, which are really excellent, and some charming portraits (No. 238) by Mr. A. Debenham, the upper pair of children (No. 250) especially being very winning. Here hangs also the frame of small portraits by Mr. J. Lafayette, for which the silver medal was awarded. They are so numerous and so good that it is difficult to make a selection from such a creditable display.

In the inner room is the large collection of mechanical prints (or "photo. etchings," as they are labelled) by R. Schuster, to one of which, *Ein Auto-dafé*, a bronze medal has been awarded. The pictures bear a striking resemblance to the photogravure process of MM. Goupil et Cie., but are somewhat softer and possess greater delicacy in the detail with corresponding absence of depth in the shadows. They are well worth the inspection of print collectors.

The Hon. Assistant Secretary of the Society shows several frames, but we prefer No. 529, consisting entirely of interiors, which are really good.

The Old Town of Hastings (No. 524), by Mr. H. J. Godbold, is a fine instantaneous picture of a gale, showing a wave breaking against a house on the quay. We note, also, stowed away in this room, two fine views, *A Breaking Wave* (No. 718) and *The Folkstone Boat* (No. 720), which, with Nos. 717 and 719, are the contribution of M. Chas. Grassin, of Boulogne.

Mr. Edwin Smithells sends a very nice collection of *genre* pictures. We like *The Unfamiliar Tune* (No. 521), or the *Reverie* (No. 486). *Just Let Loose from School* (No. 264) by the same artist has also been much admired. In the inner room a small view (No. 605) by Mr. T. A. Green (inadvertently spelled "J. A. Greene" in our last notice), the winner of the silver medal for large landscapes, is worth examining. It is not well placed and might be overlooked.

A large collection of ceramic photographs sent by Mr. H. N. White are staged in the ante room or hung in the inner room, and some of them are good examples of their class.

In concluding our notice of the pictures we are fully conscious that we may have omitted much that would be well worth drawing attention to, but out of eight hundred exhibits it is not humanly possible to give to each the attention they might deserve were time of less object than it is.

Apparatus.

Although there is not a large display of apparatus, still a particularly interesting collection—especially to amateurs—has been got together. In considering the quantity it must not be forgotten that many well-known makers do not care being exhibitors, for the principal reason, in our opinion, that the goods sent are likely to be injured; in fact, if one considers the number of people who take on themselves to handle them—a great proportion of whom know nothing about such instruments, and who seek in a very unscientific manner to find out for themselves how and when they bend or open, and in doing so cannot fail to cause injury—it is often to be wondered that any at all are sent. We note that the committee of the Exhibition have reduced this complaint to a minimum by providing locked glass cases containing the more delicate apparatus and lenses, thus ensuring their safety. Any genuine inquirer could have the cases unlocked by the Curator, who would afford every facility for *bonâ-fide* examination, and in many instances information on certain improvements which even an intelligent investigator might not readily discover for himself.

We note that a bronze medal has been awarded to Mr. J. V. Robinsen, of Dublin, for his improved patent camera. From our own knowledge of it as a working instrument we would prefer it to any we have ever used. It is extremely difficult to convey its peculiar points; but the folding fronts into the back, the manner by which the swings are obtained, the reversing arrangement (which, by-the-bye, is known and used in the camera trade in Paris, and consequently not original), and the circles on which the lens is mounted are all valuable improvements, fully justifying the special award of the Committee.

Mr. Thomas Mayne, of Dublin, shows a collection of various camera stands, ruby lamps, &c.

Messrs. Watson and Sons, and Messrs. J. F. Shew and Co., of London, also make a good display. Amongst the novelties shown for the first time in Ireland are the plate-box with glass bottom, intended to facilitate the examination of the contents for the satisfaction of custom-house officers, and the folding tripod stand, which closes up sufficiently to go into a small bag or portmanteau.

A number of instantaneous shutters are also well worthy of inspection—by amateurs in particular; indeed, we are glad to see that this section of the Exhibition is attracting the attention of almost all the practical visitors to the rooms.

As nothing "succeeds like success" we are glad to be able to announce that, financially, the Exhibition has produced much better results than was to have been expected when taking into account that the Committee had to defray all the carriage on the exhibits, and it has been proved by the number visiting it that the venture is fully appreciated. We hope, therefore, to see it repeated even on a greater scale three years hence, if not considerably sooner; in fact, it becomes now an important duty of the Photographic Society of Ireland to see this carried out.

The usual Monday evening lantern exhibition, on the 1st instant, was largely attended, although we would like to see this portion of the programme receive more attention in its details than seems to have been devoted to it. We speak critically and from a photographic-art point of view solely; for we have reason to know that the major portion of the audience were evidently pleased with the entertainment, and "where ignorance is bliss" it is, perhaps, "folly to be wise."

" 11....	Manchester	Manchester Technical School.
" 12....	Ireland	Royal College of Science, Dublin.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on the 27th ult., the chair was occupied by Mr. W. Cobb.

Mr. W. M. Ashman said that he had had a batch of plates which frilled persistently. He tried various methods of treatment without being able to get over the difficulty, until he thought of increasing the temperature of the developing solution. He tried this and found that it proved successful.

Mr. Trinks had for a similar trouble adopted a method which was in part the reverse of that employed by Mr. Ashman. After an hour's soaking in a solution of chrome alum he had developed in a dish surrounded by a freezing mixture—nitrate of ammonia. This proved effectual. Mr. Trinks then passed round a negative which, in the first place, had been placed in a dish of ferrous oxalate to develope. No image appearing after some time the pyro. developer was tried, and this had the effect of turning the whole of the film jet black. The plate was next immersed in a mixture of hydrochloric acid and water and the image appeared.

Mr. A. L. Henderson, reverting to a suggestion made at a previous meeting by Mr. F. W. Hart, to use bichloride of mercury as an antiseptic in a finished emulsion, said that he intended to try it in place of thymol.

He thought that it would be less likely to be influenced by the action of the atmosphere, and that it would at the same time harden the film and prevent frilling.

Mr. W. K. Burton remarked that he had been experimenting in the sensitising of albumenised paper with a view to obtain some test of the length of time required for floating with different papers and under different conditions. He demonstrated a method which he thought should be a good indication of the paper being brought into the proper condition. He applied a solution of potassium chromate to the back of the paper previous to floating. The change of colour in the part of the paper so touched, caused by the formation of chromate of silver, indicated that the paper had been floated for a sufficient length of time, and the time occupied in doing this was that which should be given to the particular paper on that strength of bath.

A set of prints forwarded by Messrs. Marion and Co., and printed by development upon their new paper, was then passed round. The tone and character of these productions were considered so unlike those associated with prints by development as to be indistinguishable from gold-toned albumen paper proofs.

Mr. Trinks inquired what was the experience of members as to the relative exposure required to bring out details when using the pyro. developer and that prepared with ferrous oxalate. His own practice was to find that pyro. would act with a somewhat shorter exposure than iron.

Mr. A. Cowan remarked that Captain Abney had stated that most detail was brought out by iron development when the solution was prepared in the old-fashioned way with oxalate of potash and ferrous oxalate.

Mr. Ashman had found that he could considerably reduce the exposure by using Monro's developer.

Mr. F. W. Hart said that he had further reduced the exposure to one-thirtieth part of what would otherwise have been required, by using caustic potash and pyro. He thought, however, that this developer was too energetic for practical purposes, and it produced fogging.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

The second general meeting of the session of the above Association was held in the Religious Institution Rooms on Thursday evening, the 27th ult.,—Mr. John Urie occupying the chair. The minutes of last meeting were read and approved. The question-box contained nothing of interest. Mr. Wm. G. Tannahill was elected a member of the Association.

Mr. Patrick Falconer initiated an interesting discussion on the best medium for the dark room, which was continued by several members. Numerous specimens of different-coloured glasses were shown; also some dry plates which had been exposed to different lights.

The Chairman promised to give a demonstration on the daguerreotype process at some future meeting.

After the usual vote of thanks the meeting was adjourned.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The annual meeting of this Association was held on Thursday, the 27th ult.,—Dr. Kenyon, President, in the chair.

The minutes of the October meeting were read and confirmed, and Messrs. Atkinson, Pooley, Pawson, Roose, Taylor, Webster, and Webb were elected members.

The appointment by the Council of officers for 1885 was then read by the Hon. Secretary, and confirmed by the meeting, as follows:—*President:* Mr. J. H. Day.—*Vice-Presidents:* Mr. A. W. Beer and Mr. P. H. Phillips.—*Treasurer:* Mr. J. H. T. Ellerbeck.—*Council:* Messrs. W. Atkins, Rev. G. B. Banner, Rev. T. B. Banner, Mr. R. Crowe, Mr. J. A. Forrest, Dr. Kenyon, Mr. W. H. Kirkby, Rev. H. J. Palmer, Mr. H. Rutter, Rev. A. J. Scott, Mr. E. Twigge, and Mr. W. A. Watts.—*Librarians:* Messrs. R. Crowe and W. W. Hughes.—*Auditor:* Mr. W. H. Wharmby.—*Hon. Secretary:* Mr. H. N. Atkins.

The Hon. Secretary read the annual report as follows:—

Annual Report.

At the close of the twenty-first year of the Liverpool Amateur Photographic Association the President and Council have every reason to repeat their annual congratulation of the members upon the increasing prosperity and usefulness of the Association.

The accession to the numbers of names on the books has been the largest annual increase recorded in the archives of the Society. Thirty-seven new members have been elected. There have been seven resignations, and no losses during the year by death. The numbers of members on the books at the close of each of the last five years are as follows:—1880, 71; 1881, 78; 1882, 93; 1883, 115; 1884, 145. There has been no falling off either in the interest of the monthly meetings of the year or of the numbers of members attending them.

The following papers have been read:—*Liverpool to Trieste in a Cunard Steamer.* By Mr. G. A. Thompson.—*Development of Instantaneous Negatives.* By Mr. J. H. T. Ellerbeck.—*Development of Instantaneous Negatives.* By Mr. Watts.—*A Day's Photography at Hawarden.* By the Rev. H. J. Palmer.—*On Enlarged Paper Negatives.* By Mr. H. N. Atkins.—*Stellar Photography.* By the Rev. T. E. Espin.

Mr. H. N. Atkins gave a demonstration of his method of enlarging.

During the summer months numerous excursions have been made under the auspices of the Association, and these were productive not only of much enjoyment but of profitable photographic experience and work. Among the most successful of these excursions may be mentioned those to Rufford, to Beeston Castle, and across Mid-Shropshire from Shrewsbury to Wenlock.

Donations to the Library have been received from Captain Abney, Rev. H. J. Palmer, Mr. Watts, Mr. Maurice Jones, and Mr. Stott; and to the album from Messrs. H. N. Atkins, Watts, Williams, Hartley, Wharmby and others.

The beneficial effect of the annual competitions, as incentives to useful emulation, and as spurs to careful and artistic work, has shown no diminution in the past year, and the Council trust that the subjects selected for the competition of 1885 will be productive of a similar satisfactory result. These subjects are as follow:—"Instantaneous," "Farm Yard," "Rocky Shore," "Stereoscopic," "Cottage Door," "Animal Study," "Interior," and "Shipping or Marine."

At the annual *soirée* in St. George's Hall, given by the Associated Artistic and Scientific Societies of Liverpool, our Society contributed a large and interesting exhibition of pictures and apparatus, and the Rev. H. J. Palmer gave a popular lecture on *Mountain Passes among the Alps*, with lantern illustrations from his own negatives.

A presentation print will be selected by the Council before the close of the year for distribution among the members.

The labours of the Hon. Librarian, Mr. J. H. Day, in the past year have been so arduous, and, moreover, so acceptable to the members of the Association, that the Council have requested two gentlemen to undertake the office, the one acting as coadjutor to the other, and they are glad to say that Messrs. Crowe and Hughes have consented to share the duties of the office.

The thanks of this Association are due to the Library, Museum and Arts Committee of the Corporation of Liverpool, for the use of the meeting room in the Free Library; to the Photographic Society of Great Britain for copies of the *Journal;* to Messrs. Scovill, of New York, for copies of the *Photographic Times;* to Mr. F. H. Davies, of Chicago, for copies of *Photography;* to the Liverpool Engineering, Microscopical, Field Naturalists', Philosophical, Philomathic, and Geological Societies, and to the Newcastle Photographic Association, for copies of the annual report of their proceedings and transactions.

Mr. A. Boothroyd proposed, and Mr. W. H. Kirkby seconded, a resolution that the report be adopted. This was carried.

In the absence of the Hon. Treasurer from illness, Mr. Wharmby read Mr. Ellerbeck's report, which showed a balance in hand of about £40. This also was passed.

The Rev. T. B. Banner spoke very warmly of the labours of the Hon. Secretary now about to retire from his post.

The Chairman also referred in complimentary terms to the Secretary's work on behalf of the Association.

The Rev. H. J. Palmer expressed his cordial thanks not only to the Rev. T. B. Banner and Dr. Kenyon for their kind words with regard to him, but also to every member of the Society, both present and absent, for their kindly feeling towards him, and for their forbearance in overlooking the many inefficiencies and neglectfulnesses of the discharge of his somewhat onerous duties.

The Chairman announced donations to the Library from the Rev. H. J. Palmer and Mr. Stott.

Mr. J. H. Day called attention to the large number of subscriptions still unpaid.

Mr. A. W. Beer moved an addition to the Rules, of which notice had been given:—"All members elected on and after the January meeting, 1885, shall pay an entrance fee to the Treasurer of ten shillings and sixpence" He (Mr. Beer) pointed out that, with the exception of the present year, an increase in the number of the members of the Association had invariably been followed by a decrease of the balance in hand at the close of each financial year. This was due to the fact that the meetings were now much more largely attended than of yore, and the consequent expense of the tea provided had been greatly augmented.

Mr. Day seconded the resolution, and, after discussion, it was adopted.

The Chairman reminded the members of the *soirée* in St. George's Hall on December 10th, and gave notice that all exhibits for the Association's display should be sent to Mr. Ellerbeck, 54, Bold-street, on or before December 9th, or on the 10th to the Committee in St. George's Hall.

Mr. Day proposed the re-election of the members of the Hanging Committee who had acted last year, namely, the Rev. H. J. Palmer, and Messrs. Beer, Crowe, Forrest, Guyton, Paris, and Whiteman.

Mr. Tyerman seconded the resolution, and it was carried unanimously.

At this point the judges in this year's competition—Messrs. Beer, Pelham, and Thompson—entered the room, and Mr. Pelham announced the awards as follows:—

Subject.	Prize.
The Brook	Mr. W. H. Kirkby.
Cattle	,, J. H. T. Ellerbeck.
Fruit	,, P. G. Hall.
Architecture	,, W. H. Kirkby.
Mountain Forms	,, P. G. Hall.
Snow Scene	Not awarded.
Shipping	Mr. J. H. Day.
Repose	,, P. G. Hall.
Own emulsion	,, W. H. Kirkby.
Best set of pictures	,, P. G. Hall.
Best picture of all	,, P. G. Hall.

The Chairman cordially thanked the judges for their kindness in officiating, and for the trouble they had taken in making their decisions.

Dr. Kenyon then proposed for re-election the names of the following gentlemen as hon. members:—Messrs. Thompson, Riley, and Banks.

Mr. Kirkby seconded this, and these gentlemen were re-elected, *nemine contradicente.*

The Chairman said that the Council would be glad to receive negatives suitable for enlargement for this year's presentation print, and requested that such negatives should be sent to Mr. Ellerbeck, 54, Bold-street, on or before Monday, December 15th.

Mr. Phillips proposed, and Mr. Beer seconded, a resolution that the following by-law, recommended by the Council, be adopted:—"That after due notice has been given by the Treasurer, if arrears of subscriptions be not paid within three months, members in arrears shall cease to receive notice of meetings." This was passed.

The members then adjourned to a lower room for the inspection of the competition pictures of the present year.

Correspondence.

[*All communications for the* EDITORIAL *department of the Journal should be addressed to the "Editors, 2, York-street, Covent-garden, London, W.C."*]

LANTERN TRANSPARENCIES AT THE RECENT EXHIBITION.

To the EDITORS.

GENTLEMEN,—In the letters on the above subject in your last issue, signed "George Smith" and "William Brooks," there are statements regarding matters of fact which are incorrect. Will you allow me to state that Mr. Gale personally handed to the Assistant-Secretary at the Gallery before 9 p.m., on Thursday, September 25th, a box containing twenty lantern slides made by himself from his own negatives, together with a letter of advice; that these were the only slides received from him; and that they are the same slides that were shown on the screen before the judges at the time of the competition for the medal.

The paragraphs in the Society's circular relating to lantern slides read as follows:—"Slides (which must not exceed three and a-quarter inches in height) must be sent in either on or before Thursday, September 25 (to come with other exhibits before the Judges of Awards), and will only be eligible for award when both the negatives and the slides are the work of the exhibitor. . . . The Judges are instructed to reserve one medal for lantern transparencies (if they find them worthy of awards)." It will be seen, therefore, that the award was made strictly in accordance with the regulations.

I say nothing at present with regard to the other allegations in the letters referred to, which are either beside the point at issue (the legality of the award), or are matters of opinion only.—I am, yours, &c.,

W. F. DONKIN,

November 26, 1884. *Hon. S.c., Photographic Society of Great Britain.*

[Owing to delay in transmission through the post this letter unfortunately reached us too late for insertion in our last issue.—EDS.]

THE LATE PALL MALL EXHIBITION.

To the EDITORS.

GENTLEMEN,—You were good enough to mention in your review of the late Pall Mall Exhibition my pictures, *To the Rescue* and *Rescued*, and you described them as being sensational.

From remarks I have since heard I find there is a prevalent idea that they are sensational in what I may be allowed to call its worst or theatrical sense. I am told that the rocket and line are printed in, so as to make a sensational picture, but I wish to explain that such is not the case. It is really a true transcript by photography of a scene which occurred near here. I consider it the most extraordinary photograph I have ever taken, or that I ever expect to take. Such conditions are hardly likely to occur twice in a lifetime. *Rescued* is also a true photograph of the lifeboat containing the crew of this shipwrecked vessel "Isabella" (the same as in *To the Rescue*) reaching the shore.

Those only who have tried to plant a tripod among beach stones during a strong south-west gale, upon a shore where there is no cliffs to shelter, can appreciate the difficult conditions under which these pictures were produced. It is impossible to focus even if you could guess at what point the vessel would approach the shore.—I am, yours, &c.,

8, *Grand Parade, St. Leonards-on-Sea,* H. J. GODBOLD.
December 3, 1884.

OXALIC ACID IN THE DEVELOPER.

To the EDITORS.

GENTLEMEN,—Confirming what I wrote last week, I have now to add that I find the oxalic acid is better for an over-exposed negative, and the *liquor potassæ* (B.P., sp. gr. 1058) for an *under*-exposed negative.

I should recommend operators to begin with the developer and oxalic acid, and if the picture do not come out pour off this developer; then mix some more with the *liquor potassæ* without the oxalic acid, and I think it will be found that the latter will bring out all there is to get out. I have had to give up cyanide of potassium as a fixer, the fumes being disagreeable, if not worse.—I am, yours, &c., W. T. F. M. INGALL.

Greenhithe, Kent, November 27, 1884.

"LANTERN SLIDES ON COMMERCIAL PLATES."

To the EDITORS.

GENTLEMEN,—A very characteristic and interesting article has just appeared in your Journal on the above subject by Mr. A. Pringle. The information covered a large field of chemical diagnosis (if the term may be allowed); but may I be permitted as one who is not a "tender plant," and has not the misfortune to be forbidden access to my dark room by an over-zealous medical adviser, to offer a few plain jottings on the subject.

Just now, while the days are so short, we need to have our hands at work in the long evenings at something instructive and useful lest they should be tempted into less profitable exercises. I had recent occasion to communicate my experience with a novel developer in transparency work on gelatine plates. This I emphasise in contradistinction to albumen and chloride and other well-known commercial products. However, it is one thing to make experiments and another to secure the best *final* results under a *practical* test.

This I have done with some transparencies I recently made with the soda formula now well known to the readers of the Journal. Last night I had a party of young people at my house, and gave them a magic lantern entertainment—using, of course, the lime light, &c. The results were most satisfactory in every respect, and elicited from the adult guests the greatest admiration for vigour, clearness, and exquisite detail in the shadows.

Now, the point I wish to emphasise is this—that there is a subtle power in common washing soda (of course with the adjuncts of a now tested and recognised formula), to develope a latent image on a purely commercial gelatine film which no agent has to my knowledge hitherto done. This is a point which has not been touched upon in Mr. Pringle's communication, and I was much disappointed when I discovered the omission. We all know about the successes of albumen and chloride plates by careful and conscientious adherence to the published formula of their respective authors; but we have yet to know that silver salts, so fearfully and wonderfully supported in a gelatine pellicle, may be acted upon in some very mysterious manner through an agent other than the pungent fumes of ammonia (an agent not only injurious to the valuable health of Mr. Pringle but all other unbelievers in that very commonplace factor in the cleansing influences of the wash-tub of the laundress, namely, common washing soda), or even the ferrous oxalate developer.

Some very erudite thinker has remarked "that facts are stubborn things" (I don't know what he means). As far as my experience is concerned facts are nothing of the kind; indeed, on the contrary, they are most pliable, interesting, and amiable, for I have obtained as results from the use of this agent the most refreshing surprises and albeit uniform successes. Does it not commend itself to the unhappy experience of some of my readers that *ammonia fort.* is not a very reliable agent under the most favourable conditions, not to speak of the least favourable? *Verbum sat.*

I noted a further assertion in Mr. Pringle's jottings which all but took my breath away. He notes his experience thus—"I found that negatives absolutely or all but unprintable in silver, carbon, or platinotype yielded first-rate slides for the lantern." I had almost to hold a chair when I read it. The fumes of *ammonia fort.* were nothing to the sensation it caused me. I at once thought of the large number of deceased negatives lying in a corner of my churchyard (the nearest alluvial soil to my study), but the ghastly thought sickened me. I recoiled from it with religious horror, and continued strong in my conviction that it was a most unlikely contention and far too good to be true. He tells us that those dead negative failures lying in his garret and cellar were unearthed from their limbo, and in spite of mere "technical imperfections" did good service afterwards as "first-rate lantern transparencies." Verily, startling surprises will never cease. I fancy this will not be the experience of the majority of transparency workers. It certainly is *not* mine. I have come to this sober conclusion, after a considerable number of failures in the production of lantern transparencies, that the faintest trace of any "technical imperfection" in a negative will be fatal to the hope of a decent, not to say a superior, result.

Just one point more and I have done for the present. A great bugbear of Mr. Pringle's transparency work he admits to be the well-known difficulty of not knowing when to stop. He has the *Scylla* of the "blocking up" difficulty on the one side, and the *Charybdis* of the ghostly image on the other. Poor fellow! No wonder he is often perplexed! (and all this, too, in the teeth of medical advice). I feel deeply for him. Will he accept in the generous spirit it is offered the suggestion of a certain cure for the misery of the dilemma which hedges him? Try the formula I have suggested honestly and then stick to it, and at the same time give to Messrs. Genlain and Edwards all the credit of what is without doubt one of the most remarkable discoveries in the annals of photographic research. H. VICTOR MACDONA, M.A.

The Vicarage, Cheadle-Hulme, Stockport, November 29, 1884.

THE MERCURY INTENSIFIER.

To the EDITORS.

GENTLEMEN,—I send you an improved formula for the mercury intensifier:—

A.

Bichloride of mercury; bromide of potassium { Equal quantities in solution.

B.

Cold saturated solution of sulphite of soda.

The addition of the bromide causes a quicker deposit, also a less loss of density in passing through the sulphite solution. The sulphite of soda requires to be full strength.—I am, yours, &c., J. C.

Southport, December 3, 1884.

ENLARGING APPARATUS.

To the EDITORS.

GENTLEMEN,—As the introduction of argento-bromide paper offers such great facilities for the production of enlargements, I, for one, should be very glad if some of our practical brethern would suggest the best way to make an inexpensive enlarging apparatus oneself.

I was present at the demonstration given by M. Hutinet, of Paris, some time ago, and if I recollect rightly the apparatus consisted chiefly of a box containing an argand gas burner. About six inches from that was a piece of ground glass to diffuse the light on the negative, which was placed three inches in front of the latter; then a bellows camera and a lens, which projected the enlarged image on the prepared paper, and was for convenience held in a frame under glass, supported on an easel. M. Hutinet employed gas as the illuminating power; but would not paraffine give a more actinic light? I have tried the latter, but have not been successful in obtaining sufficient intensity of light to cover (say) an $8\frac{1}{2} \times 6\frac{1}{2}$ negative. Enlarging by the lantern is, of course, practical with small negatives, but we often require to enlarge from $8\frac{1}{2} \times 6\frac{1}{2}$ or larger view negatives, and I think the suggestion of a plan of easily producing these enlargements would be a great boon to many a photographer.

I failed to notice whether a reflector were used to concentrate or diffuse the light. This would, of course, be an important point.

Basingstoke, December 3, 1884. CARL STACKEMANN.

Notes and Queries.

A. H. BAILEY inquires if there be any difference except in name between the present collodion transfer pictures and what used to be called "photo-crayon" portraits.——In reply: There is a very great difference between the pictures styled "photo-crayons" and those known as "collodion transfers." The former is a thin collodion transparency on glass, which is backed up with tinted or white crayon paper. On this paper are some hatched lines which, when judiciously used, give the finished and framed picture very much the appearance of a crayon drawing. A collodion transfer is a similar collodion transparency, though somewhat more intense, but with the film transferred from the glass to paper.

G. B. B. asks why it is that when he proceeds to develope some of his carbon prints on a flexible support many of them frill round the edges, while others do not? He adds—"Singularly enough, all those I print with a masked border—that is, those with a white margin round the picture—never frill."——The querist has unconsciously told us the reason of his failure. Those pictures which do not frill are provided with what is known as a "safe edge" in the shape of the mask. In carbon printing it is always necessary that the edges of the tissue be protected from the action of light, and this in our correspondent's case is done by the mask. If he will paste a slip of opaque paper or run a narrow band of black varnish round the edges of all his negatives he will no longer be troubled with frilling.

R. W. wishes to know the influence of nitrate of silver upon albumen.——Nitrate of silver gives a white precipitate in albumen, which precipitate is soluble in ammonia. The precipitate contains 16·15 per cent. of oxide of silver, and while moist it turns black in the air, even in the dark. Solutions of nitrate of silver containing a large excess of acid give, on the addition of albumen, a precipitate containing but 8·9 per cent. of oxide of silver, which lessening of the affinity for the oxide throws some light, perhaps, upon the preservative effect upon albumenised paper of the organic acids. The yellowing of the whites rather than the fading of the blacks of prints on albumenised paper is the point which demands the attention of chemists. Something should be done to remove the slur upon the historical value of present-day photography by abolishing fugitive positive prints.

"HAVING seen a strong recommendation in your columns to use india-rubber gloves for developing and other operations where the fingers are liable to become stained I bought a pair the other day, but they are practically useless. I cannot get them off without peeling them—that is, turning them inside out; then they take so long to put right again, and in the operation get so soiled as to stain all my hand instead of my fingers only, as occurs without gloves, that I am ten times worse off than when not using any such help. As they are such expensive articles I write to warn others against buying them.—J. OWEN."——You are quite right in holding yourself up as a warning to others; but the warning is to take better notice of what you read. There are india-rubber *and* india-rubber gloves, one sort being just as useless as you describe. As much as this was stated in the article to which you refer. You should, if you use gloves with fingers, purchase the cloth-lined sort, not too tightly fitting. You will find that they will slip on and off in an instant, and after a little practice you will be as well able to work with them as without. The objection to them is their liability to wear or, perhaps we should say, cut in handling plates. We would rather recommend, particularly for dry-plate work, the use of mittens—fingers all in one piece; there is less wear upon a single spot. Those of thick, unlined rubber may be used easily if too small a size be not chosen, and then an immense amount of wear can be got out of them.

J. E. G., Westward Ho., asks which of the following we would recommend for his dark room, which faces north:—1. Ruby.—2. Stained red.—3. Cathedral green, with canary medium.——In reply: Stained red, flashed with oxide of copper on one side and oxide of silver on the other, is better than ruby. With artificial light and the strength of the flame, together with the distance from the lantern at which development is effected, intelligently regulated according to law, No. 3 is likely to give the best light. When daylight is used canary medium is risky, because of its imperfect colour. What safety it gives is due chiefly to its thickness. The strongly-yellow bookbinders' cloth, in two layers, would be better for daylight. With variable daylight as the original source, so good a light in the developing room cannot be obtained as from a steady flame always of the same size and at the same distance behind the screen. The lantern should have all four of its sides a translucent yellow, and not one side alone translucent with the other three opaque. The light from the other three sides does not fall directly upon the developing dish, and it assists with safety in the general illumination of the room. Every operator should ascertain by experiment the fogging power of his developing-room light upon each make of plates—say at one foot distance from the screen. It gives him courage in his work, and, when fogging occurs, prevents his occasionally ascribing it to the wrong cause. Many undeserved sins are credited to the uncomplaining light of developing rooms.

"I ENCLOSE plan of my premises and my neighbour's. I should like your advice on the subject of the lights I have put out, having gone to great expense. You will perceive I am more than six feet from my neighbour's house, yet he has sent me a letter threatening me with legal proceedings if I do not take down the new lights which overlook his premises.—THETA."——In reply: Let us first inform you that, in cases of rights of light, questions of six feet, five feet, or any number of feet, have nothing to do with the matter, the popular superstition notwithstanding. So long as you do not encroach upon your neighbour's property by throwing out window sills, spouts, &c., where none projected before, there is no legal process whatever, either in common or statute law, to make you remove either your windows, lights, or even a single pane of glass. His only remedy is to block them up. He cannot knock nails into your wall; but he may build against it any erection that will shut out your light, provided you had no rights of light—that is, no window previously existing in the same wall upon which your side-lights now are. It would seem reasonable to suppose from your plans that there must have been windows already there, and in that case if he erect anything to block up your new lights it must not interfere with your old lights in the slightest degree. If he should do this you could sue him for damages, or obtain an injunction to restrain him from continuing his obstructions. The latter is a very expensive procedure, and, whatever the result, would leave you out of pocket considerably, even if you gained the day "with costs."

Exchange Column.

No charge is made for inserting these announcements; but in no case do we insert any article merely OFFERED FOR SALE, *that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a* NOM DE PLUME *be thought desirable), otherwise the notice will not appear.*

I will exchange a slide tinter or other sciopticon apparatus for photographic apparatus.—Address, S. WELLS, Goole.

Wanted, a sciopticon lantern, in exchange for a twelve-inch burnisher in perfect condition.—Address, ALEX. WALKER, photographer, Larbert, Stirlingshire.

I will exchange a hot rolling-press, *carte* size, and gem camera, twelve lenses, for interior backgrounds.—Address, A. JENNINGS, photographer, Skipton, Yorks.

I will exchange stonework pedestal, balustrade, and steps, for a round-backed garden seat and garden scene.—Address, A. WARD, 54, Brixton-road, Kennington, S.E.

I will exchange a pair of double dry-plate slides, $7\frac{1}{4} \times 4\frac{1}{2}$, for a sciopticon camera or Lancaster's quarter-plate *Le Merctoire* apparatus.—Address, JAMES THOMSON, Tynes, Fochabers.

I will exchange a large portrait lens, four-inch diameter, seventeen-inch focus, for 8×6 or 10×8 pictures. What offers?—Address, G. POIRIN, 2, Eardley Villas, Eardley-road, Streatham, S.W.

I will exchange a 10×8 burnisher, worth £2, and two ornamentally-wrought L gas pendants, cost £3 10*s*., for a 15×12 sliding-body camera or a good *carte* repeating-back ditto.—Address, 149, Cheltenham-road, Bristol.

I will exchange a first-class enlarging-lantern, four and a-half-inch condenser, also $8\frac{1}{2} \times 6\frac{1}{2}$ lenses, by Ross, cameras, rolling-press, &c., for anything useful.—Address, W. SLATER, 282, Albany-road, Camberwell

I will exchange a Right and Butler patent eclipse heating stove, five burners, in good condition, do nicely for a green-house, for anything useful in photography.—Address, F. LEWIS, 70, Station-street, Burton-on-Trent.

I will exchange two plano-convex lenses, three and a half inches diameter, mounted in wooden block for condensers, for something useful in photography.—Address, W. A. W., Charlesville, Farnworth, Widnes, Lancashire.

Wanted, a whole- or half-plate wide-angle rectilinear lens, also a half-plate bellows-body camera, in exchange for high-class oil or water-colour paintings.—Address, ARTIST, Claremont Cottage, White Hart-lane, Barnes, London, S.W.

Gem camera, new, in exchange for backgrounds, head-rest, &c.; also steam pressure-gauge, fret machine, castings, and wire for dynamo, in exchange for photographic apparatus, &c.—Address, W. W. EVERS, Wath, near Rotherham.

I will exchange a mahogany biunial lantern, by-pass gas dissolving tap, safety jets, achromatic objectives, with rack, four-inch condensers, a quantity of slides, effects, &c. What offers in good apparatus, &c.?—No. 6B, Norfolk-row, Sheffield.

I will exchange four large backgrounds on rollers, $7\frac{1}{2} \times 7\frac{1}{2}$ mahogany sliding folding-back camera complete, and two head-rests, for Dallmeyer's 2B or other good portrait lens.—Address, N. E. WHITE, 77, Crofton-road, Camberwell, S.E.

I will exchange a nickel-plated cabinet rolling-press and a handsome asbestos gas fire-stove for a rolling-press or burnisher, to take 12×10 prints, or a studio camera in good condition; difference adjusted.—Address, T. S. HICKS, 141, Cemetery-road, Sheffield.

I will exchange a good thirty-hour revolving night clock, with opal globe and lamp, almost new, cost 30*s*., or a seven-foot mahogany folding bagatelle board with cue, for a good tourist's quarter-plate bellows-body camera, with double dark slides, to take plate horizontal or vertical.—Address, A. CLARK, 48, Wellington-street, Woolwich.

Wanted, a symmetrical or wide-angle landscape lens, in exchange for Woodbury and Marcy's patent sciopticon lantern; also excellent 10 × 8 double dark slide in exchange for a good instantaneous shutter.—Address, H., Levens Hall, Milnthorp, Westmoreland.

What offers for superior archimædian double-geared studio stand, large grass mat, several backgrounds, interior and exterior, cabinet burnisher, small operating van, large rolling-machine, and several chromo printing-frames?—Address, JOHN HODGE, 31, Union-street, Stonehouse, Devon.

I will exchange a four-inch centre Brittania Company's lathe, back gear, 3 feet 6 inches gap bed, extra-large face-plate, and all tools and fittings, cost over £18, quite equal to new; also Hughes's six guinea pamphengos, new, and Entrekin's cabinet burnisher. Wanted, a 12 × 10 camera, for outdoor work, with double slides, and a studio camera and lens, and studio stand.—Address, W. DAKIN, Parade Chambers, 1, High-street, Sheffield.

I will exchange a rapid tricycle, with luggage rest, lamp, and gong, capable of carrying whole plate, outdoor kit, reversible gear for hill climbing or speed, in good condition, for a good studio or field camera and lens for *cartes* and cabinets. Camera must be in good condition and lens by good maker.—Address MANAGER, the Studio, Wote-street, Basingstoke, Hants.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

NOTICE.—*Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when though desirable, appear under a* NOM DE PLUME *as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.*

PHOTOGRAPH REGISTERED.—

Miss Catherine Midleton, Anglesea-place, Southampton.—*Photograph of the Standback.*

ERRATA.—In Mr. W. H. Harrison's article last week for "condemn real glass utterly," *read* "condemn *red* glass utterly." In last paragraph of *Notes and Queries*, for "sufficient nitrate of soda" *read* "sufficient *citrate* of soda.

AN INCANDESCENT PLATINUM LIGHT.—See reply to "Asbestos" in our issue for last week.

W. H. M.—The work is, we believe, out of print, but you may be able to procure a copy by advertising.

O. O. O.—We shall write to you privately. Thanks for the promised article. Kindly forward it at once.

H. A. B.—In putting the lens together you have evidently reversed the components. The remedy is obvious.

AMATEUR.—A stove on the principle of the calorigen will answer best. Do not let the temperature exceed 80°.

A SIX-DAY TRADESMAN.—Your letter is too strongly worded for publication; besides, the matter has been sufficiently discussed.

PUZZLED.—If you adopt the plan of mounting described a few weeks back you will not be troubled with the cockling of the mounts.

PEMBROKE MARSHALL.—At the moment we do not remember to what you refer. We certainly do not recollect the gentleman's address.

LANTERN and one or two other correspondents have not conformed to our rule by sending their names and addresses; hence their communications remain unanswered.

K. A. Y.—The cause of your failure is very obvious if you have been using the salt of which you enclosed a sample, as that is the iodide and not the bromide of ammonium.

TOODLES.—The block appears to be by the Miesenbach process. We do not know if the Miesenbach Company grant licenses to work their process. Write to them; their address is Farringdon-street, E.C.

THE BICHROMATE DISEASE.—Several correspondents who have made inquiries on the subject will find their queries answered in a leading article in last week's number, to which they are referred.

ASPIRANT.—To make the colours "take" on carbon prints rub them over with a piece of fine felt charged with cuttle-fish powder. This must be very finely powdered, otherwise it will scratch the picture.

HERTS.—We should advise you to build the studio according to sketch No. 2. There is very little difference practically between it and No. 3, except that the former will be the more convenient to work.

H. BOWMAN.—So far as we can see the pictures appear to be *bonâ fide*, and not, as you surmise they are, produced by "some dodge or trick." There is no reason why they should not be what they are represented as being.

SPOTTER.—Try the effect of spotting the prints with oil colour and allowing it to thoroughly dry. The oil colour sold in tubes and thinned with turpentine will, we think, answer your purpose. If it do not, write again.

R. M.—Your failure may be due to one of two causes:—First, that the paper you are using is not one which will yield black tones: second, that the negatives are not vigorous enough even if the paper be of the right character.

A. G.—The address of the Willesden Paper Company is Willesden, Middlesex, N.W. The best material with which you can coat the wooden vessels, so as to render them waterproof, is paraffine wax. That will have no effect on silver solutions.

J. J. W.—From the very insufficient data you give we can scarcely hazard an opinion as to the cause of the spots. From what we can see you have allowed air-bubbles to remain between the prints while they were in the fixing solution or in the first washing waters.

F. J. SHARPLES.—From the appearance of the plates we imagine you have forgotten to iodise the albumen. If this be the case no wonder you have failed. If you had followed the instructions as published you should have obtained a very different-looking plate.

GEORGE DRUMGOOLE.—The water in which you have washed the prints has evidently been contaminated with hyposulphite of soda. Perhaps you used the same dish for washing in which you had previously fixed some prints, and it had not been thoroughly washed.

A STAFFORDSHIRE AMATEUR.—Your difficulty arises from adding too large a proportion of alcohol to the emulsion. As you do not say the quantity you have used we can scarcely set you right, but you will do well to try with half of what you have been using hitherto.

H. B. J.—By all means, for that size of slide, have three and a-half inch condensers. We recommend you to get a "blow-through" jet until you have had more experience with the lime light. When you have gained this then you may with safety adopt the mixed jet.

G. MITCHELL.—The failure in your first essay in the collodion process, no doubt, proceeds from your using such a very old sample of collodion After keeping for "six or seven years" the pyroxyline has, doubtless, become decomposed. Try again, and use a collodion of more recent make.

A. X. A.—The markings on the negatives are manifestly due to the glass not being cleaned before the emulsion was applied. In order that he should see them we should advise you to send some of the negatives to the maker. Plate cleaners cannot always be relied upon, and, of course, the manufacturer cannot himself examine every plate before it is coated; hence he must always, in conducting a large business, be more or less at the mercy of his assistants.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 10th instant, the annual dinner will take place at seven o'clock p.m.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The next ordinary meeting of this Society will take place on Tuesday next, the 9th instant, at 8 p.m., in the Gallery of the Royal Society of Painters in Water-Colours (whose Winter Exhibition is now on view), 5A, Pall Mall East.

THE AMATEUR PHOTOGRAPHIC ASSOCIATION OF VICTORIA.—This Association is progressing rapidly, and has proved a great boon to amateurs in the colony, as well as to several of its members in the adjoining colony of New South Wales. At the last monthly meeting, held October 6th, a paper was read by Sergeant Fenton, on *The Preparation and Purification of Photographic Chemicals.* The reader of the paper is well known in Victoria as an efficient amateur chemist.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician,
For three Weeks ending December 3, 1884.
THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

PHOTO-CRAYON PORTRAITS.

Since allusion was incidentally made a few weeks back to the now almost, if not entirely, defunct photo-crayon portrait, we have had more than one inquiry as to what was that particular style of enlargement. Only last week we had to explain to a correspondent, in our *Notes and Queries* column, the difference between the photo-crayon and the collodion transfer picture, and whether the two styles were not identical except in name. The article on the permanence of the gold-toned collodion image in our last issue has brought further queries on the same subject, one more particularly asking why, if this process be capable of yielding such undoubtedly permanent results, as well as pictures which are said to possess considerable merit, it has fallen into a state of desuetude. As this is a very pertinent question, and one similar in purport to others received, we shall here make some remarks on the subject generally.

In the first place, it may be explained that a photo-crayon picture is an enlarged collodion transparency on glass, backed up with a piece of rough drawing or tinted crayon paper, upon which are some coarsely-hatched lines similar to those seen in crayon drawings. The manipulations in making the enlargement itself are precisely similar to those followed in the collodion transfer process, which are too well known to need description here. In a word, it may be said that a photo-crayon is essentially a collodion transfer—not transferred, but left upon the glass—with this important difference, however, namely, that the image must be *very* much thinner for the picture to be effective.

Now, the idea of producing a transparent picture on glass and afterwards backing it up with paper, both white and tinted, or with other material, such as oil or water-colour paint, at the time this particular style of picture was first introduced was by no means novel; but the backing had, in most instances, hitherto been placed in optical contact with the glass. The novelty introduced in the picture of Mr. Sarony consisted in backing the transparency with a rough-tinted crayon paper pressed close to the glass, but not in optical contact with it, which gave the picture a totally different appearance to any of its predecessors. On this paper, as we have before mentioned, were a few hatched lines put in with a crayon. These lines were always made in such a position that, when the paper was placed at the back of the picture, they would come just beneath where the image was softened off in the vignetting; hence the hatching showed through the more delicate portions of the image. These pictures were always framed in a style suitable to drawings, which added materially to the crayon-like effect. The actual claim to novelty made in the patent by Mr. Sarony was only for the production of the hatched lines by means of lithography.

Last week we made reference to the artistic merits as well as to the permanence of a series of these photo-crayon portraits which we recently had an opportunity of examining. The gentleman who afforded us this opportunity, in answer to our inquiry as to why, in his opinion, this style of picture had died out so quickly, said he believed it was because so few operators could produce them successfully unless recourse was had to mercurial toning, which, as time has proved, jeopardised their permanency. The chief difficulty experienced by those who failed, he said, was to secure a transparency sufficiently thin yet full of detail, and at the same time of a good tone.

To illustrate the thinness of image requisite one of the pictures was removed from its frame. When the backing was taken off, and the picture itself examined as a transparency in a strong light, scarcely anything was to be seen upon the glass, so thin and phantom-like was the image. When the glass was placed upon a piece of white paper, the image, though of a rich warm black, was sufficiently thin to permit of printed matter being easily read through it, as the image appeared to be composed of a delicate stain rather than of an actual deposit. Our friend remarked that the image was always very thin indeed before toning, but this operation rendered it still thinner and more transparent; at the same time it conferred upon it a blacker tone. It is colour and not density that is required for photo-crayons.

Having explained the exceeding thinness of the image, which is so essential to good results, it will easily be seen why these pictures, when finished and framed, possess such a crayon-like appearance. It is because the grain of the paper and the hatching upon it shows through the image itself, except, perhaps, in the very deepest shadows, where in a veritable crayon drawing the texture of the paper is hidden by the pigment. Hence the illusion is so perfect that if the glass bearing the image be free from imperfections, and the photograph neatly vignetted, no one, as we have said before, would imagine but that the picture was really a portrait in crayons on the paper itself.

In our volume for 1881 we advocated the employment of the photo-crayon in preference to the collodion transfer process, as a method of producing effective though inexpensive enlargements, and subsequently [see pp. 231 and 275 of the same volume] we gave some practical hints on their production. Our opinion is still unaltered that this process is one which might well be employed in the production of cheap enlargements, as it is capable of yielding far more refined and artistic pictures, and at the same or less cost than many of the "wretched daubs" which are continually being issued as the so-called "club portrait." Upon mentioning this matter to a member of a firm who produce a considerable number of the latter class of pictures, he remarked that "those who go in for club portraits like plenty of colour, and would not be satisfied unless they had it." This, in many instances, we think is a mistake, as the taste of the humbler classes, who are the main supporters of the club system, has undergone a marked change of late years, and we feel assured that if they could obtain an equally good likeness, and at the same time a picture of greater artistic merit for the same money, they would much prefer it to a gaudily-coloured collodion transfer.

There is no reason why a photo-crayon should not be tinted in such a manner as to add to the effect rather than otherwise. Some years back we saw some very satisfactory examples in this direction. The colour was roughly applied to the crayon paper with a stump, very much after the principle that water-colours are sometimes applied to a second photograph when the system of colouring from the back is employed. As the colour has to be seen through the photographic image it matters very little how roughly it is put on, provided that it occupies the right position when the paper is placed at the back of the transparency.

DIFFICULTIES IN COPYING OIL PAINTINGS.

In following the progress of the copying of an oil painting, we last week discussed the possible effect of the presence of the now common sheet of glass in front of the picture, and showed how it neither added much to the difficulty of the work nor detracted from the quality of the results. The presence of glass is the very least of the stumbling-blocks in the way to success; that is, of course, assuming the glass to be clean on its inner surface. If dimmed through being coated with actual dust, or that film so fine as to be like a stain, which sometimes forms, no picture can be expected to present an appearance of clearness and richness in the photographic transcript.

At the same time, when no difficulty be placed in the way of removing the canvas from its frame, we should by all means recommend the photographer to remove it. The frame, from its weight alone, especially in large pictures, causes any attempt at removal to be most awkward and laborious. Failing the presence—an unlikely contingency—of a well-constructed artist's easel upon the premises, the plan we have seen adopted of simply placing the picture upon the floor, then giving it a slight backward tilt to prevent its falling, and enabling it to be placed at right angles with the axis of the lens, recommends itself to us as being as efficacious as it is simple and ready; but, at the same time, a forward tilt renders the exclusion of reflections more easy of attainment.

The picture resting upon the floor, the camera placed at a suitable distance and at the right height, and tilted so as to point duly to the centre of the picture, an examination may be made as to the presence or absence of glare or reflection. If the picture be a new one—smoothly painted—and the light admitted on to it rather at a sharp angle, the front lights being covered, all will be plain sailing. If, however, the impasto be of a different character, and the paint laid on in lumps and prominent streaks, a trouble will possibly arise from points and streaks of light; but by placing the picture at such an angle to the light as it was likely to be painted under—that is, a light from the painter's left—the bulk of the irregularities will disappear. It must not be put the wrong way up, unless the light come from the opposite—the right hand—direction, and then it must be arranged cornerwise upon the floor to obtain correct lighting.

If the picture have been painted some time all its peculiarities will be revealed when it is suitably illuminated, if not before. But the experienced hand will not wait so long; he will prepare the painting for copying before he thinks of putting it in front of the camera. It may be defective in many ways. It will, unless it have been well kept, in all probability be covered with a dull film of what is neither more nor less than dirt, which can be quite removed by a sponge and cold rain-water, followed by careful wiping with a soft linen cloth; the result will often astonish. Here let us say that little beyond this washing should be permitted by anyone who is not familiar with oil paintings. The expert can do almost anything, but one who knowing nothing about paintings should tamper with them in other ways would be guilty of a great wrong. He cannot conceive the ill that would ensue by means apparently the simplest.

When all the dirt has been removed—the deposit, perhaps, of scores of years—the picture may look perfectly fresh, or it may still have a dulled appearance, which, however, may often be cured by carefully wiping it with a clean, dry cloth made into a pad, and with a few drops of nut oil sprinkled upon it. This may sometimes bring it up with marvellous richness, and in the majority of cases will do so. Too much oil must not be applied, or there will be danger of cracks being filled with it, to the detriment of the work; for there are cracks other than those plainly discernible by the naked eye.

Still another defect may be seen, and this is incurable except in the hands of the expert picture restorer. The varnish itself may be "chilled"—a name given to a peculiar opalescence that appears either in patches or over the whole picture, which photographs in consequence, in the most indifferent manner, or, if the defect be very pronounced, with scarcely any detail. The picture now quite ready for photographing is carefully focussed—an operation requiring judgment; for the difficulties of reproducing a rectangular object so as to appear rectangular upon the plate are intensified in the case of an oil painting far beyond what is experienced in copying a plan or map, whose light colour is always an aid in focussing. As these troubles, however, differ in degree only, and not in kind, a mere reference to them is all that is needed here.

The picture focussed, exposed, and developed, an opportunity will be afforded of bringing into the field a variety of other difficulties. The negative may be weak; it may give no detail though sufficiently exposed, and it may be more exposed at one side than the other. The last named—due to the mode of lighting—will be the most probable fault, for an even illumination of a large picture in a small studio is next to impossible, and even with pictures of smaller dimensions it is always a source of trouble. The copyist's own judgment must teach him when a picture is likely to be unequally lighted, and his skill will be taxed to remedy the defect. With very spacious galleries, where the pencil of light received at any one point of the picture is little different in angle or breadth from that illuminating any other, there is little probability of trouble from this cause, which is, no doubt, one reason why direct illumination from the sun has been recommended. This plan possesses many advantages, but from the irregular surfaces characterising so many pictures, and the uncertainty of the sun's direct light, there is little need in these days of gelatine plates to resort to it. Besides these points, the possibility of chance reflections being shown that with diffused light would not appear must be taken into consideration.

The thinness of the image is a matter of small moment. There are plenty of methods of intensification capable of bringing up to good printing density very thin and weak negatives, and, should they fail, a negative, if sufficiently-exposed and possessing all required detail, can always be reproduced by taking a transparency, and from it another denser negative. Indeed, we may say that a close examination of many of the continental copies of the old masters leaves an impression that all the negatives they are printed from must have been so produced. When it is worth the photographer's while to go to this trouble and spend the necessary time, very good photographs of originals almost invisible may be produced; but, then, the added work bears to so great an extent the impress of the retoucher's hand that it became absurd to term them "photographs of the originals," as they possess no more value than engravings, and they are not nearly so pretty to look at.

The slight actinic value of some colours which gives rise to this difficulty—the last we now discuss—is likely to be always a stumbling-block, despite the use of a coloured medium to photograph through, or the employment of the comparatively-new stained plates devised to give "non-actinic" colours their true colour. Enough is not known of the latter to enable a confident judgment to be formed, and in any case they must be very slow for some colours to be impressed—better slow, perhaps, than not at all. As to a coloured medium, the plan has often been recommended either to lay a temporary stain upon the picture itself or to interpose a sheet of glass in front of the lens, and either possesses some value.

It is well known that when a ray of light passes through a sheet of coloured glass a second sheet of the same glass has far less obstructive effect. Similarly, in coloured reflections, it is but reasonable to suppose that the obstructive action of a yellow or red-tinted glass must have the greatest effect upon the reflections of colours of the opposite end of the spectrum, and so the power of the blues, &c., in the picture would be lessened, while the green and such like colours would be little interfered with, the effect being to give more value in the result to the yellow tints.

ELECTRIC LIGHTING IN PHOTOGRAPHY.

In fitting up an electric light installation for photographic purposes a point to be considered is that different kinds of arc lights give varying amounts of actinic power; it, therefore, is of interest to consider the relative values of different systems for photographic employment. In all such cases up to the present time arc lights are employed, the incandescent or glow lamps being insufficiently rich in chemical rays, and too expensive as regards the amount of light obtained for the power employed. The current which will give a light of from 1,200 to 2,000 candles in an arc lamp will produce but from 200 to 250 with glow lamps, and the latter amount has been found insufficient for practical working.

There are a considerable number of arc lights which vary with the nature of the current employed. The best for photographic purposes is a lamp having carbon electrodes nearly three-quarters of an inch in diameter, taking a current of twenty-five Amperes and thirty-five to forty Volts, or, practically, one Board of Trade unit consisting of 1,000 Watts.

These electrical standards of measurement should be used in specifying the apparatus required for photography. The Volts represent the amount of potential of the current, or its power of overcoming resistances. The Amperes represent the quantity of the current, or its power of doing work, such as heating substances, or throwing down a quantity of metal in electro-plating. A flash of lightning has high potential, for it can leap through a long length of air; but, like the long spark from the frictional electrical machine, it is useless for electro-plating or for doing any kind of practical work requiring quantity. On the other hand, a current powerful in quantity may have small power in forcing its way through obstacles or in giving a long spark.

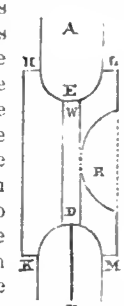
The electrical engineer, having as yet found but a small demand for his services in relation to photography, has sought more to produce a light pleasing to the eye than one rich in actinic rays, and for this reason in most of the apparatus now in the market the electrical horse-power developed is usually of low potential and rich in Amperes; that is to say, an effective light may be obtained from a current of about sixty Volts and twelve Amperes delivered at the lamp, the remainder being absorbed in the light and in the leading wires in the lamp. Such a current will give an arc varying from one-half to three-quarters of an inch in length. If the carbons be regulated to act at three-quarters of an inch apart the light is unpleasant to the eye, as an excess of the actinic rays is then produced. If, however, the lamp be so regulated that the carbons remain steadily at a distance of a-quarter of an inch from each other, the light is richer in proportion in the rays belonging to the red and yellow end of the spectrum. Should, however, the potential be reduced from sixty to forty Volts, and the proportion of Amperes increased for the transformation of the same amount of initial energy, it gives a more pleasant light still, or one richer in the rays near the red extremity of the spectrum. The carbon poles are then heated farther back, giving a more mellow and softer light. Thus, the efforts of electricians in the development of the electric light have been in the opposite direction to those required by the photographer, who, therefore, should pay attention to these points in considering the questions of relative economy and efficiency.

Experiment and study have also to be given to his own side of the problem by the photographer, if he make the demand of the electrician that the latter should give him the best light for his purpose. It may be one thing to produce a light rich in actinism, and another to produce one to give the best picture. As Professor G. G. Stokes discovered, the electric arc gives a light extraordinarily rich in the normally-invisible chemical rays of the spectrum; it gives a far longer actinic spectrum than the light of the sun. Glass is opaque to the more extreme section of these rays. How they will act when falling upon the face of a sitter, reflecting a large proportion of yellow, has yet to be examined; all may be as desired on the one hand, or possibly a tendency to blotchiness in the portrait may be produced in the other. These extreme rays when used upon bromide of silver are comparatively somewhat feeble in photographic power as compared with the blue and violet, so the former may tend to cause abrupt contrasts by absorption and unequal reflection.

There is another point arising from the foregoing conditions. The light falling upon the sitter must be diffused, and not fall directly upon him from an intensely-luminous small point. This diffusion of the electric light has been effected in practice by means of a whitened parabolic reflector, in the focus of which the electric arc is maintained. The direct rays are cut off from the sitter by a small screen, immediately in front of the reflector; the screen is not large enough to obstruct any but the direct rays from the arc. The light being reflected from the whitened surface is thereby lowered in tone and the rays of high refrangibility are degraded, so that the general effect is improved visually, whatever may be the result photographically, for the question remains whether unequal reflection of the extreme rays of the electric light has a tendency to produce blotchiness in the portrait.

By this reflection from a whitened surface there is an enormous loss of light. A translucent screen in front, intense enough to produce the required diffusion, would also very greatly reduce the luminosity, and this is one of the disadvantages of the arc light with a single lamp; but, notwithstanding this drawback, it has a great economical advantage over lamps on the incandescent system. Diffusion of the light for photographic portraiture is an absolute necessity, and almost the only hope of avoiding the present excessive waste of luminosity seems to lie in the direction of a greater division of the power, so that several small arc lamps can be substituted for one of the present normal large size.

Most of the light comes from the ignited carbon points and not from the arc itself, except in two curious methods of electric lighting now in the market. "The electric sun lamp," now at work in one of the picture galleries at South Kensington, gives a kind of combination of the electric and lime lights, and is noted for its steadiness. In this lamp, the carbons A E and B D are held firmly by springs against the hollows in the two ends of the block of marble H K L M. Through the centre of this marble the hole W D is drilled, open in its centre to the large hollow R, cut out of the side of the marble. One of the carbons has a hole through it, B D, through which a conducting needle is passed for a moment to make contact with E, and to establish the flow of the current. It is then withdrawn. When the lamp is in action the arc becomes luminous by means of the incandescent particles of lime driven off by the current, as evidenced by the exceedingly slow rate at which the carbons are consumed, for two pieces of carbon a decimetre long will last for fifty hours, whilst in the ordinary arc lamp they would probably be consumed in two hours. This light is of a reddish colour.



We shall resume this subject in a week or two.

We learn that the Northampton Photographic Exhibition will be formally opened by a *soirée* on Wednesday, the 17th instant, and *not* on the 16th instant, as previously announced. The Exhibition will remain open to the public until January 10, 1885.

Last Wednesday afternoon Mr. W. St. Chad Boscawen gave one of a series of well-attended lectures on Assyria, at the British Museum. He stated that modern research has given much exact knowledge about the Cities of Nimrod mentioned in the Book of Genesis; so that the customs of the inhabitants are now known, even down to their private affairs and their family squabbles, notwithstanding the lapse of three or four thousand years. The true translation of the name "Babylon" is "The Gate of God." The dwellers in the Cities of Nimrod knew the colours assumed by light. Mars was described as red, and Mercury as blue. In a hymn a scribe speaks of the sky being as blue as the sea. The Assyrians had names for the compound as well as the primary colours, including grey, reddish-brown, and green. Blue and purple gave them some idea of darkness, and he thought, but was not sure, that the same was the case in Homeric times. These public lectures on Wednesdays by Mr. Boscawen awaken so much interest that special abstracts of them are sent by Atlantic cable to one of the New York daily newspapers.

In the October number of the *American Journal of Science* there is an interesting paper, by Mr. Nichols, on the duration of colour impressions upon the eye. Plateau investigated the subject fifty years ago, yet but little further has since been done. Mr. Nichols' results, in the main, agree with Plateau's, and he has taken up other points. His researches bring out the fact that the stronger the light the shorter the time the impression lasts, and, further, that the duration of this impression is governed by the length of time the image has continued upon the retina, increase of time, like increase of brilliancy, reducing the duration of the after-image.

It is estimated by those who have studied the subject that the atmosphere of the earth absorbs twenty per cent. of the sun's rays falling upon it; but Professor Langley would double that estimate, founding his belief upon the numerous observations made by him at an altitude of fifteen thousand feet. He further believes that this absorption arises from other causes besides those usually assigned, dust—both near to the surface and at a great altitude—playing a more important part, both in general and selective absorption, than is usually believed. Photographers, who notice atmospheric changes more than other people, will be ready to coincide with Professor Langley's theory, for it is next to impossible, on any basis of absorption through moisture, to account for these singular variations in the actinic power of the light under apparently similar conditions.

A photograph of remarkable interest has been recently taken in Dakota by Mr. F. N. Robinson, of Miner County, and forwarded to the editor of *Nature* for publication. It is a photograph of a genuine tornado which, during its progress, killed several people and destroyed a vast amount of property. It was in sight for about two hours, and passed at a distance of twenty-two miles from the city. The huge mass of cloud seems in the picture to be roughly parallel to the horizon, and just from the middle of its lower surface projects the huge spout of the whirlwind reaching to the ground, while two other elementary spouts seem as if about to form and assist its career of destruction. A more emphatic testimony of the value of photography in depicting natural phenomena it would be difficult to conceive. On occasions of such extraordinary excitement as accompany the observation of this phenomenon it must be almost impossible to keep the hand from following the brain and describing exaggerated representations of the actual state of things.

We fully described to our readers last year Dr. Huggins' method of photographing the sun's corona, and at the vice-presidential address at the Royal Society's anniversary meeting an interesting account was given of work done under the system at Riffell, near Zermatt, in Switzerland. It may be remembered that a sum of two hundred and fifty pounds was granted by the Society and placed at the disposal of a committee for the purpose of making further experiments in the direction of photographing the solar corona without an eclipse. Mr. C. Ray Woods, whose name is well known to our readers, arrived at Riffell—a station eight thousand five hundred feet high—in July last, and, erecting the necessary instruments, continued at work till September 21st. It has unfortunately happened, however, that the present year has been exceptionally unfavourable for this class of work in consequence of an unusual want of transparency in the higher regions of the atmosphere. Mr. Woods thinks the results of the Krakatoa eruption may have caused this want of transparency; but, whatever the cause, the effect has remained, and, most unfortunately, when the atmosphere has been clear the sun has been surrounded with a large aureola. Dr. Huggins has been utterly unable to get satisfactory results in this country; but Mr. Woods has, notwithstanding all these difficulties, been able to obtain about one hundred and fifty photographs, of which more than half are sufficiently good to show the general form, and a smaller number the stronger details, of that part of the corona which lies within eight to ten minutes of arc of the sun's limb.

The Vice-President said it would be premature to discuss results, but he congratulated the Society upon the confirmation of the hope expressed at the last anniversary by the President that a new and powerful method of investigation had been placed in the hands of students of solar physics. Our readers will be glad to know how the opportunity of discussion is to be afforded, and will probably imagine that the negatives, or, at least, prints from them, were to be placed in members' hands. Nothing of the sort is projected. According to the report of the Vice-President's speech, which lies before us, we learn that the photographs "are now being *drawn*" preparatory to a full discussion. Photography is to be the drudge—the maid of all work—for science, but everything she does is to be covered over, as it is not sufficiently pretty. Prettiness first and correctness afterwards! We constantly raise our voice against this continued pandering to a false taste, and shall continue to do so until photographic results are given to the world in the shape of photographs, and not in a shape from which no one can formulate a rational judgment; for if he pin his faith to a theory founded upon appearances in an engraved reproduction he may at any moment be confronted with the original photographs to show that he is arguing upon false premises.

It is interesting to note the material of which Mr. Ray Woods' observing room was made. It was the Willesden paper, an account of the properties of which was brought before photographers some little time ago, and excited considerable attention.

In the same address some remarks pregnant with instruction were made upon the subject of the metric system to the International Congress, to which the Government recently gave their adhesion. This adhesion does not in any way bind the hands of the Government to adopt the system in any form. It simply enables them to pay their share of the expenses and, through their representative, to take part in the discussion, and to receive the benefit of the appliances at the command of the Bureau, whose standards far surpass in accuracy anything that is at present available in this country.

In the minds of many—mostly those who are, in effect, ignorant of the practical application of weights and measures among the mass of the people—an impression prevails that the metric system is proved to be undoubtedly the best that could be devised, and that the last word has been said. The truth is it is of great value for scientific purposes, if only because of its uniformity; but it is founded upon a theoretical measure which is inaccurately taken, so that the real standard is merely a piece of something carefully preserved for reference, while among the populations where it is established by law the metric system is found to be practically inconvenient from the size of the measures and weights being either too large or too small. In some countries, where by law it is established, it is not made use of by the people, and it is patent to anyone that a system of tens, which are only divisable into two equal parts, must be inferior for practical purposes to a system of twelves, which can be divided into three. The Vice-President said:—"Whatever may be the advantages of the metric system from a scientific point of view, the question whether a scale of weights, money, and measures, founded on a duodecimal rather than a decimal system, is not better adapted for the convenience of daily life is one that by many is regarded as fairly open to discussion."

THE SIEMENS' UNIT LAMP FOR PHOTOGRAPHERS.

[A communication to the Photographic Society of Great Britain.]

There are so many difficulties regarding a standard light that it has struck me I might say a few words with advantage regarding the auxiliary standard which was proposed by Dr. Werner Siemens at the late Electrical Congress held in Paris in April last. Recently Dr. Siemens kindly presented me with one of them, and I have experimented with it, both for photometric and photographic purposes. The lamp is illustrated in the diagram. The two principal portions of it are a tube five-sixteenths of an inch in internal diameter, through which the wick passes, and a gauge to measure the height of the flame, which has to be 2·6 inches high. Whether the wick be a closely-compressed one or loose does not seem to matter; cotton wool will answer every purpose. The material burnt is acetate of amyl which, though dear when obtained pure, is very cheap at all events in Germany, being sold at a few shillings a pound. It has a characteristic smell of pear drops, and is much used in confectionery, I am told, to give this particular flavour. The flame you see before you is a steady one when no draughts are about. In case of draught it may be enclosed in a glass tube with an air space beneath, but as a rule this is unnecessary.

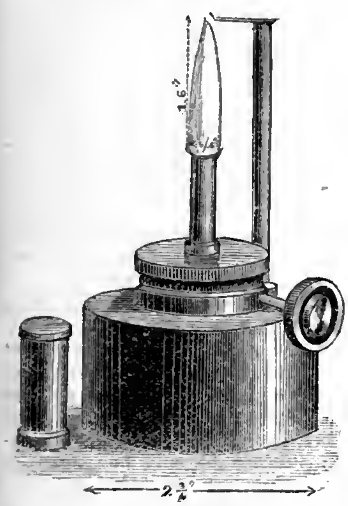
The wick is trimmed even with the tube, and when out of use there is an extinguisher or cap which screws over it, making it air-tight and thus precluding the evaporation of amyl acetate. After the lamp has been lighted a couple of minutes the flame assumes its normal height, and is regulated so that the point is just the height of the gauge. In this state it emits the light of a candle. It should be remarked that the acetate of amyl contains a large quantity of oxygen in proportion to the carbon, and hence requires but a small supply.

SUPPLEMENT TO THE BRITISH JOURNAL OF PHOTOGRAPHY. DECEMBER 12TH 1884.

MR ANDREW PRINGLE.

I have been trying this unit lamp for use with the sensitometer, and find that at a distance of eighteen and a-half inches from the plate, and with half-a-minute's exposure, it gives the same illumination as the phosphorescent tablet which is in my possession. I have repeatedly tried the same batch of plates at different times with the lamp, purposely disturbing the wick between times, and readjusting it to the height of the gauge. This gave always the same results on the plate exposed behind the sensitometer, showing that for this purpose it is a thoroughly reliable source of illumination. I cannot trace any effect of a difference in height of the barometer or thermometer. It is to be presumed that some slight variation must exist, but so far inappreciable, which is more than can be said when using the standard candle.

It may be asked, why substitute such a standard for the phosphorescent plate? The reason why I would do so is that the light emitted by the phosphorescence is confined to one small portion of the spectrum, as a previous paper of mine has shown, and that as you mix iodide with bromide the comparison of two plates—one iodo-bromide and the other bromide alone — when made by phosphorescence is in favour of the latter, since the place of a maximum sensitiveness of the former is below the point in the spectrum at which the phosphorescent tablet emits light. This being the case I should like to see some such standard as this used, as it is handy, and only requires the application of a match to start it. It is also convenient for use in taking transparencies by contact.



The exposure of a plate behind an ordinary dense negative, which registers 24 on the sensitometer at two feet distance, takes one minute to give a good image. Such a lamp, too, is handy for travelling. It can be enclosed in a shade of orange paper, or by the cardboard lantern which I long ago recommended, and which is the simplest form of any lantern with which I am acquainted, and plates can be changed or developed by its light. Now, as to the manufacture of such a lamp there is no difficulty; the form I have here is more expensive than is necessary. It will be seen that an ordinary spirit-lamp could be adapted to it by replacing the tube usually supplied by a slightly longer one, and making the glass cover a little longer than is now done; even this is not necessary. The point to be attended to is to keep the heat at a fair distance from the spirit. I need scarcely enter into the subject of photometry with this lamp; suffice it to say that if the burner be of the dimensions I have given, and the flame kept to the standard height, every one has it in his power to reproduce the light of an unfluctuating standard candle. Here, then, is a point gained at once. Mr. Spurge brought forward the idea of using a gas flame of a certain height, and issuing from a hole of fixed diameter, to illuminate the screen he proposed to use with his sensitometer. As gas is not always available it is probable that a modification, founded on the principles of the Siemens unit lamp, might be utilised.

W. de W. Abney.

WASHED COLLODION EMULSION *VERSUS* UNWASHED COLLODION FOR THE PREPARATION OF LANTERN SLIDES.

I venture again to broach this very interesting subject after reading the article by Mr. Andrew Pringle, and also the leading article on the same subject in last week's issue. I trust by the following remarks it will not be thought they have been written in any opposition to the Editors' leading article of last week, but are the results of a long practical experience extending over many years.

I commenced to make collodion emulsion as soon as it was introduced by the inventors, and have never ceased to work it in its various forms and phases. In the year (I think) 1875 I commenced to use it for making lantern slides. I then saw the beautiful results that could be obtained by the process, using unwashed emulsion with a preservative; then, as soon as washed emulsion was introduced, I decidedly gave the preference to it in that form for reasons which I will hereafter explain. As I undoubtedly prefer a washed emulsion to an unwashed emulsion for lantern transparencies, I will treat upon that point first.

I found that, as a rule, an emulsion which was in its best condition for negatives was but of little use for transparencies of the highest order, although with careful study exceedingly good results can be obtained; but it is far better to make an emulsion suitable for the purpose. A washed emulsion is far more expeditious in use than the sloppy mess of having to wash each plate singly. It very often occurs that I want (say) half-a-dozen slides in a hurry, and have no plates coated. I at once set to work coating the number I require—half-a-dozen or a dozen, as the case may be—which takes but a very few minutes. When I have coated the last one I immediately take the first ones coated and lay them on a hot-water bath that I keep for the purpose. They dry perfectly in about two minutes. I am then ready to make my slides, and nothing can be more simple.

I notice Mr. Pringle appears to have a little trouble with the india-rubber edging. This I have not the least trouble with. Perhaps he uses it too thin; if so I can understand his difficulty. I use mine as thick as possible—about the consistency of thick treacle, and with me the film never slips or becomes loose. I always use cyanide for fixing, as it is much more easy to get rid of the last traces out of the film than hyposulphite—the latter, if there be a trace of it left, being an enemy to toning. These remarks apply to all washed collodion emulsions.

In the leading article referred to reference is made to the emulsion of Mr. G. F. Williams. I have had a peculiar experience with that emulsion only a few days since. It is, I should think, about three years since that I made about one pint, working correctly to the form as he gave it; it worked well at the time, and in about twelve months after it gave a thin, poor image for negatives and a still worse one for positives. It has never been touched since, but a few days ago, after a vigorous shaking to take up all the sediment, I coated a plate; it worked splendidly, and gave an image of a nice sepia tint, which was capable of being toned to other pleasing tints. As a rule, in most old collodion emulsions, the first thing to give way is the pyroxyline; for, after coating the plate, it at once splits up into shreds on drying. This, being perfectly washed, had not done so, but had improved by age, which to me is remarkable, as my experience has been just the opposite.

I always prefer to use the emulsion as thick as possible, as I find that the image is far more bold and plucky. With a thin film, as a rule, the image is generally poor. All collodion emulsions I have found are insensitive to weak light—far more so than either gelatine or wet collodion plates. In a good light in summer time, with a fair printing negative, I find sometimes one second's exposure quite sufficient. With the old wet-collodion negatives the exposures can be judged far more readily than with the new gelatine plates. With the latter there is always a certain tinge of yellow or green, to which a collodion emulsion plate is very insensitive, but with contact it is a matter of very little importance. The difficulty is when the exposures have to be made in the camera; then with the gelatine negatives exposures have to be considerably increased. The best way to work is by sunlight diffused by a piece of ground glass about two inches from the negative. When there is no sun the ground glass is better removed and the negative pointed direct to the sky. With the diffused sunlight I seldom give more than one minute, unless the negative be very dense; with diffused light at this time of the year about a-quarter of an hour. The best style of gelatine negatives I ever saw were by Mr. W. F. Donkin; with diffused light five minutes were ample. The lens I always use is a Dallmeyer compound stereo. of three and a-half inches back focus. I prefer this lens to any other for the purpose. Practical experience is by far the best tutor.

Unwashed emulsion, I readily admit, is capable of producing good results, but for some subjects it has one fatal drawback, and that is owing to the preservative, be it either ale, coffee, tannin, &c. The plate, after being washed, is flooded with either of the foregoing preservatives, according to choice, and if the picture have any flat, delicate tints they are found to be more or less mottled or uneven, owing to the preservative. Another fault is those detestable drying marks which very often make their appearance and ruin the picture, and one is never safe from these defects. With a washed emulsion there is perfect freedom therefrom. I think if I were bound to go back to preservatives I would rather go back to wet collodion and silver bath. I find that a washed emulsion is developed quite as readily as an unwashed, and I have developed thousands. With a properly-prepared washed emulsion any amount of density can be obtained—quite as much as with the unwashed;

and, as far as my experience goes, I do not see there is any difference as regards fineness of film in the result.

I will give an instance of how readily a transparency can be made by one who is used to it. I timed myself one day as to how short a time I could make and finish a slide. The plate was already dry and ready for exposure. I made the exposure by contact, developed it, fixed, washed, toned, dried, and varnished it, and also mounted it within a-quarter of an hour. I did this as I had to catch a train. I do not think it could be done in a much shorter time—not even by an American.

I have not attempted to write upon this subject for some years, knowing that there was but little interest taken in the matter, and that only by a very small section. If the interest be now sufficient I should be pleased to write an article on development, which is very varied and produces different results, and also on toning, should the Editors approve of it. I think I may say that I have tried almost every known process, and have come to the conclusion that a washed collodion emulsion will equal, if not beat, the whole, and is far more simple.

Wm. Brooks.

HYDROXYLAMINE USED AS A DEVELOPING AGENT.

[A communication to the Photographic Society of Great Britain.]

Nearly two months have elapsed since Herr Carl Egli and myself published in the *News* the suggestion to use hydroxylamine as a developing agent, and I take this earliest opportunity to communicate to the Society the results of my further experiments. As hydroxylamine, prior to our publication, had not been introduced into the photographer's laboratory, perhaps it will not be out of place if I describe briefly the properties and preparation of the compound under consideration.

Hydroxylamine was discovered by Lossen, when investigating the intermediary products of the reduction of nitric acid to ammonia. This compound, which is represented chemically by the symbol NH_3O, is formed on the ammonia type, by the replacement of one of the atoms of hydrogen by the hydroxyl radical HO, as is seen in the following graphical representations:—

Ammonia.	Hydroxylamine.
$N\begin{cases} H \\ H \\ H \end{cases}$	$N\begin{cases} OH \\ H \\ H \end{cases}$

Like ammonia, it is a strong base, capable of forming several salts. It has not yet been obtained in the free state, but it can easily be produced in an aqueous solution. It possesses the somewhat remarkable property of behaving both as an oxidising and as a reducing agent. Perhaps no better example of its reducing action can be taken than the decomposition of silver bromide in the presence of caustic alkali, whereby metallic silver, alkaline bromide, and nitrous oxide, or laughing gas, are produced.

The reaction is represented by the following formula:—

$$2NH_3O + 4AgBr. + 4NaOH = Ag_4 + 3H_2O + 4NaBr. + N_2O.$$

Another important fact in considering the properties of hydroxylamine is that it does not absorb oxygen, even in the presence of alkali; thus, during the process of development, there need be no fear of the developing solution becoming decomposed from contact with the atmosphere.

The preparation of this compound has not received much attention from chemists, and thus the process generally adopted is the same as that originally proposed by the discoverer, namely, the reduction of nitric ether by tin and hydrochloric acid. When this method is resorted to a large proportion of the hydroxylamine is converted into ammonia, and thus the yield is comparatively small. Dr. Divers has recently published in the *Journal of the Chemical Society* a series of experiments on the formation of hydroxylamine from nitric acid. This investigator finds that a large yield of the desired compound is obtained by the direct action of tin and hydrochloric acid on nitric acid; in one experiment 87 per cent. of the nitric acid was converted into the base. It may be of interest to know that the hydrochloride, or hydrochlorate, is already in the market, but as this compound has hitherto only been used for scientific investigations the price is at present rather high, and would debar the professional photographer from adopting this method in his everyday practice; but there is very little doubt that, should a demand arise, the substance could be produced at a reasonable price.

With this, as with other developers, there is some difficulty in prescribing a definite formula, but the following, which is a modification of one recently described in an editorial article in the *News*, may be taken, I think, as a fair standard, and has given excellent results with certain brands of plates.

The following solutions are required:—

A.

Hydroxylamine hydrochlorine	30 grains.
Alcohol	1 ounce.

B.

Caustic potash	1 drachm.
Water	1 ounce.

C.

Potassium bromide	20 grains.
Water	1 ounce.

The ingredients used are in principle similar to those employed with pyro. Caustic potash takes the place of ammonia, for the latter alkali is not sufficiently powerful to assist the reduction of silver bromide. The soluble bromide is used, as with pyro. or oxalate, to restrain the action of the developer.

To develope a quarter-plate with the above solutions: take half-a-drachm of A, forty minims of B, and ten minims of C, diluted to one ounce with water. The exposed film is plunged straight into the developer without previous moistening. The process proceeds rapidly, and is completed in about five minutes.

The advantages claimed for this developer are:—Wide latitude of exposure, non-deterioration of the solution from external sources, and absolute freedom from stain—a gain that cannot too strongly be accented, especially at this time of the year, when printing is so slow.

Against the important advantages I should state that there is a minor objection, and that is the liability to cause reticulation, with plates prepared with soft gelatine, from the softening of the film by the caustic alkali, and the evolution of the nitrous oxide gas from the decomposition of hydroxylamine.

This developer is particularly suitable for gelatino-bromide paper, for while the resulting tone is apparently identical with that obtained by ferrous oxalate, there is no after treatment with acid required to remove the brown stain which is so objectionable when the latter is employed.

Gelatino-chloride is very amenable to this developer, and by varying the alkali used different tones are produced. Thus, potassium and sodium carbonates produce a *sepia-brown* tone; the same, but modified by the addition of a trace of ammonia, give a *chocolate;* and ammonia *per se* a brilliant *purple.*

A curious *dichroic* image is obtained with the ammonia developer by reducing the alkali therein to one-fifth the normal amount, and exposing the plate about fivefold; the deposit, when moist, appears of a brilliant *chestnut* colour, which dries to a deep *purple.* The same purple image again appears as a *brown* in gaslight. My experience with gelatino-chloride is confined to only one make of plates, so that probably the tones would be somewhat modified when this developer is used with other brands; for Dr. Eder has already shown that films prepared according to various methods often yield different tones, even when the same developer is used.

For the development of gelatino-chloride films the following solutions are required:—

D.

Hydroxylamine hydrochloride	15 grains.
Alcohol	1 ounce.

E.

Potassium carbonate	6 drachms.
Water	1 ounce.

F.

Ammonia, ·880	1 drachm.
Water	1 ounce.

A normal exposure for use with this developer is about ten minutes, one foot from a fish-tail burner. For a *sepia-brown* tone take half a drachm of D, forty minims of E, and one ounce of water. For *chocolate* tones the above mixture, to which has been added one minim of F. A *purple* image is obtained with half a drachm of F and half a drachm of D diluted with one ounce of water. To obtain the dichroic tone: expose fivefold normal and develope with half a drachm of D six minims of F to one ounce of water. The latter solution will probably prove useful for the development of gelatino-chloride prints, for I find that by backing a thin transparency of the dichroic kind with paper, a picture possessing a beautiful warm-brown tone is obtained.

In advocating the hydroxylamine developer for gelatino-chloride I claim freedom from stain, density of deposit, and variation of tone. It should be remarked that as the alkalies used are comparatively weak, no reticulation of the film is produced when the small proportion of alcohol included in the formula is used. In conclusion, I beg to express the hope that photographers will give hydroxylamine a fair trial, and communicate the results of their experience.

ARNOLD SPILLER,
Member of the German Chemical Society.

DEVELOPERS AND DEVELOPMENT.

[A communication to the Dundee and East of Scotland Photographic Association.]

WHAT I am to read this evening is not intended for professional photographers or proficients, but I would like to say my say to those who are wanting and willing to learn. There are many developers and many modes of using the same developer. Some allow a rapid and and others a slow mode of working. Some like to use a rapid developer, and to get freedom from stain or fog (and with some plates this is necessary); others slow, so as to have more control over results. Each is good in its way, and excellent results may be got in either direction, but much depends upon the nature of the subject.

As to which is the best formula, or whether slow or rapid development is the correct thing, I am not able to say, for I believe each worker will have some pet formula that will yield what he considers the best results, while the same formula in the hands of another might yield nothing but failure. There is no doubt but what a rapid-working developer is best or most suitable for portraiture in the professional photographer's hands, as it would be annoying and costly to have to keep customers waiting so long after each exposure till the operator could report upon the result and allow the sitter to depart. As far as the amateur is concerned medium or slow development is, or I think should be, the most suitable, as it enables him to have more command over his plate. There are times, however, when rapid working would yield better results.

The professional photographer, working constantly with his apparatus and plates, can always estimate correctly or, at least within very narrow limits, what is the correct exposure to be given, and either rapid or slow development will give satisfactory results; but the amateur has necessarily a hap-hazard mode of guessing his exposure, and the result may be a very wide margin on either side of the correct one. In this case slow development will give him more chance of correcting either over- or under-exposure. Again: there are some plates that will only yield fair results with very slow development, and if hurried in any way will only give ghosts of what they should be. Other plates will not give good results with slow development. Of course, if it were possible to get one good developer which would act equally well with all makes of plates it would be a great step in advance, but I fear that cannot be. I remember some time ago having got some Swan's plates which gave me very good results with the developer I then used (I believe Edwards's), and I heard others complain of them as being bad. I put them aside as useless, but some time after I had to fall back on them, as I had no others at hand. This time, fortunately, I thought I would try Swan's own developer, which works very rapidly. The result was a firm conviction that I had never used more satisfactory plates. I again tried my other developer, but with no better results than before. I had repeatedly used the same developer with Swan's plates without finding anything of which to complain.

Again: about two months ago I required some very rapid plates—large sizes—and the only ones I could get were Wratten and Wainwright's drop-shutter plates. When developing I used the formula accompanying the packets, and the result was failure. A brother amateur developed some of them with the sulphite developer, the result being as bad. I then tried the remainder of them with the potash developer, and the result was better—fair negatives, considering the subjects and the time. I may here say, in passing, that plates of my own make and also England's (twenty-five times), used on the same subjects and same exposure, gave much better results and were far more rapid than the drop-shutter plates, so that makers' statements as to rapidity should not always be considered correct till tried.

During the last few years there has been a constant stream of new developers or modifications of old ones. The pyro., ammonia, and bromide have branched off into endless combinations—Edwards's, with glycerine and alcohol; Nelson's, with sugar; and Berkeley's, with sulphite of soda and citric acid. Then there is the soda developer, the potash, and the combination of both. We have the ferrous oxalate, the hydrokinone, and now we are threatened with a new one with a regular jaw-breaker of a name which I am almost afraid to try and pronounce—hydroxylamine, hydrochlorate, and caustic soda. There is an endless variation in the proportions of the ingredients, and, of course, each one is best.

There is no use to lay down formal rules for development, for no hard-and-fast line can be drawn. Though formulæ are given, it is impossible to use them always in the proportions mentioned, even supposing the exposures to be correctly timed. There are so many cases in which a little more or a little less of any one or more of the ingredients is required to bring about the best result. One of our leading scientific writers on photography says that he rarely uses the same proportion in his developer twice in succession, as there are so many extraneous circumstances to take into consideration—light, exposure, nature of subject, class of negative wanted, and many other things—which only can be provided for as they occur. You cannot take a formula as given by any plate-maker and adhere to it for all subjects—that is, if you want to make the most of the plates. We all know that pyro. gives density, ammonia, soda, or potash (whichever is used) detail, while bromide restrains and keeps the shadows clear; but that is not all, for you must have a knowledge of how to proportion them so as to give the best results for each class of subject. For instance: we will suppose you have a number of exposed plates to develope, that correct exposure has in all cases been given, and that you have open landscapes, architectural subjects, woodland scenes, and interiors, one strength of developer will not give the best results with all. For landscapes having hills in the distance, or open country, the pyro. must be increased and the ammonia and bromide reduced. For landscapes having buildings in the foreground and no distance, or for architectural subjects, slightly increase the proportion of ammonia and reduce the bromide. For subjects having very deep, dark shadows, such as woodland scenes, reduce the pyro. and increase the ammonia. If your subjects have strong contrasts of light and shade keep down the pyro. and develope rapidly. If the subject be wanting in contrast increase the pyro. and, at the same time, develope slowly. The slower you do it the better; in nine cases out of ten you will get more brilliant negatives.

There are very few plates in the market but what will develope with any of the standard formulæ, if only they are watched and studied in the proportion of the ingredients; and there are very few photographers, professional or amateur, who do not have a favourite formula—one which seems to give better results in their hands than any of the others. I have my favourite—1. Ferrous oxalate; and 2, the pyro. and potash, though I very often use the sulphite of soda and ammonia developer. I think the best for amateurs is neutral oxalate of potash (saturated solution), protosulphate of iron (saturated solution), to which is added one drop of sulphuric acid to each four ounces of solution, and used in the proportion of one to three. I find this developer gives good results with almost all makes of plates, and is very much under control. Any strength of negative can be made if the exposure be correct, the shadows clear and full of detail, and the high lights perfectly dense. If the plates are over-exposed a very small addition of bromide of potassium will give perfect command of the result, while, if the plate has been under-exposed and will not come up with sufficient density and detail, one or two drops of a one-per-cent. solution of hyposulphite of soda will do all that can be desired.

ALFRED GUTHRIE.

(To be concluded in our next.)

HOME PORTRAITURE.

[A communication to the Glasgow and West of Scotland Amateur Photographic Association.]

IN drawing attention to the subjects we are to consider tonight I wish you to understand that I do so more particularly in regard to their bearing on that delightful branch of our art—portraiture. It seems to me that by far the larger proportion of amateurs give their attention to landscape work—at least in my circle of acquaintance. I seldom find those who seem to take a special delight in portraiture; nor is the reason far to seek.

It is generally thought that, without the aid of a studio, with its special advantages for lighting, &c., the amateur can have no chance alongside a professional photographer who possesses this benefit. Now, I am not one of those who think thus; on the contrary, I maintain, and hope to be able to demonstrate to you tonight, that there is no reason why an amateur should not produce quite as good results in portraiture as the professional. At the outset I wish it to be distinctly understood that I do not underrate the necessity for a proper lighting of the subject. I consider it, perhaps, the most important of the whole; still, with a little practice any well-lighted room can at times be made to give most excellent results—indeed, quite as good as can be obtained in many studios—and it may be news to some of you to be told that professionals have to labour long before they arrive at the best manner of lighting their sitters, even in their specially-constructed glass-houses.

Now, although lighting does not form part of our subject for consideration, seeing it is so intimately associated with the success of home portraiture, I must ask your indulgence for a few minutes, while, in passing, I give the results of my experience.

In the first place, allow me to say that one of the chief errors amateurs fall into lies in using too strong a light. If, for instance, you place a sitter (say) about five feet from any ordinary window having a good northerly or north-westerly exposure, and step back and carefully observe the effect of the lighting on the face, you will at once see that the contrast from light to shade is too great; the side next the window is too light, while the off side is too dark. This is the result of a want of diffused light.

Now, diffusion of light may be divided into two classes:—1, natural diffusion; and, 2, artificial diffusion. Natural diffusion may be described as follows:—The atmosphere everywhere and at all times is filled with floating particles of matter, and all of these are more or less opaque. Those which are opaque reflect a portion of light and absorb a portion. Those that are transparent refract a portion and absorb a portion; this constant changing of the course of the rays until they are thrown in every conceivable direction is known as "diffusion"—that is, natural diffusion. When any translucent screen is made to intercept the direct rays of light, and the atoms of which the screen is composed reflect or refract the rays, so that those which come through have lost their general direction—some passing one way and some another—are said to be "diffused." This is artificial diffusion. Natural diffusion is beyond our control; not so artificial diffusion. With it we have all to do, and we bring it to our aid. By it we soften high lights, break up too strong shadows, and give proper modulation and solidity to our image.

Now, to obtain artificial diffusion; procure a muslin screen like this. I made it myself, and it cost me about threepence. Place it between the sitter and the window, out of range of the lens, in such a manner that all the rays of light which fall on the face must pass through the gauze. Step back again and take another look, when you will at once see that a very material change has taken place. Not only has the high light on the face been softened down, so to speak, but the dark side of the face will appear to have been lighted up, thus reducing the violent contrast which had previously existed. Now procure an ordinary clothes-horse commonly used for drying clothes on, throw over it a white sheet, and so fold the divisions of it into such positions that a reflected light (not too much of it, mind) just increases the light on the darkest part of the shaded side, and at the same time throws a little front light on the face, so as to soften or blend the high light into the shade, taking care to preserve some light and shade, which is the soul of portraiture, as well as other branches of our art. This done, your subject should be well lighted, which may be ascertained by seeing that the catch-lights are the same on both eyes.

Having said so much about what we may call the proper "quality" of light, it may be interesting to learn a little about the strength or actinic power of this mode of lighting, or, in other words, what is the average time of exposure. Later on I shall have the pleasure of handing round some specimens of my home work, and these will give you an idea of what can be done in the manner stated. On tolerably good days I obtain a properly-exposed negative, using a No. 3A Dallmeyer lens, with its No. 2 stop, in from seven to ten seconds, on a Wratten's plate. On very bright days I, of course, expose for less time. Now these exposures will compare favourably with those of many studios. If a person seat himself in front of an ordinary window having (say) a clear aperture of about seven by three and a-half feet, and ascertain the vertical and horizontal angle of the light that falls upon him, he will find that it is in excess of the light commonly admitted in photographic studios. This is a fact that may be determined by simple measurement and comparison. It is not the size of the studio or its window that determines the force of the illumination, but the angular relation of the window to the sitter; hence a window which is twelve feet square may in reality admit a far less degree of light, so far as a special sitter is concerned, than one of six feet square, the area of which is only one-fourth of the former.

From what I have said you will have perceived that if a person sit sufficiently near a window more light will fall on him than would be the case in many studios. For the same reason it will be seen that in proportion as he removes himself from the window the light diminishes according to the square of the distance, thus showing that any ordinary window with its diffused light can be made to give quite as much light as a studio. But you may ask me—"What about the facilities for various modes of lighting?" Let us examine into this also, and I think we shall find that the amateur is not tied down in the matter.

If you examine the specimens I have brought with me tonight you will find at least four entirely different styles of lighting. No. 1 is an example of the Rembrandt style, and is a picture of my little girl. She was placed about four feet from the window with her side to it, so I moved my camera, as it were, into the middle of the room, and pointed against the light. No. 2 is an example of three-quarter lighting. The sitter was placed about five feet from the window and almost facing the glass, and then the head was just turned round until only a dash of light fell on the off cheek. In this case the camera was placed so that the lens pointed from the source of light on to the sitter—almost the reverse of the Rembrandt style. No. 3 is a style very popular with Americans. In this instance the sitter, as it were, turned the head away from the light, so that the light came from the direction of behind the ear, thus giving a full side view with the off cheek in shadow. Another pleasant way is to place the sitter so that the light falls on the cheek next the window, the off cheek being in shadow. A full face is obtained by this means.

You will thus see that the amateur is not tied down to any one style of lighting, but that he has quite a choice; so he may exercise his discretion in choosing this or that one as most suitable to the requirements of his various sitters. Can more than this be obtained in any studio? I think not.

Having said so much about lighting I now come more particularly to the subjects we are specially to consider, in which later on I hope to give some practical demonstration, namely, retouching and enamelling. No matter how well and artistically you may light your subject (passing over the consideration of proper exposure, development, printing, toning, &c., with which, no doubt, you are all conversant), unless the amateur be able to retouch his negatives and then to finish his prints in a superior style he will still be far behind the professional. Later on I hope to show you the *modus operandi* of retouching, and also how to enamel prints. I claim no singularity in either case, as you will learn. I propose to deal first with enamelling, and before proceeding to give you a practical demonstration of it I will just say that, whatever may be urged for this or that one's opinion for or against enamelling, there can be no doubt that most of the leading professionals now adopt this style of finishing their portraits. I maintain that increased softness and detail in the shadows are brought out in an enamelled print which would be lost otherwise. In discussing this matter with several of my friends I was struck with the similarity of their objections, which nearly all came to this—that it was very troublesome and not worth the mess. Now, this is all nonsense. With a little practice and ordinary care an amateur can enamel his prints with great ease and success, and this is the first thing I propose to do tonight. I have no doubt many, if not all, of you have read about enamelling, and know well enough how it is done. Still, I am inclined to think very few of our members have ever practised it, and were they to proceed to do it from the knowledge which they have acquired from what they have read, I do not hesitate for a moment to state that nine out of their first ten attempts would end in failure; but when you come to have ocular demonstration the thing becomes easy of accomplishment and within the range of practical photography for amateurs. T. N. Armstrong.

(To be concluded in our next.)

RECENT PATENTS.

PATENT SEALED.

No. 4,989.—"Changing Sensitised Plates in Photographic Cameras." James Sturrock, Dundee.—*Dated March* 17, 1884.

APPLICATIONS FOR PATENTS.

No. 15,887.—"Photographic Cameras." W. Middlemiss.—*Dated December* 3, 1884.

No. 16,087.—"Photographic Cameras." C. Sands and J. J. Hunter.—*Dated December* 6, 1884.

An Improved Form of Lantern Front for Magic Lanterns.

William Charles Hughes, Optician, 82, Mortimer-road, Kingsland-road, London.

This patent, illustrated with drawings, refers to the construction of the brasswork front of the lantern, for carrying slides varying in size, and permitting the use of long-focus objectives with advantage. The condenser tubes have an extending arrangement.

THE SOIRÉE OF THE ASSOCIATED SCIENTIFIC SOCIETIES OF LIVERPOOL.

This year's *soirée* of the combined learned societies of Liverpool took place on Wednesday last, the 10th inst., at St. George's Hall.

The Liverpool Amateur Photographic Association collected together for exhibition probably the finest gathering of pictures and apparatus ever placed before the Liverpool public. The hanging committee, Messrs. Beer, Crowe, and Guyton, under the superintendence of the Hon. Secretary, the Rev. H. J. Palmer, were at work the greater part of the day of the *soirée*, and by opening time had arranged their display very effectively.

Among the exhibits may be mentioned the splendid series of enlargements of Alpine negatives by Mr. W. F. Donkin, which gained for him the gold medal at the recent Pall Mall exhibition. Mr. J. H. T. Ellerbeck displayed an extraordinary number of good pictures of this year's work in Norway and in Wales. Dr. Watling showed a large selection of the prize pictures of the Amateur Society of England. Dr. Paul's very fine series of illustrations of Norfolk abbeys and towns were greatly admired, as also were the framed enlargements exhibited by Messrs. Beer and Cornish. The Rev. H. J. Palmer also showed a fine enlargement illustrating this year's work in Switzerland. Among the other exhibits by members of the Association may be mentioned, as specially worthy of praise, the competition pictures of this year, which are unusually good; and collections by Messrs. Cross, Beer, Atkins, Haworth, and Crowe.

Outside the Society were a splendid collection of Egyptian pictures exhibited by Mr. Pugh. Every phase of Egyptian life, manners, and architecture were represented here, and greatly was this portion of the exhibition appreciated. Messrs. Robinson and Thompson contributed some very beautiful pictures, and among them an enlargement in opal of a portrait of the Premier by the Rev. H. J. Palmer. Messrs. Cussons and Co. showed cameras and apparatus of every kind.

On the whole, the Association may be congratulated on having produced in Liverpool an exhibition of such singular interest and merit.

BURY PHOTOGRAPHIC AND ARTS CLUB EXHIBITION.

The second annual exhibition and *conversazione* of the above Club was closed on Saturday last. It proved very successful, and met with the cordial support of the public. Mr. F. Cooper, one of the Vice-Presidents of the Society, sent twenty views, which were excellent in every respect. Mr. C. H. Openshaw, one of the younger members, contributed sixteen pictures. Mr. F. W. Livsey contributed a very large collection (no less than eighty-five) to the photographic portion of the Exhibition. Miss Rosa Scott sent seven capital photographs of local views. Mr. T. J. Hutchinson contributed an equal number, and Mr. T. Entwistle four of views near Whitefield. The photographs exhibited by Mr. J. Nelson were very excellent indeed, and some of the finest in the room.

Mr. H. M. Dearden contributed sixty views of Welsh scenery, Prestwich Clough, and other objects of interest in the neighbourhood. Of the thirty pictures shown by Mr. Robert Grundy, Jun., of Parkhills, many dealt with Welsh scenery and were beautiful in their effects. Mr. E. W. Mellor, of Polefield, Prestwich, sent a number of small photographs, which were deservedly admired.

The oil paintings and water colours were hung on a wall immediately below the gallery, and included two by Mr. C. H. Wood—one lent by Mr. Walter Ashworth, and the other by Mr. Grundy. Mr. W. S. Barlow sent half-a-dozen paintings, which were extremely good in colour. Mr. F. W Livsey sent *Boat on Conway Bay*, and a large picture, which occupied the place of honour in the centre, *The Finding of the Body of Harold*—a copy of the picture by J. C. Hook, R.A. Mr. J. Holding, of Manchester, had two landscapes in monochrome and three water colours. Mr. Whitehead lent a picture by Mr. J. Shaw, representing the top of Bolton-street in days gone by; and Mr. Joshua Entwistle had a study in colours and some plaques.

Mr. E. W. Mellor exhibited Beard's patent self-centering slide carrier, which had been kindly lent by Messrs. Stewart, of London, and met with the general approval of the members.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.

,, 18 ..	London and Provincial	Masons' Hall, Basinghall-street.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

THE ordinary monthly meeting of this Society was held on Tuesday evening last, at 5A, Pall Mall East,—Mr. James Glaisher, F.R.S., President, in the chair. The proceedings were opened with the usual routine business, and three new ordinary members elected.

Captain ABNEY, R.E., F.R.S., read a paper upon *Testing Gelatine*, which set forth that dry-plate makers were aware that the quality of gelatine varies as regards tendency to frill, and their idea that this tendency is governed by the amount of water different specimens would take up was generally but not altogether true. Different gelatines dried in different times, and threw those stains upon the plate which were the cause of the tendency to frill. He, therefore, prepared a solution of gelatine of such a strength that five grains of the colloid were made to form a film upon each quarter-plate; after being dried the films were stripped from the glass and accurately measured. Some were then placed in water to soak; others were treated with ammonia of the strength usually employed in developing, while more were soaked respectively in solutions of monocarbonates of soda and potash, in which they were allowed to swell for one hour. The tabulated results showed that ammonia promotes swelling, whilst the monocarbonates of potash and soda have less tendency so to do; consequently they are in this respect better for developing. He added that an easy method of getting emulsion to flow freely over a glass plate was to cover a squeegee with swansdown and to rub it over the plate just before coating with emulsion. His experience with silicates as a substratum to promote the flow of gelatine had not been good.

Mr. W. BEDFORD wished to know if Captain Abney would have obtained the same results had he used soft gelatine artificially hardened with alum.

Mr. LEON WARNERKE was in favour of the use of monocarbonate of potash, as he had recently stated in public, and he agreed that it gave less tendency to frilling. Gelatine was firmer the quicker it was developed. When he wanted to avoid frilling he added alum to the first washing water in which the emulsion was squeezed out in fine threads; the succeeding washings cleared out the alum again. He used ordinary alum—not chrome alum. The threads became crisp under the treatment, and did not increase in bulk. The plates developed quicker than when there had been no treatment with alum at all, but the increase in rapidity of development was small.

Mr. W. K. BURTON wished to know the proportion of alum used in the first washing water.

Mr. WARNERKE replied that the maximum was five per cent.

Mr. T. SEBASTIAN DAVIS stated that, if gelatine were moist for a long time, decomposition had a tendency to set in near the centre of the plate. He had made one batch of plates with Heinrich's very hard gelatine, and another batch with Nelson's No. 1—a very soft gelatine. The latter were four or five days in drying without artificial appliances for the purpose, whilst the former dried in forty-eight hours under similar circumstances. The hard gelatine had no direct tendency to blister.

Colonel STUART WORTLEY remarked that, of course, the long drying was for experimental purposes, and not for ordinary practical applications.

Mr. SEBASTIAN DAVIS said that for practical purposes he liked plates to get quite hard within twenty-four or thirty-six hours.

Mr. WARNERKE had no doubt the experiments had been carefully made, but the results did not harmonise with his experience, for he found that when plates dried too quickly there was liability to blister. He liked to keep his plates in the drying-room from four to six hours, and then to store them.

Mr. SEBASTIAN DAVIS found twenty-four hours to be a good time for drying, but thought three or four days promoted blistering under development.

Mr. WILLIAM ENGLAND found twelve hours to be a reasonable time for the drying of plates. When the time was longer they increased in sensitiveness in the centre.

Mr. JOHN SPILLER, F.C.S., stated that alum or a very little sulphate of zinc was sometimes put into glue by the manufacturers to promote the hardening. The effect of metallic salts upon gelatine ought to be tried by experiment, for probably some of them would be found to give the plate much less tendency to frill.

Mr. W. E. DEBENHAM asked the proportion of sulphate of zinc sometimes used by gluemakers.

Mr. SPILLER did not know, but it was exceedingly small—a mere trace, in fact. In very hot or very cold weather they could not get the films to dry when spread out on the netting. The least touch of frost spoilt the glue.

Colonel STUART WORTLEY said that the gluemakers employed one-half per cent. of sulphate of zinc.

Captain ABNEY, in reply, stated that his experience with soft gelatine artificially hardened was that its expansive power was materially lessened. If plates were forty-eight hours in drying he should be astonished if they did not frill and blister. He should get perfect fog under the circumstances. The use of a substratum prevented the mark round the edge of the plate in drying. Not less than eight hours or more than twenty-four hours was the best time for drying, and quick drying by alcohol tended to blistering. Altogether, sixteen hours was a good time for the drying of plates. Mr. England was a good and experienced plate-maker, but his experience in relation to the effect of slow drying on the centre of the plate showed that his emulsion was not sensitive enough at the time of coating if he desired the maximum of rapidity. Nitrate of zinc had a hardening effect upon gelatine, and with the use of bromide of zinc for decomposing the nitrate of silver there was no risk of getting slowness; but the zinc salt was not so "certain" as the potassium salt.

Mr. GORDON then exhibited a washing machine, in which each print was placed upon a separate wire work frame, and washed separately in the same bath with other prints. Mechanical arrangements at the side of the bath emptied the water now and then, allowed a certain time for the prints to drain, and then admitted a fresh supply of water. The number of changes of water per hour could be automatically governed at will. There might, for instance, be twenty, six, or four changes of water per hour, according as desired. The apparatus would go on working by itself so long as the water supply lasted.

Mr. DEBENHAM had seen one of these machines at work in the hands of a friend, and was so pleased with its action that he intended to buy one for himself. It would hold as many prints as an ordinary photographer would be likely to require to wash at the end of a day's work. The lower prints were drained by it as well as those uppermost.

Colonel STUART WORTLEY thought the wood of the frames would get saturated with thiosulphate of soda.

Mr. ENGLAND recommended the substition of sheets of gutta-percha perforated with holes.

Mr. W. M. ASHMAN recommended soaking the present frames in melted paraffine.

Mr. GORDON had had the present frames in use for two years without disadvantage.

The proceedings closed with the usual votes of thanks.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE annual meeting of the above-mentioned Society was held in the House of the Society of Arts, John-street, Adelphi, on Thursday, the 4th instant,—Mr. E. W. Foxlee in the chair. In opening the meeting, the CHAIRMAN proposed that the members should constitute this an ordinary meeting as well as an annual one. Several of those who had on the last general meeting been proposed as members of Committee had withdrawn their names, so that at present there were not sufficient names to form a committee of twelve, as was intended. The gentlemen who had withdrawn their names were Mr. A. L. Henderson and Mr. A. Mackie. Several of those who had been proposed were found not to be members of the Society. Mr. T. Bolas was proposed as Vice-President, and in that capacity would be a member of committee. If the meeting were constituted a general one new names could be added to the list.

The proposal was agreed to, and the meeting, therefore, proceeded as an annual ordinary meeting.

The Hon. Secretary read the report of the past session, and also the Treasurer's report. The reports were adopted.

TWENTY-FIFTH ANNUAL REPORT.

IN submitting the annual report the Committee regret to have to record the great losses the Society has sustained by the hand of death during the past year of the Rev. F. F. Statham, M.A., F.G.S., who had been President from the Society's formation in 1859; Mr. Jabez Hughes, one of its earliest members, and for many years one of its Vice-Presidents; and Mr. H. Baden Pritchard.

The death of the Rev. F. F. Statham was unquestionably a great blow to the Society, and so severely was this felt to be that suggestions were made to bring the Society to an end in consequence. In order to ascertain the feeling of the members on this question, a special meeting was held and circulars were sent to them. The Committee much regret that so few took sufficient interest either to attend the meeting or reply to the circulars.

The annual lantern meeting in January was, as usual, crowded. Slides were exhibited by Messrs. Beasley, Jun., Page, H. Trueman Wood, F. York, J. J. Brigginshaw, J. Gale, W. Brooks, F. A. Bridge, Wheeler, W. Cobb, and others.

During the year papers have been read as follows:—*Willesden Paper*, by Mr. F. A. Bridge; *Old Photographs*, by Mr. E. Dunmore; *Polarised Light*, by Messrs. C. and F. Darker; *Composition*, by Mr. Norman Macbeth, R.S.A., and *Furnell's Lens*, by Mr. W. Ackland.

Numerous questions from the question-box have also been discussed. It had been arranged to hold a festival dinner on the twenty-fifth anniversary of the Society (May 10). The lamented decease of the President, however, necessitated its being abandoned.

An outdoor meeting was held in July as usual, and, notwithstanding the unpropitious state of the weather, a pleasant meeting resulted.

It having been decided that the last technical meeting was deficient in interest, Mr. J. Traill Taylor kindly promised a lecture on *Florida* for the November meeting, which was well attended.

With regard to the artistic competitions, the Committee are scarcely in a position to report, the pictures having only just been received. They trust, however, the result will be satisfactory, and hope this distinctive feature of the Society will meet with the success it deserves.

The Treasurer's report showed that the Society had a balance of £1 6s. 1d. in hand.

The Secretary went on to remark on the number of subscriptions that were in arrears, pointing out that the balance in hand was now very small.

After this there was a great deal of desultory conversation as to whether it was possible to continue the existence of the Society at all or not, and, if so, how it was to be done.

A letter from Mr. W. M. Ashman to the Secretary, in which he (Mr. Ashman) warmly advocated the continuance of the Society, and proposed certain modifications in its method of working, was read.

The CHAIRMAN pointed out that the Society *did* exist, and that the only way in which to bring about its end, were that desired, was by some member proposing, and another seconding, a resolution to the effect that the Society cease to exist.

Mr. A. COWAN, in proposing that the Society be brought to a close, said that he had the greatest respect for the South London Photographic Society. He thought that his respect for it was shown by the fact that since he had become a member he had never missed a single meeting. Now, however, he thought the Society must cease to exist, and he, therefore, moved that it be brought to a termination.

Mr. H. TRUEMAN WOOD thought it would be well that a motion be taken, and that the matter be settled one way or another. There was a sufficient attendance that night to show that there were enough members to keep the Society going. Nevertheless, it would be better for the Society to take this opportunity of ceasing to exist than that it should die in a miserable fashion. It would be best for the members to express their opinion by a vote. For his own part he thought there was room for a Society such as the South London Photographic Society, although he knew the great difficulty in its continuing to exist was that the field was taken up by the weekly meetings, which were of a more convivial nature. Still, he did not see why, because these weekly societies were somewhat more free and easy than this one, there should not be room for a society where the science of photography was treated in a rather more serious manner than at the weekly societies. He thought, moreover, that there should be room for both the Parent Society and the South London Photographic Society. The present, when photography was increasing so greatly in popularity, was not a time for a society to cease to exist. However, if the the thing were not to go on in a vigorous way it were better that it be wound up respectably than allow it to die a lingering death. He did not know that it would be quite regular for him to second Mr. Cowan's motion after what he had said, but if no one else would second it he would.

The CHAIRMAN, in putting the motion to the meeting, said that as, perhaps, the oldest member of the Society, he now found himself in a very unpleasant position. He had been proposed as a member of the Society by the late Mr. Jabez Hughes at its second or third meeting, and had made it a rule to attend every meeting at a time when he was younger and perhaps more enthusiastic than at present. Since his election he had been continuously a member of the South London Photographic Society, and since the North London Photographic Association had ceased to exist he had belonged to no other until he joined the offshoot of the South London Photographic Society—the Photographic Club. He had his own opinion as to the desirability of the continuance of the Society or the reverse, but, being Chairman, he did not feel called upon to express them. It was with pain that he put the motion to the meeting.

It was carried by a large majority that the Society should not cease to exist.

The following gentlemen were then proposed as members of the committee in addition to those who had been suggested at the last meeting:—Messrs. C. Poirson, T. J. Collins, Jun., W. M. Ayres, and G. A. Garrett.

A ballot then took place, and the following gentlemen were elected as officers of the Society:—*President:* Mr. W. Ackland.—*Vice-Presidents:* Messrs. T. Bolas, H. T. Wood, and F. York.—*Committee:* Messrs. W. Ashman, W. K. Burton, W. Cobb, E. Dunmore, J. A. Harrison, W. H. Prestwich, H. Wilmer, C. Poirson, T. J. Collins, C. Hussey, Jun., W. M. Ayres, and G. A. Garrett.—*Hon. Secretary* and *Treasurer:* Mr. F. A. Bridge.

A vote of thanks to the officers for the past year was proposed by Mr. Burton, seconded by Mr. A. Mackie, and carried unanimously.

The Secretary proposed a vote of thanks to the Society of Arts, coupled with the name of Mr. H. Trueman Wood, for their kindness in lending their room. This was carried by acclamation.

The CHAIRMAN proposed a vote of thanks to Mr. F. A. Bridge for his exertions as Secretary and Treasurer. This was also carried by acclamation.

The January meeting was appointed for the exhibition of lantern slides, and Messrs. King, Cowan, Wheeler, Poirson, Garrett, and Ashman promised to bring slides.

It was then announced that the annual dinner of the Society would take place at the Holborn Restaurant, on Tuesday evening, the 16th instant, at half-past six o'clock.

Mr. Ashman promised a paper for the February meeting.

The meeting was then adjourned.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society, held on the 4th instant, the chair was occupied by Mr. A. L. Henderson.

Mr. W. E. DEBENHAM said that when Mr. J. T. Taylor some little time since showed an American vignetting-frame he had observed that in some points it resembled those which he was accustomed to use, and he now brought examples of his vignette presses and appliances to illustrate the system of working which he employed. An ordinary printing-frame had a double thickness of millboard attached to the front, with openings cut through both thicknesses opposite to where the figure would come upon the negative. These openings were slightly larger than the largest opening required in the vignette "form." The vignette "forms" themselves were cards with openings cut in them of the various sizes that would be required. In order to have a system of numbering and identifying the size of opening used with any negative, so that the same might be taken at another time, the "forms" were numbered according to the eighths of an inch that the openings were long. Thus No. 8 represented one inch, No. 14 an inch and three-quarters, and so on. Any that were either wider or narrower than the standard proportion were marked W or N in addition to the number written on the card. The cards were pushed between the two millboards, and might be adjusted to any position over the face or figure of the sitter without fear of slipping during the printing of an order. The frames having no projection were turned over upon the bench to be changed exactly as with ordinary presses. This system he had had in use for about twenty years, and he continued now to employ it; but when carbon printing and vignetting with tinted margins came into practice about seven or eight years ago he had arranged another frame, of which an example was also shown. In this frame the adjustment was made by shifting the negative upon a plate glass which the press contained. There was a movable front consisting of a deal frame which buttoned into the front of the pressure-frame, and into which were buttoned, when double printing was required, glasses containing an opaque paper mask. For tinting the margin a corresponding mask, but with the centre opaque, replaced the mask with central opening. The paper was kept in the same registry for printing and margin tinting by being laid against the top and one side of an inner back.

The CHAIRMAN thought the whole system good. It was much like the plan that he himself adopted, but in his frames the openings were cut in opaque "empire" cloth. This cloth was held between two glasses, and the adjustment was made by pulling the edges of the cloth, which were allowed to project beyond the edges of the glasses, through spaces left in the binding. He thought it an advantage to use glass in the front of the vignetting-frames, as they need not be so hurriedly brought in and wiped in case rain came on.

Mr. DEBENHAM said that his vignettes were printed under a sash glazed wit ground glass.

The CHAIRMAN inquired whether Mr. Trinks could speak of vignetting as applied to photo-mechanical printing.

Mr. J. H. TRINKS said that vignetting had always been a difficulty in phototype processes. In the production of plates for this purpose it was necessary in order to obtain the finest results to print with parallel rays. A satisfactory method of keeping the rays parallel was to have a projection rising some distance from the front of the printing-frame, and to note that the shadow of this projection fell always upon the same part of the frame.

Mr. W. H. PRESTWICH said that no doubt Mr. Debenham's plan was a splendid one. There had lately been published a specification of a patent for a process for vignetting in the camera itself, by having a screen in front of the lens, with a opening in it, and vandyke edges. It seemed to be what he had used many years before for vignetting positives.

The CHAIRMAN said that in 1872 he had advocated the use of a vignetting screen, made up of several layers of wire gauze, the opening in each layer being cut a little larger than that in the next layer, and had pointed out that such a screen might be used either in the camera or in the ordinary way. In the collodion positive days it was necessary to vignette upon the plate itself, and this was commonly done by a screen with a central opening placed between the camera and the sitter. He had preferred, however, to produce the effect by exposing the plate to diffused light, either before or after exposure in the camera. There was a glass in front of the plate with an opaque central disc preserving the figure from the destroying action of the light.

Mr. J. B. B. WELLINGTON said he believed it was generally understood that colloid bodies acted as restrainers in the developer. He had added glycerine to ferrous oxalate developer in order to restrain it, but found that it served as an accelerator, less exposure being required than without it. If equal exposures were given the plate developed with the added glycerine came out the quicker.

Mr. TRINKS said that he wished to offer a prize of £50 for competition, the subject to be decided by the Society itself—whether process, apparatus, or what might be thought best.

The proposition was warmly received, and it was arranged that at the meeting to be held on the 18th instant the subject should be chosen. Members unable to attend were invited to send suggestions by post to the Secretary.

Mr. WELLINGTON inquired whether the Chairman had experimented with bichloride of mercury as an antiseptic in emulsion, as he had proposed to do. He (Mr. Wellington) had tried it in tho proportion of half-a-grain to a ten-ounce batch. He had mixed it with the bromide in the first instance, and found that it slowed the emulsion very much, the resulting plate giving 9 on the sensitometer instead of 20. The plate, however, was remarkably clean; there was no green fog whatever.

Mr. DEBENHAM observed that chloride of mercury appeared to have a remarkable desensitising effect upon chloride of silver. In the old process for whitening positives bichloride of mercury was used, and chlorides of silver and mercury were left upon the plate. The chloride of silver, however, did not blacken by exposure to light as it would do in the absence of the chloride of mercury.

Mr. F. W. HART had some positives that were whitened in this manner some thirty-six years ago, and the chloride of silver was still white.

The CHAIRMAN thanked Mr. Wellington for relating his experience with bichloride of mercury. He (the Chairman) intended to experiment with it, and should have used a comparatively strong addition, but would now commence with a very small quantity, and would add it after the emulsion was made up. That might make a difference in the effect as regarded slowing the plate.

Mr. HART said that a much smaller quantity than that used by Mr. Wellington would prove a sufficient antiseptic. The pits sometimes formed in plates when setting were, he believed, due to a fungus, and to such organisms bichloride of mercury was fatal.

The CHAIRMAN said he had never seen pits in emulsion plates which could not be prevented by adding ammonia, more or less, to the emulsion.

It was announced that at the meeting to be held on the 18th instant Messrs. Marion and Co. would demonstrate the printing and development of their new paper.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

At the usual Board meeting of the above Association, held on the 3rd instant, at 181, Aldersgate-street, E.C., Mr. W. T. Smith, of Liverpool, and Mr. J. G. Gibson, of Tynemouth, were elected members. The Board considered the advisability of appointing local secretaries in large towns, and would be glad to hear from any persons willing to act in that capacity.

After disposing of other business the meeting was adjourned until January 7th, 1885. Assistance in response to applications was granted at this and a previous Board meeting after due consideration.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The second meeting for the current session was held in the Society's rooms, on Wednesday, the 3rd instant,—Mr. Norman Macbeth, R.S.A., President, in the chair.

The minutes of last meeting having been read and approved of, the ballot box was opened, and the following gentlemen declared duly elected:—Messrs. W. A. Bryson, G. Napier, Charles Murray, Aitken, W. Skinner, J. W. Miller, Henry Cowe, Herbert W. Eibbs, Robert Lindsay, Donald Mackenzie, and Alexander Thompson.

The following candidates were proposed for election at next ordinary meeting:—Messrs. John Coubrough, Thomas Burns, A. N. M'Alpine, B.Sc., George Gowie, William Grey, H. Pummell, David J. Lawson, James Sharp, George W. Heathcote, and T. A. Douglas Wood.

The report of the Council on the study of the picturesque was then submitted, as appeared in last month's *Transactions*.

The Chairman, in submitting this report, stated that of course this was a mere experiment, and it was impossible to say yet how it would succeed. It was thought by some that it would be well to hang the pictures for criticism on the walls; but after consideration it had been decided that it would be better to hand the pictures round for examination individually, and after all had been examined to give the members an opportunity of being heard on their merits and defects. A large number of pictures were then laid on the table and handed round for inspection, after which, when they were all returned, the Chairman called the attention of the members to a portrait of a lady. He said that, in the meantime, the names of the artists were to be withheld, so that members might freely express their opinions; afterwards he would, so far as he knew, inform the members of the names of the parties submitting the work.

Mr. Crook said the picture submitted appeared to him harsh in tone in the whites; there was a want of detail in the delicate shadows, while the arm and hand which fell upon the white dress was much too dark. Then the pose of the head and the hand on which it was leaning were too forced; the head ought to have inclined towards the hand, and shown that it was resting on it. This was not so in the present case, and the pose was altogether too evidently studied and artificial, and it seemed under-exposed. Twice the exposure would, he thought, have improved the picture to a very great extent, and given a much better effect.

Mr. Mitchell stated that the figure was too low down in the picture, and that to raise the head a little and cut a portion off the left side of the picture would improve its effect.

Mr. McKean thought that more exposure would have done no good, but rather increased the harshness to which allusion had already been made. He thought the fault lay entirely in the lighting; but the pose was also bad. The hand at the head was too prominent and badly arranged, while that on the dress was too dark; the lines were too straight.

Mr. Howie said it was by no means a pleasingly-arranged picture. The position was angular, the figure fronting too much, the dress too white, wanting in detail, and needing to be subdued in tone; while the hand on the dress had too much the appearance of a claw, and was not carefully posed.

Mr. Turnbull thought that had the hand been a little bent it would have improved the picture, while the fingers at the side of the head were too low, and the portrait was rather much of the front face for the portrait of a lady who had a large mouth, which was too markedly shown.

Mr. Brebner considered the chief fault of the picture was that the contrasts were too prominent. There was probably too little colour in it; it needed half-tones and more grey, otherwise he liked the picture very much.

The Chairman stated that to his mind the picture was remarkable for its breadth—a quality rarely seen in a photograph, because many of the lines of and connected with a subject could not be controlled, and this was a power the painter had which the photographer had not. He said the portrait was that of a celebrated Russian actress taken by Mr. Kareline, who gained the gold medal at the great photographic exhibition in Edinburgh, and it was considered one of the best specimens of portraiture in the exhibition at the time. Since then it had considerably faded; many of the finer half-tones and lines had disappeared, and the background had begun to get stained. He quite agreed that the head was too low on the picture, that there was far too little in the skirts of the dress, and he would be inclined to cut of a portion both at the top and at the sides. There was a considerable force of character shown in the face, but there was a weakness shown in the hand at the head as if she were studying too much not to spoil the lines of the face and hand by pressure. He had brought this picture with a view to mark the peculiar characteristics of Kareline's treatment, and he thought that one of the objects in keeping out the lines of the dress was to give value to the flesh tints, which he thought were most beautifully represented.

The next picture offered for criticism was a mezzotint engraving after Sir Thomas Lawrence, also belonging to the Chairman, who stated that his object in bringing it was to show the members what he considered, perhaps, one of the most elegant poses possible—a very fine example of composition in lady portraiture, for which Sir Thomas was famous. It was certainly tinged with mannerism, but that was probably the fault of the time in which he lived. This picture passed without comment.

There was then shown a picture by Mr. H. P. Robinson—*Yn Cymraeg y Saesneg*—two young women reading a notice bill printed "in Welsh and English" pasted on a deserted cottage door.

Mr. Howie said he had a feeling that comment on the pictures sent in by Mr. Robinson might to a great extent be impertinent; but he felt that in this picture the figures seemed too obviously posed for effect. The subject of the notice was not one likely to interest two country girls.

Mr. Brebner thought the subject a very difficult one to treat. It seemed to him that there was a want of balance in the picture.

Mr. Crook said the two girls might be interested in the notice, and thinking that "there was as good fish in the sea as ever came out."

The Chairman said his feeling was that the bare stonework on the left was rather too prominent, and swamped the delicacy of the figures. It was a difficult thing to contend with light dresses against a strongly-marked stone wall. The picture required some object, however small, to break the monotony of that wall, and give balance to the picture. The other side was well contrived, and the placing of the broken sieve on the ground, and the piece of wood put into the window, were very admirable. It was difficult to control the square forms of doors, and this was admirably done here.

The next was a photograph of some sheep, also by Mr. Robinson.

Mr. Crook thought the sky was too palpably printed in; the clouds of the horizon were too large and round to be true to nature. The direction of the light and everything else in the picture was beautiful.

Mr. Simpson considered that there was not enough light on the foreground, while the sheep were well lit, and the two did not correspond.

Mr. M'Kean stated that this was a fault common to all shutter pictures.

Mr. Stewart pointed out that this could not have been an instantaneous picture, as several of the sheep had moved during the exposure.

Mr. Bashford said this, to his mind, was one of the prettiest photographs he had ever seen. He had a copy for some years, and had picked it out of a number as one of the sweetest expressions of a sunny landscape possible. It was well balanced, the details were exquisite, and the picture of the sheep and their surroundings was very pleasant.

The Chairman shared Mr. Simpson's opinion as to the lighting, and there was too much uninteresting foreground which could have been remedied either by cutting a bit off the bottom or by placing a single sheep immediately in front.

Mr. Howie thought the latter would be a mistake.

Mr. Brebner differed from Mr. Howie. The base line of the picture being straight, the horizon line being straight, and the line of the sheep straight, the placing of a stray sheep would have removed the objectionable repetition of the straight line.

A Short Road in Summer, by Mr. Robinson, was then submitted.

Mr. Tamkin said his objection to the picture was that the figures were placed too exactly in the centre of the picture. He placed two cards over portions, cutting off about half-an-inch from the bottom and an inch and a-half from the right side, and showed how greatly the value of the picture was enhanced by this means.

Mr. Brebner perfectly agreed with Mr. Tamkin.

The Chairman concurred in this opinion. The picture was too evenly balanced; there was nothing left for the mind to do—it was too satisfying. The alteration shown by throwing the figures out of the exact centre set the mind in action to find the balance, and that gave the picture the interest it now wanted. Otherwise it was a very beautiful representation of a well-chosen little bit of nature.

Artist and Model by Mr. Robinson was the next picture put up for criticism.

Mr. Tamkin thought that the clouds in this picture were not well chosen. The sky was over-crowded, and not in keeping with the rest of the picture. The models, again, were standing in a peculiar way—neither natural nor graceful.

The Chairman pointed out how well this picture illustrated the power of balance, one single figure balancing the large group on the other side.

Mr. Robinson's picture, *Haymaking*, came next.

Mr. Simpson said this picture contained many elements of interest, and the feeling of relief in it was superb.

The Chairman said the effect was admirable, but the posing was too apparent. The action of the girls with the rakes was not that of country girls making hay. There were too many repetitions of the same pose, and too much apparent self-consciousness of posing for the purpose. A picture of *Loading Grain*, by another artist, was shown in contrast to this, in which the artist had much more successfully caught the natural positions and expresions of the workers. This was a much less pretensious picture, but there was an utter want of self-consciousness that made it more successful.

Owing to the lateness of the hour the further examination and criticism of the pictures, of which a very large number had been sent in, had to be postponed.

The Chairman hoped that the owners of those pictures which had not been commented on would either permit them to remain in the hands of the Curator, or would return them for a future occasion. He thought that the night's proceedings had been full of interest and education for the members, and they certainly seemed to be thoroughly appreciated by them. In regard to Mr. Robinson's pictures, he (the Chairman) said that these had been sent in consequence of a part of his address at last meeting, in which he had expressed a fear lest professional photographers would not send pictures for criticism. Mr. Robinson had certainly been generous enough, as these were not nearly all he had sent. He handed round a printed list of Mr. Robinson's pictures, and stated that members wishing to have copies of these pictures could be supplied at the prices there stated. He concluded by stating he could guarantee that all meetings for conference of this nature would be as full of interest as this had been.

Mr. J. B. READMAN then read *A Plea for a Work Room for the Use of Members.*

Mr. M'KEAN was heartily glad that this subject had come up again. What was wanted was not only a dark room for amateurs, but one in communication with the meeting-room, so that facilities might be had for practical demonstrations without the inconvenience which now attended them. The Society consisted of professional and amateur photographers. The professional did not need such accommodation as this proposed, but the amateurs, who constituted a very large proportion of the Society, do; and unless such a convenience as this were provided they might possibly get one for themselves and form a fresh society, splitting up this one, which would be left by such a split in a very awkward position. The question required careful consideration, and he trusted it would be taken up and considered, and the sooner the better.

Mr. TAMKIN thought that if it were found necessary for amateurs to separate from the professionals in this matter they might separate altogether, and it was matter for serious consideration whether more suitable premises could not be found having this convenience.

Mr. CRIGHTON did not understand that there was any proposal to sever the connection between the amateurs and the professionals. To him it had always been a great drawback that the Society had no place in which, besides holding ordinary meetings, they could meet informally to talk over matters, see the photographic papers, and where amateurs could have facilities for developing and printing their pictures. But he deprecated any idea of severance.

The idea brought forward in this paper struck Mr. BREBNER as being a peculiarly happy one, and, if carried into effect, would, he thought, meet a long and generally-felt want, not only for a dark room but also a reading-room and library, and a meeting-room for the members. A great many members, both amateur and professional, were theoretical enthusiasts; and it might happen that a man had a theory on which he desired to have the opinions of others, like himself, but had no facilities in his own premises for this. To such men a proper dark room and meeting-room would be invaluable.

Mr. BASHFORD said this was a subject which had often been before the Society, and last year it was remitted to a committee to make inquiries with a view to finding other premises which would meet the requirements of the Society. They failed, however, to find any place to suit except one, the rent of which was so heavy that the idea of taking that was abandoned. Under these circumstances the Council, he thought, were justified in coming to the conclusion that in the meantime they could advise no change in the place of meeting.

Mr. HUME highly approved of Mr. Readman's proposal, but it seemed to him entirely a matter of expense. By taking increased subscriptions from the members who desired the use of such a convenience, there would be no difficulty in getting what was wanted. But very great care would have to be taken, and stringent rules made about leaving chemicals around loose, and other matters of that kind. He had had some experience of students having uncontrolled use of a laboratory, and certainly, unless very stringent rules as to its use were made and enforced, the whole thing would very soon go to wreck.

Mr. TURNBULL stated that rooms apart from the ordinary meeting-rooms could easily be got at a moderate rent, if sufficient members came forward willing to pay (say) ten shillings extra per annum for such accommodation.

The CHAIRMAN said the Society was extremely indebted to Mr. Readman for bringing forward the matter, and for the trouble he had taken in getting so much information enabling him to put the proposal in practical shape, and he proposed that the matter be now remitted to the Council for inquiry, discussion, and report. In the meantime those willing to join in such a scheme might send in their names to the Secretary. He proposed a hearty vote of thanks to Mr. Readman for his interesting paper.

Mr. Bashford then exhibited to the meeting "ye phantom shutter"—a most ingenious invention by Mr. A. A. Pearson, of Leeds, combining an instantaneous drop shutter and a flap for ordinary hand exposure. After explaining its working he handed it round for inspection by the members, who greatly admired and commended it. Some interesting photographs taken by Mr. Pearson with the aid of the shutter were passed round, and also an exceedingly-successful photograph of a drawing room taken at night by gas illumination.

The CHAIRMAN called the attention of the members to the circular which accompanied the billet regarding the annual dinner of the Society, fixed to take place on Friday, the 12th inst., at half-past six.

A vote of thanks to the Chairman closed the proceedings.

GLASGOW AND WEST OF SCOTLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of the above Association was held in their Rooms, 180, West Regent-street, Glasgow, on Tuesday evening, the 2nd instant,—Mr. Hugh Reid, President, in the chair.

After the approval of the minutes the following new members were admitted:—Miss M. H. Thomson, Miss A. L. Robertson, Rev. Thomas Summerville, Messrs. C. W. Laing, W. F. Finlayson, W. H. Gowans, James Fleming, John Dove, W. H. Turner, James Watt, and Robert Dalglish.

The election of office-bearers was then proceeded with, the result being that Mr. W. Snell Anderson was elected Treasurer, and the following six gentlemen members of Council for 1885, viz.:—Mr. James Elder, C. E., Mr. W. Goodwin, Mr. R. Cutting, Mr. A. Bovenstone, Mr. T. N. Armstrong, and Mr. Charles Coulson.

Mr. T. N. Armstrong then read his interesting paper on *Home Portraiture* [see page 791], showing how variety of posing and lighting could be obtained in an ordinary sitting-room. He (Mr. Armstrong) then gave a demonstration of enamelling and retouching. His demonstration of enamelling was particularly good, and he turned out a number of prints at the meeting finished in the very finest manner and quite equal to the best professional work.

Mr. PARKER, in a few well-chosen sentences, moved a vote of thanks to Mr. Armstrong, and said that he personally, and he was sure few in the Association, had any idea that such first-rate portraits could be done at home.

After some conversation about the Exhibition, which opens in the Fine Art Galleries, on Wednesday, the 17th instant, the meeting was adjourned.

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

THE third monthly meeting for the winter session was held on Thursday, the 4th instant, in Lamb's Hotel, Dundee, when there were about fifty members present. Mr. J. C. Cox presided.

An exhibition committee was elected, and Mr. D. Ireland, Jun., was chosen as honorary secretary to the Exhibition, the joint treasurers being Mr. John Robertson and Mr. V. C. Baird.

Mr. Alfred Guthrie then read an extremely able paper on *Developers and Development* [see page 791], detailing his experiences with the different formulæ.

On the motion of the Chairman a very hearty vote of thanks was awarded to Mr. Guthrie for his instructive communication.

The Society's lime-light lanterns were then put in operation and a large number of slides were shown, the exhibitors being Messrs. Valentine, Mathewson, Ireland, Lawdon, and Jones. With the exception of Messrs. Valentine and Lawdon's slides, most of the others were on gelatino-chloride plates, which are now being extensively used for this purpose. Mr. John W. Lawdon, assisted by the Hon. Secretary, presided at the lanterns, and a vote of thanks was passed to these gentlemen for their services.

The Treasurer (Mr. Robertson) showed some large transparencies on gelatino-chloride plates of his own preparation, and another member kindly sent two frames of West's instantaneous photographs for exhibition.

The meeting was then adjourned.

LEEDS PHOTOGRAPHIC SOCIETY.

THE annual meeting of this Society was held on Thursday, the 4th instant,—Dr. Thorpe, F.R.S., in the chair. There was a very large attendance. After the confirmation of the minutes, the Chairman called upon the Hon. Secretary to read the following

ANNUAL REPORT.

THE Committee, in presenting their report, congratulate the members on the success that has followed the alteration in the constitution of the Society. At the first meeting held after the alteration the number of members on the roll was thirty-six. During the year forty-one new members were elected, but eleven have been excluded for non-payment of subscription, leaving the number of members sixty-six.

During the year the following gentlemen have delivered addresses or made communications to the Society:—Presidential address, by Dr. Thorpe, F.R.S. *Enlarging on Gelatino-Bromide Paper*, by Mr. J. W. Reffitt. *Notes on Developers*, by Mr. A. C. Pocklington. *Experiences of a Beginner*, by Mr. C. H. Bothamley. *Lenses*, by Professor Rucker, F.R.S. *Sodium Sulphite, with Bichloride of Mercury as an Intensifier*, by Mr. F. W. Branson. *Ferro-Prussiate Process*, by Mr. W. L. Wildey. *Photographing in Savoy*, by Mr. D. G. Law. Lantern demonstration, by Messrs. Bridge and Brook. Two of the ordinary meetings have been spent in general conversation and the exhibition of prints. The open lantern night in March was a great success, and the Committee are arranging for another to be held in February, 1885.

Excursions have been made by the members of the Society to Adel Moor, Otley, Knaresboro', and Gledhow Woods.

The *Transactions* of the Society have been, at some expense, printed and distributed to the members monthly. The Committee, believing this to be of great service, are desirous to continue the publication. The preparation of these reports would be greatly facilitated if gentlemen making communications would furnish the Secretary with an abstract of their remarks.

After the adoption of the report, the meeting proceeded to the election of the Committee for 1885. Upon the collection of the voting papers the Chairman declared the following elected:—Messrs. F. W. Branson, W. Denham, T. A. Marshall, J. W. Ramsden, J. W. Reffitt, H. Rodwell, W. Teasdale, F. E. Thorpe, Thos. W. Thornton, and S. A. Warburton. The Committee elected the following officers:—*President:* Dr. Thorpe, F.R.S. *Vice-President:* J. W. Ramsden. *Treasurer:* J. W. Reffitt. *Hon. Secretary:* Thos. W. Thornton.

This being the night arranged for the annual technical meeting, the Society proceeded to the consideration of the following exhibits:—An enlarging apparatus, consisting of a pamphengos lamp and a bellows camera, by Mr. J. W. Reffitt. The light was thrown on the negative by a six-inch condenser, and a twelve-inch focus rapid rectilinear lens was used as objective.—Mr. F. W. Branson exhibited photomicrographical apparatus, consisting of a photographic camera, to which was adapted a removable extending bellows front to connect the camera to a monocular microscope with eyepiece. The illumination devised by the exhibitor was by means of a two and a-half candle Swan's incandescent electric lamp, with frosted surface, placed in close proximity to the stage of the microscope, no condensing lenses being used. Mr. Branson also exhibited a drop and flap shutter adjustable for instantaneous exposures, and having in addition a pneumatic flap action for slow exposures of any duration.—Mr. W. Teasdale: camera for taking photomicrographs, also another for taking microphotographs, and specimen of work done by each; two forms of extension fronts for ordinary cameras; simple forms of exposure shutters; view meter; and Gorham's pupil photometer. He also exhibited his form of sensitometer for testing with ease and certainty not only the relative sensitiveness of plates but also their capabilities in the way of rendering gradation of tones. Mr. Teasdale said the principle was that of accurately-timed exposure on the sensitive surface to be tested, and registration of the effect in graded bands. His form of sensitometer differed from the ingenious one devised by Mr. Spurge, chiefly in the matter of the exposure being timed rather than measured by area of aperture and equal diffusion; but he and Mr. Spurge were in accord regarding all forms of sensitometers as more or less unsatisfactory which involved the use of a graded medium to be printed through. Mr. Teasdale also exhibited a recent portrait of Mr. W. B. Woodbury and prints by the stannotype process, and, in illustration of the sensibility of the ferro-prussiate and other printing processes for copying delicate line tracery, numerous sheets of such were exhibited.—Mr. Warburton: an old-fashioned folding camera, very ingeniously converted into a modern bellows camera, and simple apparatus for the making of gelatino-bromide emulsian.—Mr. J. W. Foster: McKellen's new treble patent camera, size 12 × 10; weight with slides, seven pounds.—Mr. Pearson: an improved patent camera by Middlemiss, Bradford, the first of which had been finished that day and shown by the exhibitor. The cameras, from half-plate to 12 × 10, fold up when closed to under two and a-half inches. The tripod top—a mahogany board which, when not in use, serves as a protection to the ground glass—brings the total thickness to a little under two and three-quarter inches. The extension front draws out to twice the length of the longest side of plate used, one-half of the extension being performed rapidly by the hand, and the other half having a rackwork adjustment actuated by one pinion. The front swings in a vertical direction; the back has both vertical and side swing. The rising front carries the bellows with it, the whole sliding in a framework supported by a strong brass strut—not pivoted like a looking glass; this makes it extremely firm and rigid, and renders any displacement by accident impossible. The fact of the bellows being attached to the rising front prevents the cutting off of the top part of the light rays, which would otherwiso inevitably occur with the taper bellows. The back is reversible, enabling horizontal or vertical pictures to be taken without altering the camera. The compactness when closed and the long extension when opened out enables the shortest-focus lens or the one-half of a symmetrical or rectilinear to be used with equal facility. Mr. Pearson also exhibited forms of drop and flap shutters, and prints from negatives taken in a drawing-room by means of gaslight.—Mr. Thomas W. Thornton, Hon. Secretary: prints from Marion's new alpha paper, pocket slide by Blakey, Emerson's patent carriage head-rest, and other articles.

In addition to the above a large number of exhibits was on view, and were inspected with much interest by the members.

BRADFORD AMATEUR PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held on Thursday evening, the 4th instant, in the Law Institute,—Mr. Duncan G. Law, President, in the chair.

Several 15 × 12 photographs of Yorkshire scenery were exhibited by Mr. Forsyth, one of the members, including some shown in the Pall Mall Exhibition. Mr. G. D. Scorah (Hon. Secretary) exhibited specimens on Marion's new alpha paper, which were lent for the occasion by Mr. H. C. Lewis, their representative, and were much admired. A new French head-rest was also brought forward by the Secretary; it was of metal, nickel plated, and very strong but light. It fixes to the back of an ordinary chair, and is, therefore, suitable for use when taking portraits in rooms. A new patent camera was shown by Mr. Middlemiss, which had double swing front and back and some novel points in its construction, besides being portable.

The meeting was then adjourned.

HALIFAX PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held on Tuesday evening, the 2nd instant,—the Rev. W. E. Hancock, M.A., President, in the chair.

The minutes of the last meeting were confirmed, after which the following new members were elected:—Colonel Charles Grove Edwards (of Ashday Hall), the Rev. J. W. Hall, Mr. L. Hanson, Mr. Rowley, Mr. W. Simpson, and Mr. J. Helliwell (all of Halifax); also Messrs. Charles and James Smithson (of Lightcliffe).

Mr. F. Myott, who was to have given a practical demonstration of emulsion-making, having been called away unexpectedly,

The Chairman very considerately volunteered to exhibit his new four-wick lantern, together with a number of slides made from his own negatives. The great brilliancy of the light was a matter of much surprise to all the members. For pictures up to six feet in diameter it seemed to compare favourably with the lime light. The slides were produced by the wet collodion process, and were of high-class quality.

As the next meeting would fall inconveniently near the festive season of Christmas, it was decided to postpone the date to Tuesday evening, January 14th, when the usual annual lime-light exhibition would be given, the Chairman operating with his biunial lantern, and all the slides used on the occasion to be the work of the members. As many of the members have had some rather varied experiences with the camera in foreign lands during the past season, a very enjoyable meeting is looked forward to.

Mr. E. A. Caw understood there was a considerable number of amateurs who would like to join the Society, but were prevented from doing so from, possibly, a feeling of diffidence or an exaggerated idea of their own shortcomings in the art. He thought this feeling was only natural, but as there was always an emoryo stage to everything, the Society, to give encouragement to such, ought to have evenings set apart for the special edification of those just entering the portals of the art.

Mr. Thomas Illingworth quite concurred with the views expressed by Mr. Caw. It was a very hard struggle for an amateur to attain technical excellence in matters photographic unaided. There were times when a little help set a man on his legs, after which he was able to run without stumbling. He was prepared to lead the way by giving an elementary demonstration of developing, and he would endeavour to treat the subject in as clear and comprehensive a manner as possible, giving examples of the treatment necessary for under, over, and correct exposures, using for this purpose the several developing agents now in favour.

Mr. W. Clement Williams, without meaning any slight to the professional element, said there were very few even amongst that august body who could lay claim to any mentionable knowledge of photographic chemistry, but who—like the officer who had seen much active service, though he could not pray, knew how to fight—could take photographic pictures nevertheless. He thought it would prove to the benefit of all members if certain half-hours of the meetings were devoted to the study of this branch of chemistry, for it was only by a correct understanding of the nature and of the powers and properties of the chemicals used all round in the formation of the photographic image that success could be expected. He did not believe in "flukes" in photography; nor in its truest sense this did not mean success, neither did it conduce to the making of *old* photographers.

Mr. Councillor Smith always liked to know the why and wherefore of everything. He infinitely preferred dabbling and experimenting among his chemicals, even if at times it ended in failure, than to be content with simply purchasing his plates and developing by a rule-of-thumb formula. He would be glad to do all in his power to assist in carrying out the proposals of Mr. Williams.

The Chairman looked upon photographic societies as having educational duties to perform as well as those of a mere social character. He was sure that if they could carry out the ideas already expressed a great good would follow, and he was prepared to do all in his power to further such praiseworthy objects.

Mr. Joseph Whiteley promised to give lessons in making paper negatives. He had practised this branch of photography before glass was introduced for photographic uses, and had, therefore, served a fair term of apprenticeship. Apart from the use of paper negatives to take the place of glass, they would be found exceedingly useful for combination printing.

Mr. Edward Gledhill would give a demonstration of microphotography.

Mr. W. Clement Williams would read papers on the *Artistic Printing of Negatives, Composition, Light, and Shade in Landscape Photography.*

Messrs. Birtwhistle, Hancock, Smith, Bingley, and Jones were also willing to contribute papers, the subjects of which to be left for future settlement.

It was stated that Mr. Middlemiss would attend at the next meeting to introduce his new patent camera, the Chairman reporting very favourably of its merits.

A vote of thanks to the Chairman for his lantern exhibition terminated the meeting.

NORTH STAFFORDSHIRE AMATEUR PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held on Wednesday, the 3rd instant, at the Mechanics' Institute, Hanley,—Mr. C. Alfieri, President, in the chair.

A number of photographs from various sources were exhibited for the purpose of selecting a presentation print for the year 1884. Upon taking a vote of the members it was found that a 12 × 10 photograph, by Valentine, entitled *After the Storm*, had secured the greatest number of votes. A requisite amount of copies was, therefore, ordered to be obtained.

After general conversation upon various topics of photographic interest the meeting terminated.

ST. HELENS ASSOCIATION FOR THE PURSUIT OF SCIENCE, LITERATURE, AND ART.

Photographic Section.

A meeting of this section was held on the 19th ult., at the Association Rooms, 4, Salisbury-street,—Mr. Heather in the chair.

Mr. R. G. Brook showed a large number of full-plate negatives of American scenery, and Mr. Heather a series of lantern slides made from them.

Mr. Brook read a paper on *Experiences with the Camera with the British Association*, illustrated by transparencies. [This paper will be given in our next number.]

On the motion of the Chairman a hearty vote of thanks was passed to Mr. Brook, which brought the meeting to a close.

DERBY PHOTOGRAPHIC SOCIETY.

The first annual meeting of this Society was held at the London Restaurant, Irongate, on Wednesday evening, the 3rd instant,— Mr. Richard Keene occupying the chair.

Among those present were Messrs. R. J. Billinton, C. Bourdin, A. H. Bennett, A. J. Cox, H. Jarvis, J. E. Kaye, R. Keene, C. B. Keene, E. J. Lovejoy, J. Merry, Male, J. W. Price, F. W. Simpson, J. Scotton, and R. L. Warham.

The minutes of the last monthly meeting having been read and confirmed, the following officers were re-elected for the year 1885:—*President:* Captain W. de W. Abney, R.E., F.R.S.—*Vice-Presidents:*—Messrs. C. E. Abney, B.A.; H. A. Bemrose, M.A.; and R. Keene.—*Committee:* Messrs. A. J. Cox, James E. Kaye, and Thomas Scotton.—*Hon. Secretary and Treasurer:* Mr. Fred. W. Simpson, Hamilton Villas, Mill Hill.

The Hon. Secretary then read the following

Annual Report.

The Committee, in presenting their first annual report, congratulate the Society on the successful start which it has made. Although the Society has only been in existence for six months the members now on the books number twenty-eight. The indoor meetings have been very fairly attended, and the following papers have been read:—*Landscape Photography*, by Mr. R. Keene.—*Photography*, by Captain Abney.—*A Photographic Tour in Wales*, by Mr. C. E. Abney.—*Scraps from My Holiday*, by Mr. H. A. Bemrose.—*Reminiscences of the Old Collodion Days*, by Mr. J. W. Price. The Committee regret that the outdoor meetings have not been so well attended, and trust that they may be more successful during the coming season. Excursions have been made to Duffield and Matlock during the past season. The thanks of the Society are due to Captain Abney as President, to the retiring office-bearers, to Mr. A. J. Cox for his kindness in providing a room for committee meetings, and to the proprietors of The British Journal of Photography, the *Photographic News*, and the *Amateur Photographer* for copies of their papers. The balance-sheet shows the financial position to be satisfactory. This report is necessarily short, as the Society did not commence work until the middle of the present year.

The report was unanimously adopted.

A vote of thanks was passed to the Hon. Secretary, Mr. F. W. Simpson, for his services during the past year, on the motion of Mr. A. J. Cox, seconded by Mr. J. Merry.

Mr. Thomas Scotton then read a paper on *The Photographic Processes Used in Copying Drawings*, which he illustrated by some exceedingly-fine specimens of the various processes, those by Pellet's process certainly carrying off the palm.

Votes of thanks were passed to the Chairman and Mr. Scotton, and the meeting was brought to a close.

Correspondence.

[*All communications for the* Editorial *department of the Journal should be addressed to the "Editors, 2, York-street, Covent-garden, London, W.C."*]

December Meeting of the Photographic Society of France.—Sulphocyanide of Ammonium as a Developing Agent for Carbon Prints and a Fixing Agent for Gelatino-Bromide of Silver Negatives.—A Bust of Daguerre.—Gelatino-Chloride Positives on Opal Glass.—An Appeal to all Inventors, &c., &c.—An Imperishable Coating for Photographic Trays, &c.—Typo-photographic Proofs.—An Old Method Brought Forward to Calculate the Rapidity of Rapid Shutters.—A Proposition for an Actinometer Made to the Society.—Report on the French Alpine Club.—A Cold Varnish for Negatives.—Presentation by M. Balaguy.

The Photographic Society of France held their monthly meeting on Friday evening last, the 5th instant,—M. Peligot in the chair.

A communication was received from a photographer at St. Denis (Ile de la Réunion). He proposes that all carbon proofs should be developed in a solution of sulphocyanide of ammonium instead of the usual plan of hot water. He says the same solution is of great utility in fixing gelatino-bromide of silver negatives, as no slipping of the film can take place when once the gelatine film has been treated by alum, as it is rendered completely insoluble with a prolonged immersion in a solution of sulphocyanide of ammonium.

M. Davanne informed the members that a small bust of Daguerre had been ordered by M. Cheron, so that all lovers of photography could possess the image of one of the fathers of that interesting art.

M. Hutinet presented some positives on opal plates made by the gelatino-chloride process, all produced by direct contact. This process is so little known here that it caused astonishment among many present. The development of gelatino-chloride plates lies in the future.

Messrs. Morgan and Kidd have endeavoured to popularise the process, as well as enlargements upon their paper, but their exertions have not met with the reward they merit.

I had the honour to present to the Society specimens of lanterns and other photographic novelties forwarded to me by Mr. J. J. Atkinson, of Liverpool. The members expressed their pleasure at receiving anything new from other countries.

M. Chala presented a great number of pieces of cloth, canvas, linen, zinc, wood, slate, iron, &c., which had been covered by a solution rendering them impermeable to damp, acids, &c. This solution was suggested as a means to enable amateurs to carry on their excursions very light trays for developing and other purposes. A simple sheet of paper covered with this composition and bent into the form of a tray will render as much service as the most elaborately-made tray. A zinc tray was made by M. Hermont, which, having been covered with this composition, was submitted to the action of nitric, hydrochloric, and sulphuric acids during two hours without the slightest alteration. It was then submitted to other tests, such as boiling water, steam, carbonic acid gas, &c. This composition will render great service to photographers not only for repairing their trays and other receptacles, but to paint their walls to keep damp from penetrating, or to prevent it from entering from the exterior.

M. Alexeeff, a Russian gentleman, presented a number of specimens of his new typo-photographic process. The results are not superior to what we have been accustomed to notice in The British Journal of Photography, where the Editors give us the pleasure of seeing some of our photographic celebrities.

A Young Member then described his method of controlling the rapidity of his instantaneous shutter. "I take," said he, "a black background three yards high, and I place upon it a white rule divided into feet and inches by dense black lines. I place my camera at a certain distance from this rule and focus sharp. I place a gelatino-bromide of silver plate in the camera and set the rapid shutter I wish to try. I now take a metallic sphere or ball (silvered, if possible). An ivory billiard ball would do, but I prefer a silvered one. I then hold the ball to the top of the rule, and when everything is ready I let go the ball. When I think it has fallen about a foot I set the instantaneous shutter to work. I develope the image, and, according to the shape of the image of the metallic ball upon the plate, I know the rapidity of the shutter. If the image of the ball be round it is rapid; the longer the ellipse the slower has been the opening and shutting of the lens. The exact calculation can be made by the law of falling bodies, as it is well known that an object goes through a certain distance in such a length of time for the first yard or foot. Its increased velocity is known after a certain number of yards, therefore the ellipsis formed by the falling metallic sphere can be accurately measured and the exact time given." This is all true, but a complicated calculation must take place; for who can undertake to make the portrait of the sphere when it has travelled a foot from the hand which held it, unless the ball by an electric combination could in its flight automatically open the lens? But a hindrance, however slight, would derange the calculation and be a great source of errors. For myself, I prefer the system suggested by my friend M. Vidal, and which I explained in one of my late letters to The British Journal of Photography—that of a long needle or clock hand making a revolution round a dial face in a given time. The hand being set in motion, no irregularities in its speed need take place, and the distance it has advanced during the opening of the lens can be seen on the dial face, so that no mathematical calculation whatever is necessary. Simplicity must be the motto for all who come forward with apparatus and ideas for the benefit of photography.

M. Vidal proposed that the members should devote themselves to the attempt to create or construct a photographic sensitometer or, at the least, a standard. He mentioned the proposition of a gentleman at Angoulême, which consisted in the superposition of a certain number of strips of tissue paper, one upon the other, so that in the instrument the first little square was formed by one thickness of paper, whereas at the other end the twenty-five thicknesses.

A long discussion took place, and paper was set aside as wholly unfit for the purpose, no two sheets being alike. It was proposed to take the idea of Mr. Warnerke and employ a tinted film obtained by Woodbury's photomechanical process, the Society to have a standard and compare all others by the standard, and thus render signal service to the photographic community by giving their guarantee that every actinometer bearing the mark of the Society agreed with the standard belonging to the Society. Opposition was rife against the Society selling a mercantile object, but it was proved to the satisfaction of all that a loss would attend such a transaction, and therefore no one would undertake to manufacture, and that a rich amateur must undertake it *pro bono publico*. As Mr. Warnerke's system was good, it was proposed to base the actinometer upon his system. This instrument would be all that is required if those that are in the market were exactly alike, but, alas! notwithstanding the care taken by the inventor, a great difference is apparent between some of them.

The best and most regular light which could be employed (after a long discussion) was found to be the Carcel moderator lamp burning a given quantity of oil per hour. M. Bardy spoke with great eloquence of the "Siemens' unit" lamp. He proposed experiments to be made with this lamp.

M. Pector then read an analysis he had made of the report of the French Alpine Club. The number of amateurs of our art, he said, was increasing rapidly, and the service which photography did in demonstrating and illustrating the different excursions made by the Club was incalculable.

The new photographic varnish which had been deposited at the last meeting was very favourably reported upon by all the members who had tried it.

M. Balaguy exhibited films attached to wood, zinc, &c., in order that the amateur could use films without danger while on a tour.

E. Stebbing, *Prof.*

25, *Rue des Apennins, Paris, December* 8, 1884.

THE MERCURY INTENSIFIER.

To the Editors.

Gentlemen,—In your last issue, "J. C.," of Southport, in a letter to the Editors has published an improved formula for the mercury intensifier. Feeling that it would be a matter of interest not only to myself but to photographers generally, might I ask him, through the medium of

the Journal, to give fuller particulars as to proportions employed both in A and B, and his method of using them.—I am, yours, &c., H. B. H.
Elm Rectory, Frome, December 6, 1884.

LANTERN TRANSPARENCIES AT THE RECENT EXHIBITION.

To the EDITORS.

GENTLEMEN,—I think it only fair in disputes of this kind for either party to bring forward any evidence that may tend to an amicable settlement of differences.

A short time since I was in conversation with a gentleman—a perfectly disinterested party in the matter—who told me that he was present when Mr. Gale's slides were handed in in due time, which makes it perfectly clear that the conditions were fully complied with on the part of Mr. Gale, as by other competitors.

I make this statement in fairness to Mr. Gale; and at the same time wish to tender an apology to that gentleman for any imputation or reflection that he may have thought my letter, published a fortnight since in these pages, cast on him, and I entirely withdraw anything that he may have thought unjust. The cause of my grievance was and is with the Executive of the Society, and that body alone are, I consider, entirely to blame. I believe they have treated Mr. Gale unfairly in not bringing his slides forward for exhibition, and in not cataloguing them the same in common with the other competitors, as I am sure he has nothing to be ashamed of in the class of work he produces.

Being a *competitive* exhibition it is imperative that all works must be on exhibition and in the catalogue. The Society make the rules, and the Executive are responsible for the way in which they are carried out. I, for one, was fairly startled when I saw a name appear in the journals with the award which was in neither edition of the catalogue or on exhibition. I wrote to the Society asking the reason, and in reply I was coolly told "That it was immaterial whether the work in question was either in the catalogue or on exhibition;" and that "the rules of the circular had not been violated" (!!!). I have been a competitor in exhibitions for the past twenty years, and never heard of such conditions before.

If the slides had been put on one side and forgotten until the last moment, why not have said so?—I am, yours, &c., W. BROOKS.
Reigate, December 6, 1884.

THE CARBONATE OF SODA DEVELOPER.

To the EDITORS.

GENTLEMEN,—After the very strong recommendation given by the Rev. Mr. Macdona that the washing soda developer was the thing for lantern transparencies, I at once set to work to make the developer with all care, making a pint of solution. The result of my experience is absolute failure. The image took nearly a-quarter of an hour in appearing, and when it did show itself no amount of coaxing could force up any density. Mr. Macdona writes again this week reiterating the praises of the formula, so I feel bound to give my experience and to ask for the experiences of others. I may mention that the developer was tried on plates of my own making, which developed beautifully with the tartaric acid developer recommended by Mr. J. C. Stenning in last year's ALMANAC. The clearing solution recommended at the same time I can thoroughly recommend.—I am, yours, &c., WM. WAINWRIGHT, JUN.
Hoe Place, Woking, December 8, 1884.

THE PHOTOGRAPHIC EXHIBITION.

To the EDITORS.

GENTLEMEN,—Mr. Donkin's letter in reply to Mr. Smith on the lantern slide award does *not* correctly state the case. As Mr. Gale's slides were not to be found on view anywhere in the Exhibition, as were the other slides, they could not come before the judges of awards with the other exhibits at the opening of the Exhibition, as per rules; and, if they were sent in in time, why were they left out of the catalogue? Pictures at an exhibition are supposed to be on view the whole time it is open to the public, and to be catalogued. If Mr. West's and Mr. Robinson's pictures had been omitted from the catalogue, and had been shut up in boxes out of sight—like Mr. Gale's were—would they have been considered on view, and awarded medals? In making this award to one out of the competition the judges have acted most dishonourably to those few who complied strictly with the regulations.—I am, yours, &c., P. H. FINCHAM.
December 10, 1884.

THE LIME LIGHT.

To the EDITORS.

GENTLEMEN,—I have been much interested in the articles on the lime light which have appeared in THE BRITISH JOURNAL OF PHOTOGRAPHY. It is more than twenty years ago since I first obtained Mr. Highley's price list, and I was a subscriber for his book on the manufacture of slides, but I think it was never published.

I was rather surprised to see him mention lead as the most suitable material from which to construct a hydrogen generator. Lead is very heavy, and is very easily injured. It is a fact (although not a well-known one) that dilute sulphuric acid has no effect on copper. I have a hydrogenator that has been in occasional use for over six years, and it is quite good still. He mentions one shilling as being the price of scrap zinc per pound. There must be a mistake, as I get it from the plumbers at three-halfpence. Never having used gas bottles I cannot speak about them, but I know it is next to impossible to get all the gas out of bags.

It may surprise Mr. Brooks to know that a regulator for bottles or bags such as he requires is already invented, and was described in your pages with diagrams about eight years ago. If he wish to learn more about regulators he can communicate with me. I can fully endorse Mr. Baker's statement that better definition can be obtained with the lime light than with any form of lamp. How any person could think of getting the best results with a gas or lamp flame it is difficult to conceive. There is even much difference in the lime lights. Mr. Baker, in your last number, gives three forms. The carburetted and the pure hydrogen forms he clubs together, although there is a marked difference between them. One takes two parts of oxygen to one of carburetted hydrogen, and with pure hydrogen there is only one part of oxyen to two of hydrogen. The former only gives half the light of the latter, and the light is somewhat brown. The lime light with pure hydrogen gives the purest, the strongest, and the cheapest light, and the luminous area on the lime is the smallest, thus giving the best definition. Much valuable information on the subject is published in the appendix to Tomlainson's *Encyclopædia*, the results of experiments being given, and not the mere opinion of anyone who happened to be quite innocent of any knowledge of the matter. My experience is that with pure hydrogen one-quarter of a pound of chlorate of potash lasts with one jet, with a sixteen-feet circle, three-quarters of an hour, and six ounces of acid by measure lasts a little longer. The last chlorate of potash I bought cost one shilling per pound, and the acid three-halfpence by weight, but the latter would only cost half of that if a carboy were taken.

There is a want of commonsense in the construction of lime-light apparatus. For instance: the limes are put in non-collapsible tins or bottles, allowing more air to get at the limes when there are fewer cylinders to absorb it. I make my own limes, and have little tubes made of thin india-rubber, cartridge shape, so that no air can get at the lime cylinders. When an expensive jet with lime burner is bought the screw is so fine that the pits in the lime are not turned wholly clear of the jet when it comes round again. As I make my own jets, buying only the nozzles, I can make them to suit myself; but with the majority of those who use or may use them such is not the case. Why should we be confined to cylinders? Why not use lime of any shape so long as it has a flat face? If Mr. Brooks will try the india-rubber tubes for his limes he would never go back to the tin or bottle, with all the mess the powdered lime makes.—I am, yours, &c., WILLIAM BIRRELL.
Hamilton, December 9, 1884.

Notes and Queries.

W. WILSON wishes to know if his varnished, mercurially-intensified negatives are likely to fade soon, as he noticed that some of them in which one-half only is varnished already look paler in the varnished than in the unvarnished side.——If Mr. Wilson will varnish one-half of another negative, intensified in a similar manner, he will most probably notice a lowering in the density, this effect being almost always produced with a collodion negative, and frequently with a gelatine one. Although it has been stated that many of the "insoluble" salts of mercury, such as the sulphide, &c., are soluble in spirits of wine, we incline to the supposition that this effect is optical rather than chemical, the particles being bedded, as it were, into a transparent solid such as the film left after varnishing. There is thus less hindrance to the passage of light rays than when the particles are not in optical contact with a medium entirely surrounding them. Mr. Wilson need have no fear (at anyrate on this account) of his negatives fading, for rather the reverse would be expected.

R. BATSON writes as follows:—"Having heard that some French opticians supply with their portrait lenses two extra lenses—one a convex to shorten the focus, and the other a concave to lengthen it—and having also read that single or non-achromatic lenses may be added to a well-corrected lens without materially interfering with its correctness, I thought by placing a double concave lens—a spectacle glass—between the lenses of my 8 × 5 rapid symmetrical near the stop I should lengthen out the focus sufficient to make it cover a 10 × 8 plate. But I find, now that the extra lens is added, I cannot focus the image at all. What is the reason? Should the concave lens be in the front or at the back, instead of the middle of the combination?"——Our correspondent has placed the lens in the proper position and in the only place it can be efficient; but he has selected a lens with too deep a concavity. Another lens must be obtained with much shallower curves. Its strongly negative character is too great for the combination. Any working optician will supply lens of different depths for a few pence each. A number may be purchased, and the one while on trial is most suitable utilised.

W. W. says:—"I went to Kew Gardens the other day, and attempted to take a photograph in the palm house, but it was impossible to get definition on the focussing-screen, owing to the condensed vapour, which simply poured down the lens and camera. As I have seen photographs taken in such situations, how is it done?"——In the first place, we will explain the reason of the difficulty experienced by our correspondent. The atmosphere within the palm house is always highly charged with moisture—frequently almost to saturation. This moisture always has a tendency to condense on anything that is cold. Now our querist, no doubt, on a cold day, took his apparatus, which was of the temperature of the outside atmosphere, direct into the building; hence, as a natural consequence, the moisture at once condensed upon it, the same as moisture in a warm room condenses upon cold tumblers or wine glasses, and forms dew upon their surface. The remedy is to keep the apparatus for some time in an apartment where the temperature is somewhat higher than that in the palm house, so that if the apparatus is made somewhat warmer there will be no possibility of the moisture giving rise to trouble.

G. P. asks about the photographic uses of the salts of silver in which the fatty acids enter into the composition. This branch of investigation has not, we believe, been pursued to any great extent, although sometimes a film with a soapy surface has been treated with nitrate of silver for photographic purposes. Stearic acid is one of the most important of the fatty acids, and it forms a powdery salt with oxide of silver, which salt exhibits electrical properties. It darkens in the light when moist, and is unalterable when dry. It is usually made by adding an alcoholic solution of nitrate of silver to an alcoholic solution of stearate of soda.

Exchange Column.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

Photographs Registered.—

Miss Catherine Middleton, Anglesea-place, Southampton.—*Photograph of the Staubbach.*

William Pankhurst Marsh, Norfolk Cottage, Bognor.—*Two Photographs of Breaking Waves at Bognor.*

Erratum.—Our attention has been directed to an inaccuracy which crept into our list of the awards at the Dublin Exhibition. The "extra" medal awarded to Mr. George Mansfield was *not* given by the Amateur Photographic Society, as stated. No such Society exists.

Enamel.—Write to Mr. Berryman, photographer, Redhill.

J. B. O. G.—Yes; the City and Guilds of London Institute.

Optician.—Messrs. Nettlefold and Co., High Holborn, will no doubt supply what you require.

G. Kedgwin.—A burnisher will confer a greater gloss than a rolling press. To your second query, see reply to "L. T."

J. H.—1. Any stout, smooth paper will answer the purpose quite well. A thin cartridge paper will be very suitable.—2. Yes.

Amateur.—One or two minims of a saturated solution per ounce is the proportion generally employed. Better use up the emulsion at once.

T. C.—Your neighbour can certainly build upon his premises and stop out your light. From your short tenancy you cannot claim "ancient lights."

White Rose.—You do not say whether you wish to print on paper or glass. The blue tint may be obtained from one or other of the blue dyes sold in sixpenny bottles.

L. T.—Messrs. Marion and Co. supply such a paper. Consult our advertising columns for the apparatus. We cannot undertake to recommend any particular manufacturer.

Mary E. Evans.—The *Spiritualist* newspaper of that date first published the fact that some of the so-called spirit photographs were forgeries. You cannot do better than consult its pages for full details.

B. A. Davies.—No special knowledge is required, but much will depend upon skill and judgment. Until you have acquired a considerable amount of both you cannot hope for any great success in your new undertaking.

Sigma.—Shake up the albumen sensitising bath with a little kaolin, and filter before use. The sensitised albumen or collodio-albumen film should be very much thinner in appearance than the film on a gelatine plate. You are working correctly.

Alf. A. Bott.—You have proceeded wrongly. By waxing the glass upon which you have produced your carbon lantern slides you have facilitated their splitting off with the heat. The glass should never be waxed in the carbon process unless the film is to be transferred.

Priory.—1. Possibly the plates themselves are unsuitable for the production of that particular colour. Try another sample.—2. No; but you might try the effect of substituting hydrochloric for the citric acid.

J. S. B.—1. Better try the experiment and see for yourself. The only means we have of knowing if the lenses will cover the size you say would be to try them.—2. Probably the slides admit light. See to this.

H. J. Murray.—There is no "good recent work" on the subject published in this country. The best information to be had on the subject is that contained in the series of articles, by Mr. Thomas Bolas, F.C.S., which appeared in our columns a few years back. The albertype is a collotype process, and is not patented in England.

Coleswegen.—From your description we surmise that the iron bed plate you have substituted for the wooden one is not of the same thickness; hence the cog wheels do not gear so well as they did formerly. Possibly the iron bed is thinner than the wooden one, so that the cog wheels are brought close together, and the teeth of the one work too deep into those of the other.

Southendon.—1. Make the reduction in the camera.—2. Purchase stereoscopic-sized plates and cut them in half.—3. Ferrous oxalate.—4. There is no work published on the subject.—5. Of course you can make the transparencies by the wet collodion process. If you have never succeeded in getting a good negative on a dry plate, where does the fault lie—with you or the plates?

Wm. Potts complains that in transferring carbon prints from the flexible support to ivory he cannot get the picture free from "glistening spots," which he imagines are air-bubbles. He is quite correct in his surmise. His mode of procedure appears correct, so that the imprisonment of the air-bells must be due to something in the manipulation. A little more care will, doubtless, overcome the difficulty.

W. H. S.—The dimensions of the studio will do very well. It will not be a bit too large. Instead of making six feet at each end opaque, four feet six or five feet will be much better. The design is very good. With the landscape lens you certainly *may* take portraits in the studio, but for general purposes it will not prove an efficient instrument, as it will be too slow. You must bear in mind that yours is the slowest form of landscape lens, as it must be worked with a comparatively small aperture.

Received.—J. H.; W. Hudson; W. Jones; E. Grant; Friese Greene; W. J.; "Country Cousin;" W.; M. E. W.; W. H. H.; Photo. Artist; Herbert Seely. In our next.

Mr. Andrew Pringle.—We regret that, though we give our esteemed friend's portrait in the current number, we are unable to include the necessary notice which should accompany it. This we shall do in our next issue.

International Inventions Exhibition. — The applications for space have now all been examined by Sub-Committees of the Council, and a selection has been made of the most promising. The number of applications has been so great that it has been decided to limit very strictly the admissions in those classes which may be considered to have been fully represented in the exhibitions of the present and of the past year. The Council will, therefore, be obliged to refuse many valuable exhibits in such classes as those relating to food, clothing, and building construction. It will even be a difficult matter to accommodate those which have been selected, and it is feared that the list will have to be still further reduced. As soon as possible information will be sent to those who have applied for space; but the enormous number of applications—far in excess of what was expected—have made it impossible to do this up to the present. The guarantee fund now amounts to £48,280—a sum considerably in excess of that subscribed for the Health Exhibition, or for the Fisheries, the amount for the former being £26,518, and that for the latter £26,656. —*Journal of the Society of Arts.*

The Photographic Club.—The annual dinner of this Club was held at Anderton's Hotel, Fleet-street, on Wednesday last, the 10th instant, —Mr. W. Ackland, Trustee, in the chair, Mr. E. Charters White occupying the vice-chair. About sixty members were present. The toasts usual on such occasions were given and responded to. The proceedings were enlivened with songs and recitations by different members, and original compositions were rendered by Messrs. W. Cobb and C. Ray Woods. An important feature of the evening was a testimonial in the shape of a massive silver inkstand and gold pen, which was presented to the Hon. Secretary and Treasurer, Mr. E. Dunmore. In presenting this the Chairman highly eulogised the abilities of Mr. Dunmore, and said that much of the success of the Photographic Club was due to his indefatigable exertions.——At the forthcoming meeting of the Club, to be held on Wednesday next, the 17th instant, the subject for discussion will be on *Microscopic Photography*—demonstration by Mr. E. C. White.

COLLODION EMULSION FOR TRANSPARENCIES.

Resuming the subject where we left it a fortnight ago, we may first of all say a word or two on our friend Mr. William Brooks's article in our last number. No one, probably, has had greater practical experience in the use of collodion emulsions—both unwashed and washed—than Mr. Brooks has, and his opinion is, therefore, worthy of every attention. But, if we may venture to make the suggestion, it is probably the very extent of his practical knowledge of washed emulsion-making, as well as of its use, that enables him to perform what others with less experience would fail to achieve successfully. We should be the last in the world to cry down the results obtainable with washed emulsion in the hands of such operators as Mr. Brooks; but we do not hesitate to say that the beginner in collodion emulsion work, if he make his own emulsion—as he will be almost compelled to do—will succeed better at first with an unwashed preparation.

The reason of this is not far to seek, and lies chiefly with the pyroxyline. This, though readily obtainable—or, rather, though formerly easily obtained—of a quality perfectly suited for unwashed emulsion, will not always bear the operation of washing in bulk, though when spread in a thin film upon glass it passes through the ordeal successfully. It is not necessary to discuss here why this should be so, but every collodion emulsion-worker knows that such is the case; the reason will be explained as we proceed with the details of the process. A few years ago, as we have said, it was easy to procure samples of pyroxyline commercially, which were quite suited for unwashed emulsion and less easily, and, at a higher price, to procure special samples for washed emulsion purposes. But, since the demand for collodion emulsion has disappeared before the wave of gelatino-bromide, it is doubtful whether such special brands are now obtainable at all.

However, for the benefit of those who may prefer to purchase rather than to make the pyroxyline we may mention Messrs. Rouch and Co., Messrs. Wratten and Wainwright, and Messrs. Hopkin and Williams as having in the past made a speciality of emulsion pyroxyline, and these firms may probably still make it at least to order. Another sample with which we produced very excellent results, both in washed and unwashed emulsion, was Anthony's No. 2—an American brand—formerly obtainable from Mr. J. J. Atkinson, of Liverpool. Schering's "celloidin," which may be had from any London dealer, is also very suitable for the purpose, and in consequence of its being perfectly soluble and not requiring filtering after solution is one of the best to employ. It, moreover, gives an exceedingly firm and structureless film—eminently suitable for transpariencies; but it presents some little inconvenience in use, unless a whole cake be dissolved at once, owing to its containing an uncertain and constantly changing proportion of alcohol.

Should any difficulty be experienced in obtaining a commercial supply of the article, we shall here append a few formulæ by which the photographer may prepare a home supply. The quantity required for a season's work on a private scale is not large, and the time and trouble involved are comparatively small; while, if the directions are closely followed, the operator may be sure of possessing a product suited to his requirements.

One of the best formulæ for pyroxyline for collodio-bromide—that is, for unwashed emulsion—is one given by the late Mr. Henry Cooper in the Almanac for 1871. With this formula we have produced some of the best dry collodion films it was ever our lot to use; and to save trouble we repeat it for the benefit of those who may not have the opportunity of reference. Take—

Sulphuric acid, s.g.	1·845	4 fluid ounces.
Nitric acid, „	1·45	2 „
Water		1 fluid ounce.
Cotton (dry)		100 grains.

The temperature should be 150° Fahr., and the cotton should be immersed for ten minutes.

Many amateurs of the present day have probably never tried their hands at pyroxyline making, so we may give them a few hints as to the mode of procedure. To prepare the cotton let it be pulled out into tufts and boiled in a rather weak solution of washing soda, then carefully washed until every trace of alkali is gone; or a weak solution of ammonia may be used, in which case the alkali is more easily got rid of. Squeeze out as much of the water as possible, pull into tufts, and dry thoroughly in an oven or otherwise.

The utmost importance attaches to the strength of the acids and their temperature, and the time of immersion must not be varied to any great extent. If the acids be weaker than the strengt given above, less water must be used. It must be borne in mind that weak acids and high temperature both tend to cause the cotton to dissolve, and also to render the product rotten and powdery.

Have ready an iron box or dish—an old saucepan will do—filled with sand; in this is bedded the basin or vessel in which the operation is to be performed. A water bath would be in some respects preferable, but the steam from it has a tendency to weaken the acids, owing to the strong affinity of sulphuric acid for moisture. Place the saucepan on the fire until the thermometer shows that the sand has reached nearly the required temperature, then pour into the basin the acids and the water. The temperature will probably rise above that given, in which case the mixture must be allowed to cool down to the proper point. Meanwhile, the cotton pulled into loose balls about the size of a walnut are spread upon a sheet of clean paper in a warm oven to become thoroughly dry and warm. The cotton, especially after treatment with alkali, is extremely hygroscopic and rapidly attracts moisture from the atmosphere, which, when it comes in contact with the mixed acids, raises the temperature, and probably causes the cotton to partially dissolve.

All being ready the tufts of cotton are taken one by one, and, with a couple of glass rods, pushed well below the surface of the acid, and, when the whole is in, allowed to stand for ten minutes. While this is going on, get ready a large basin or tub of cold water; when the time of immersion has elapsed, lift out the mass of cotton by means of the two glass rods or a couple of clean pieces of stick, and on a plate or in another basin squeeze out as much as possible of the acid. Then loosen its fibres by "teasing" it out with glass rods or sticks and pass it quickly into the water, moving it about rapidly and pulling it out as loosely as possible with the fingers in order that the cold water may get at it and remove the strong acid as rapidly as possible. If this be not attended to—if the cotton be thrown in in a solid mass—the water penetrates it slowly, and in mixing with the acid causes a great rise of temperature, partial solution of the cotton, and deterioration of the rest. A pair of rubber gloves will be useful in this part of the process, but if the operation be dexterously performed the acid will have no effect on the fingers. The earlier portion of the process should be carried out on the hob, or in such a position that the fumes may be carried up the flue.

Wash the product for some hours in running water, wringing it out thoroughly at intervals until it shows no trace of acidity. Upon the completeness of the washing will depend the keeping qualities both of the pyroxyline and of the resulting collodion or emulsion. If it be desired to work with washed emulsion, the following modification of the above formula will give superior results :—

Sulphuric acid, s.g. 1·845	6 fluid ounces.
Nitric acid, s.g. 1·45	2 „
Water	1 ounce.
Cotton	100 grains.

Temperature 140° Fahr., and time of immersion ten minutes. Here the larger proportion of sulphuric acid, the greater strength of the mixed acids (there being only one part of water in nine, instead of in seven, as in the other formulæ), and the lower temperature all combine to give qualities which enable the product when converted into collodion to bear the ordeal of washing in bulk. The various operations are the same as in the former case.

Very excellent emulsion, giving clear, structureless films especially suitable for transparencies, is obtained from papyroxyline—*i.e.*, pyroxyline made from paper. The following formulæ, published by us some years ago for washed emulsion, are equally suited for collodio-bromide :—

	No. 1.	No. 2.
Sulphuric acid, s.g. 1·843	3 fluid ounces	2 ounces.
Nitric acid, s.g. 1·42	2 „	1½ „
Water	......	½ ounce.
White blotting paper	145 grains	...... 120 grains.
Temperature	100° Fahr.	...... 90° Fahr.
Time of immersion	30 min.	...... 30 min.

It will be noticed that the temperature is much lower than in the case of cotton, and also that the time of immersion is longer. The various operations are in every way identical. Either of these formulæ will work well, whether washed or unwashed.

Our next article will deal with making the collodion.

THE CONDENSATION OF MOISTURE.—A SEASONABLE WARNING.

During the winter season photographers very frequently experience considerable inconvenience from the condensation of moisture, arising from a sudden elevation of the temperature (which is usually accompanied with great humidity of the atmosphere), and that, too, in many instances without the actual cause of the trouble being suspected.

Everyone knows the effect of taking a lens from a cold apartment into a warm studio. Moisture generally present in the air at once condenses upon the glasses. The same thing happens if the lenses have been left in the studio on a very cold night, and the temperature be suddenly raised by lighting a large fire. The effect of the condensation is often not noticed until it is attempted to focus, when it is found impossible to obtain a clear image. After the dew has been removed from the outer surfaces of the glasses the inner ones are usually found to be also obscured, which necessitates taking the combination asunder and thoroughly cleaning the lenses. Even after this treatment, if the glasses still remain cold, fresh moisture condenses, and it is only when the instrument attains the same temperature as the room that it can be employed. However, it is not with the condensation of moisture when it is palpably manifest that we propose to deal, as the trouble when once seen is easily remedied. It is rather with a view to point out what trouble may be, and often is, caused by condensation without the true cause being suspected.

Let us take the case of the printing department. During the winter months, when the weather is fine, the actual printing is usually conducted in open air ; consequently, if the temperature be very low, the frames and negatives become exceedingly cold. The frames are then brought into the room to change the prints. Here the atmosphere is warm and not unfrequently very moist ; therefore, when the frame is opened moisture at once condenses—not only upon the cold glass (if any) of the frame, but upon the surface of the negative as well. Hence the silver paper, as a rule, is put direct upon a damp surface. No very serious injury in practice results from this, if the negative be well protected with an impervious varnish. But it is the custom with many to get several proofs from gelatine negatives before they are varnished. Now, it is manifest that if the silver paper be placed on an unvarnished negative, with a layer of moisture upon its surface, stains in the film may easily be accounted for, particularly if, as is by no means unusual, the last trace of hyposulphite of soda has not been eliminated.

There is another example of the unseen action of moisture from condensation. It is well known in carbon printing that the presence of moisture in the tissue greatly enhances its sensitiveness, and also the so-called "continuating action of light." Now, if the tissue be put on a moist negative print, and after printing more moisture be allowed to condense upon it, then if it afterwards be kept several hours before development it will readily be conceived that the picture may turn out much darker than was anticipated. The effect thus produced is too often attributed to the imaginary "uncertainties" of the carbon process.

Everyone has noticed, when a sudden thaw sets in after a long spell of frosty weather, how the internal walls of houses, however dry they may be normally, teem with moisture. When this occurs photographers should at once direct attention to their stock of negatives. Glass being a bad conductor of heat, when it once becomes abnormally cold takes a long time to get warm again, during the whole of which period it continues to condense moisture upon its surface, should any be present in the atmosphere. The well-known map-like lines in some old collodion negatives caused by the cracking of the film is attributable to damp—frequently from the constant condensation of moisture upon them alone.

When a large number of negatives, as is often the case, are allowed to stand in close contact leaning against the wall they become equivalent to a solid block of glass. When such a mass becomes thoroughly cold throughout, and a sudden "rise" in the temperature occurs, it sometimes requires many days for the glass, owing to its bad conducting properties, to acquire the temperature of the surrounding atmosphere. During all this time the moisture present in the air continues to condense upon the edges of the negatives. The water so formed is then drawn between the plates by capillary attraction, and when the negatives are separated—perhaps not until weeks afterwards—they are found to be quite wet and utterly ruined. Thousands of negatives have been destroyed in this manner.

Here is another example of trouble that may be brought about by the unnoticed condensation of moisture. A packet of dry plates which have been kept in a cold place are brought suddenly into a warm and moist atmosphere and opened to fill the slides, or, may be, in the case of a professional photographer, to replenish the plate-box for the day's use. Moisture will, of course, condense upon them, and eventually be absorbed by the film. If the plates be used up quickly no practical harm will result, but if what are not used be packed up again, with the moisture still upon them, the case may be somewhat different. Sometimes, when a packet of plates have been opened, to save trouble they are repacked with pieces of blotting-paper between them. When this is done it is easy to account for stains or markings should any be present when the picture is developed.

Many other instances could be cited where the unnoticed condensation of moisture may, and often does, prove an undiscovered source of trouble in photography ; but sufficient has been said to direct attention to the subject, so that all may be put upon their guard at this season when sudden changes in the temperature may always be anticipated.

Condensation upon any particular substance or article can at all times be prevented by rendering it as warm or, better, slightly warmer than the surrounding atmosphere. Hence, if (say) a packet of dry-plates be kept for some hours in a warmer temperature than that of the apartment in which they are opened, there need be no fear of condensation of the moisture.

In the case of stock negatives, care should be taken during the winter months that they are never allowed to acquire an abnormally low temperature, and then all risk will be avoided.

POPULAR ERRORS REGARDING ILLUMINATION.

We recently observed in and otherwise interesting and excellent paper, read at a photographic society's meeting, the repetition of an error which, from its pseudo-scientific wording, long ago seized the popular fancy and has ever since been repeated from time to time as though it were a recognised and established canon of practice, notwithstanding our having called attention to its falsity on several occasions. We are alluding to the assertion that the light received from a window by any object diminishes as the square of the distance from that window. The belief in the truth of this dictum —which is obviously an imperfect attempt to apply a well-known and proved rule—is deeply rooted, and it is worth the expenditure of a little space to prove how misleading it is and to show how the actual theory which is thus travestied does not apply to the case at all.

"It will be seen that in proportion as he (the sitter) removes himself from the window the light diminishes according to the square of the distance." These are the words in the article to which we allude. Let us now take an example of the application of the rule. If the words imply anything they mean that an object situated at a given distance from a window and receiving a certain amount of light will, if removed two, three, or four times that distance, receive respectively, a fourth, a ninth, or a sixteenth of that amount of light. Thus, a picture placed for copying (say) two inches from the window would, if removed two feet away, receive only one hundred and forty-fourth as much light, and, in consequence, require more than two and a-quarter minutes' exposure if the first position needed one second only, and at a couple of yards away the one second would have to be increased to twenty minutes. It is sufficient, thus to place the application of the rule into plain figures, to show its ridiculous character, and we trust that after this exposition we may hear no more of the absurdity.

The error has arisen through treating a window as a light-emitting centre, under which conditions the rule would be sufficiently exact; for it is quite true that the amount of light received by an object does decrease according to the square of its distance from that object.

It may be said that the rule would apply in the case of "ground" or "obscured" glass, and the statement would be correct if this medium did so refract rays, which it received at any incidence, equally in all directions—a condition, however, which the most superficial observation would prove to be non-existent.

There, nevertheless, prevail some erroneous notions regarding the functions of obscured glass in the studio. Upon the fact that this glass may at times give an increase of light in a room owing to its scattering of incident light, it is too readily assumed that it does not on this account weaken the light entering into a room. The truth is that it may increase or it may weaken the light received by the sitter just according to the conditions of the case. If the sitter, posed for being photographed, can see through the window panes nothing but sky ground glass would have the effect of diminishing the light falling upon him, unless under very exceptional circumstances; while if, on the contrary, he should be able to see a red brick wall, for example, when looking out of the window, the interposition of the obscured glass over the window space till all such objects were hidden would augment the light he received to an appreciable extent. The reason is that in the former case some of the light which would otherwise reach the sitter is scattered or thrown into another direction, and in the latter, as there is no light he can receive through the particular portion of the windows described, the light that might have gone to illuminate the floor is made use of by a portion being refracted to the sitter's direction.

Closely connected with this branch of the question is the use of blue-coloured glass for studio lights. There cannot be a doubt that to some extent the glare of the light is mitigated by its use, and there is more relief to the eye under such a roof; but to suppose that no weakening of the light is brought about, or, as some maintain, that by being coloured blue it is caused to become quicker, is complete error. The part is less than the whole, and the light is only rendered blue by filtering out some of the other colours whose presence is never any opposition to the action of the quicker rays, and at the same time it is impossible to avoid robbing white light of some of its actinic qualities in causing it to become blue.

Another common fallacy is the idea that the size of the room governs the rapidity of working, the fact being that size has nothing whatever to do with the matter. The angle, vertical and horizontal, at which the light falls upon the sitter or object to be photographed is the only criterion as to its rapidity; and it clearly follows that the height of the solid walls, and not the proportion or area of glass, governs the working capabilities of a room. For light at a certain angle to be received, it follows that the smaller the room the lower the unglazed wall should be. If a room six feet wide need a wall four feet high, then a room eighteen feet wide would require a wall nine feet high for the light to arrive at the same angle at a point upon the floor in the middle of the room, which point would then be illuminated to precisely the same extent. The advantage of a large room lies in the fact that there is less inequality in the distribution of light over objects covering a large area, and also less variation in the amount of light received upon the various portions of a standing figure. In a small room with (say) a four-foot wall the feet would receive much less light than the head, while in a large one the inequality would be almost unnoticeable.

We may conclude by referring to the common views held about studios with a north aspect. In the first place, those who discuss this matter do not all attach the same meaning to the phrase. One man will say it means a studio running north and south, so that the sitter may face the north, while others suppose it to mean a room with the main skylight directed to the north. The latter we believe to be the best, as then the dominant light comes from the most equable quarter; but in the former the chief light will come from east or west, according to the mode of lighting, and in either case the illumination is more irregular, and the screening to be made for getting rid of the sun's direct light becomes more difficult. Unless the studio be short or it have a high wall at the south end it will be impossible to get rid of its rays without a series of screens more or less translucent.

We have now completed our survey of errors, but the greatest of all is that first named, and we trust that our words may have robbed even so long-existent a myth of the last trace of vitality.

Referring to the subject of astro-photography, which now has assumed such an important aspect, an interesting discussion took place at the last meeting of the Royal Dublin Society. Mr. Howard Grubb exhibited star maps photographed by the Rev. T. E. Espin, of the Liverpool Astronomical Society, and he elicited the opinion from Dr. Stoney, F.R.S., that the method was a revolution in one branch of photography. The photographs were taken with a camera mounted equatorially; and, as a strong proof of the value of the new mode of making star maps, the cluster pointed out by Mr. Grubb, wherein seventeen stars were shown while the best published maps only gave five, could not well be exceeded.

In a recently-published journal appears a paper, signed E. Vogel, San Francisco, California, of a very remarkable character as to the atomic weights of the elements. There has been for some time, as we have informed our readers, a strong undercurrent of opinion among scientific men that the atomic weights of the elements are not of the fixed and invariable value that, since Dalton's wonderful theory was first propounded, it has been the custom to consider

Strong proof has been brought forward to prove their variability, and in our own pages Mr. L. Warnerke and other experimentalists have brought to light discrepancies between practice and theory in regard to the combining proportions of cadmium, which are rather startling. We cannot give Herr Vogel's paper *in extenso*, but we may quote his words to show the conclusion which, in his eyes, the facts he marshals indicate:—"The evidence is such that no doubt seems to be admissible as to the reality of a variation in the atomic weights. This conclusion is independent of any value of the atomic weights; for the discrepancies exhibited in the results of Professor Clarke's recalculation from the same experimental data above quoted were inevitable if the variation of the atomic weights is not taken into account." The theories of chemical union have undergone great changes during the last twenty years, but complete proof of the variability of the atomic weights would be like removing a main pillar of the fabric of modern chemistry.

We have more than once heard a clergyman in his sermon introduce the terms employed in photography as a mental simile, but we have no recollection of having met with the word itself in the title of a work not connected with photography. Yet we learn that the title of the late Mr. Grenville Murray's work, the last chapters of which were completed only a few hours before his death, is to be *Under the Lens: Social Photography*.

Photographs of lightning are now quite common, but perhaps the most interesting yet published is one which appears in our contemporary *La Nature*—a reproduction by heliogravure of an instantaneous photograph taken by M. Desquesnes, of Billancourt, on the 13th of July last, but only presented to the Paris Academy of Science on the 21st ult. This remarkable photograph represents clouds and other *silhouettes* of trees, being in the latter respect different from other photographs of the same class. M. Desquesnes explains the presence of the trees by the illumination of the background of clouds through the repeated discharges which took place below the horizon while the camera was *in situ* with the lens uncovered. Having intended for some time to experiment in photographing lightning flashes he had marked his camera to focus for distance, and on the day in question, seeing that a storm was brewing, he placed the camera in a suitable place and waited for the lightning flash, the illumination of the sky by the unseen lightning flashes enabling him to discern the image on the ground glass, and so to point his camera without difficulty in the required direction. When the storm appeared at its height a flash of great brilliancy was seen, and he hastened to cover the lens and remove the plate before a second flash should be photographed. The effect is most remarkable, and as utterly unlike the conventional lightning-flash illustration as it is possible to conceive. The flash is seen to dart from a deep cloud, at once to split into two, and then to develope fresh departures till its course represents nothing so well as the roots of a plant spreading out in all directions, horizontally and downwards, with a few upward fibres, as we may call them to continue our simile. The photograph is likely to be of signal value in assisting to arrive at a true understanding of the track of lightning flash.

Mr. Edward Hart, of Lafayette College, U.S.A., is the author of a new method for the detection of iodine, bromine, and chlorine published in our contemporary the *Chemical News*. The process is very simple, and the apparatus to be employed equally so—consisting, as it does, of nothing but a flask, a bent tube, and a beaker. The tube ascends a short distance from the flask to which it is connected by a cork, then it is bent at right angles and ends, after a horizontal length suffices to clear the flask in a U-shaped prolongation, the U being furnished with three bulbs, and dipping into the beaker filled with cold water. The chemicals required are permanganate of potash, starch paste, chloroform, and solution of ferric sulphate. This latter is made by precipitating solution of ordinary sulphate of iron that has been boiled with nitric acid of ammonia, redissolving the precipitate to saturation in sulphuric acid diluted with its own volume of water, and then adding to the filtered solution a further quantity of dilute acid equal in bulk to that already used. It is recommended in the case of silver compounds of the haloids to fuse them first with carbonate of soda; but this is not an essential, though if nitrates, chlorates, bromates, or ioxates be present it is necessary to reduce them by fusion with carbonate of soda and charcoal. The substance is placed in the flask with some water, a few drops of the above iron solution, and a small quantity of starch paste placed in the bulbs (which are kept cold by immersion in the beaker of water). The contents of the flask are boiled. If iodine be present it will be given off and will colour the starch blue. Continued boiling will eliminate all the iodine, the absence of which may be shown by a fresh supply of starch, more iron being added if necessary. The bulbs are cleaned, and a few drops of chloroform and some water dropped into them. Bromine is liberated by adding a very small crystal of permanganate, and will be shown by colouring the chloroform in the usual manner. Boiling is continued till all the bromine is driven off, alcohol is added to decolourise the permanganate, and chlorine may then be shown after filtering the liquid by adding nitrate of silver. Mr. Hart states that the method is capable of showing the presence of ·0001 gramme of bromide of potassium, but that the presence of a large amount of bromine decreases the delicacy of the test for iodine. This method would seem to be very simple for ascertaining the composition of an unknown sample of gelatine plate if it be desired to ascertain which haloids are employed.

ANDREW PRINGLE.

Mr. Andrew Pringle, the well-known amateur photographer and writer, whose portrait we gave last week, was born in 1850. He was educated at Eton, Trinity College, Cambridge, and Royal Military Academy, Sandhurst, and entered the army as cornet in the 8th King's Royal Irish Hussars. He, however, did not remain long in the army, and, after travelling for some time, settled in Roxburghshire. Mr. Pringle commenced photography as an amusement about ten years ago, and with but a slight interval has continued to work enthusiastically at it ever since—with what succcess visitors to the various exhibitions can judge. Fond of travel, Mr. Pringle is invariably accompanied by his camera, and the readers of this Journal have had the benefit of his experiences on the continent as well as on the occasion of his trip round the world. We believe he has in prospect still another foreign trip of which we shall no doubt publish an account in due course. Mr. Pringle's writings are always practical and to the point, and carry with them the value that must attach to the opinions of a successful worker. Our picture, like the last one of Mr. Glaisher, is from a portrait by Mr. Mayall, of 164, New Bond-street, and shows how thoroughly under control is the electric light.

A METHOD OF MAKING TRANSPARENCIES AND REPRODUCING NEGATIVES.

Now that gelatino-bromide paper has become so general an article of commerce the following hints upon a new application may be useful to some of the readers of the Journal. Though I have not worked the process to any great extent I have succeeded in the few experimental trials I have made in producing perfectly satisfactory results; indeed, there is nothing in the whole method to be described which is not perfectly plain and straightforward.

The new application of gelatino-bromide paper to which I refer is the production of transparencies, or more particularly the reproduction of negatives. Whoever heard of paper transparencies? I fancy I heard somebody say. Well I have myself both heard of and seen them, but I am not going to describe anything of that sort, nor even paper negatives, as the readers will soon see. I need not here recapitulate the various processes of reproduction which have hitherto been put forward and used, but will just say that I think this one is new.

To plunge *in medias res:* the process consists in treating the gelatino-bromide paper as if it were ordinary "carbon" tissue, with bromide of silver as the pigment. It is sensitised in the usual way on a bath of potassium bichromate of such strength as may suit the particular purpose in hand, and exposed, when dry, in the printing-frame; then wetted, squeegeed on to glass or other support, and developed in the ordinary manner in hot water. The picture thus obtained is next submitted to the action of alkaline pyro., ferrous oxalate, or acid pyro. and silver, until an image of sufficient density is secured and all is finished.

The process differs from that published a few years ago, in which a gelatino-bromide plate was sensitised in bichromate, exposed, developed with ferrous oxalate, and fixed in the ordinary way, inasmuch as the latter produced a negative from a negative, and is entirely distinct in the principle of action. It differs also from Mr. Warnerke's patented process, because in that the combined action of exposure to light and of development bring about the state of insolubility of the film upon which the image depends; moreover, a comparatively thin layer of gelatino-bromide suffices in my method to produce any desired intensity, while in Mr. Warnerke's a considerable body of emulsion is required.

In the few trials I have made the following has been my *modus operandi*:—For transparencies from negatives of ordinary character the tissue (as I shall call the bromide paper) is sensitised on a five-per-cent. solution of bichromate, and if the best results are required squeegeed on to collodionised glass and allowed to dry. But it suffices on removing it from the sensitising bath to lay it face downwards on a sheet of clean plate glass, and, after squeegeeing out the superfluous solution, to remove it at once from the glass and hang it up to dry. The drying takes place much more rapidly than in the case of carbon tissue, owing to the thinner layer of gelatine the silver paper possesses.

When dry the tissue presents a strong, orange-yellow colour, and in this state is no more sensitive than carbon tissue—that is to say, the silver salt the film contains is practically insensitive to light owing to the presence of the bichromate. The printing is performed in the ordinary manner, but the operation may be watched as in the case of a silver print, for the brown image produced by light is plainly visible on the yellow ground and forms a perfect guide as to depth of printing. A "safe edge" must be used just as in carbon printing; in fact so far as concerns the "carbon" portion of the operations the procedure is just as usual.

When the development is complete the picture presents by reflected light a very delicate negative image of a bluish-white tinge, and, by looking through an equally-delicate positive image in various gradations of golden yellow. It consists, in fact, of a positive image in undeveloped bromide of silver. If in this state it be exposed to daylight the image will discolour more or less, some samples of paper, even by the same maker, showing more discolouration than others, while in the case of the paper supplied by one maker the image blackens by mere exposure to light sufficiently to give proper intensity. This is possibly due to the presence of chloride in the film, and it is very probable if such an article as gelatino-chloride paper be obtainable that the next stage of redevelopment might be dispensed with altogether, or by employing ferrous-citro-oxalate all the advantages of variety of tone that chloride gives might be gained.

The redevelopment is performed in the ordinary way after a short exposure to light. I prefer pyro. to ferrous oxalate on account of the better tone it gives, and also because there is *less liability to stains*. This latter may be deemed a somewhat extraordinary statement by those who are accustomed to the working of dry plates with both developers; but, if it be borne in mind that in the image produced as above described the high lights are clear glass with no film of gelatine to stain, it is obvious that what would be pyro. stain on an ordinary gelatino-bromide film will here be merely an alteration of tone. On the other hand, in using ferrous oxalate, the deposition of oxalate of lime upon the surface of the film takes place just as it does in the negative process.

It will be found that extraordinary density is obtainable with a very thin image; therefore care should be taken not to over-expose in the printing-frame, and so form too thick a layer of insoluble gelatine.

In reproducing negatives the only difference is that the operation is a double one—that is, a transparency must first be made. This intermediary step may be performed by any process, of course, but where the original is a very thin and unprintable negative *both* operations are better performed with the gelatino-silver tissue in consequence of the great power it gives in modifying the character of the gradations. In fact, whenever the printing qualities of the original require considerable modification, whether in the direction of greater vigour or increased softness, this process offers all the advantages that the carbon process presents. Thus, by altering the strength of the sensitising bath, by greater depth of printing, and adopting the method of "toning" so often described in connection with carbon, surprising results can be obtained.

With this process, however, the power is far in advance of that possessed with carbon; for, in addition to the capacity of the gelatine film to absorb colouring matters or "stains," the pigment itself is not only capable of reduction to metallic silver, but possesses the power of intensification by the piling-on methods just as an ordinary silver image in collodion.

I do not know that I need say any more on the subject at present. To those who are acquainted with the manipulations of the carbon process many possibilities and improvements will suggest themselves, and I have no doubt that before long some more competent pen than mine will take the matter up.

H. Y. E. Cotesworth.

THE STANDARD SYSTEM OF APERTURES FOR LENSES.

One of the most useful developments of scientific labour is the elaboration and settling of systems of standards. In all departments of modern science the want of definite standards upon which to base comparison has been felt, and the recognition of the want has been followed by a careful consideration of what should be the unit to be adopted. The decision upon which of several proposed units shall be taken has commonly been delegated to a comparatively small body of men, whose decision has been generally accepted; and, the standard having thus been fixed, a great convenience has resulted from its use.

When the difficulties in the way of arriving at a standard are considered, and the great confusion that would ensue from the setting up of rival standards or the changing of one that has already been accepted is borne in mind, it is much to be deprecated that an attempt should be made to supplant one standard by another, or to depreciate the utility of one that has already been discussed and accepted, unless some valid reason can be shown for making a change.

The Standard for Rapidity of Lenses.

Amongst the various standards that have been in late years fixed and accepted as aids to systematic working, and as helping to eliminate those failures which proceed from guesswork, one particularly interesting and useful to photographers is that which resulted from the labours of the Committee appointed by the Photographic Society of Great Britain for settling upon standards—the standard for rapidity of lenses, and the diaphragms or stops used therewith. Failures proceeding from incorrect exposures, due to mistaken judgment of the power and quality of the light upon the subject to be photographed, are no doubt sometimes inevitable; but that this cause of difficulty should be intensified and complicated by uncertainty as to the comparative rapidity of the various lenses, and diaphragms even of the same lens, is a quite unnecessary aggravation of the photographer's difficulties. It is, therefore, a matter for congratulation that opticians, having accepted the standard decided upon, should be engraving their lenses and diaphragms with numbers in accordance with that standard; and, on the other hand, it is to be regretted that an attempt should be made to unsettle the minds of photographers with regard to the usefulness or efficiency of such a standard, unless some solid ground can be taken for arguments against it.

It appears, from a paper recently read by Mr. C. W. Dean before a photographic society in New York, that in some quarters various objections are being raised to the already approved standard system. These objections, however, are not accompanied by a proposition for any standard more definite than that of marking the stops for each particular lens with a number showing its relation to the focal length, and its speed compared with other apertures for that particular lens.

Taking the objections to to the standard in detail, President Barnard, of Columbia College, is quoted as follows:—"The hypothesis upon which the Photographic Society of Great Britain has founded its law is that chemical changes affected by light are more rapid in proportion as the intensity of light is greater, and this with so severe mathematical accuracy that a double intensity will reduce the time necessary for exposure by one-half. But this is entirely an *à priori* assumption. It has been adopted because it seemed as if it ought to be so, and not because experiment has proved it to be so. Before attempting to construct a formula, which should express the relation of intensity of light to the duration of exposure required to produce a definite amount of chemical change, we should require to know more than we do about the laws which govern chemical changes during their progress; for the law which you find to fail takes it for granted that the resistance to change opposed by a chemical compound to the action of light is uniform from beginning to end—a thing which we have no right to affirm. I know of no better means of demonstrating this relation between area of lens and the proper duration of exposure than careful experiments systematically conducted with lenses of various areas and with similar illumination throughout. An empirical law might thus be ascertained, which for practical purposes would answer quite as well as a theoretical formula mathematically expressed."

The assumption of which Mr. Barnard complains—that double the intensity of light will work in half the time—is so natural a one that it might be supposed that when objecting to it he would have brought forward some arguments, based on experiments, to show that it is not true, and that some other relation does in fact exist. His statement, however, that "the assumption is entirely an *à priori* one, and not proved by experiment," can only be taken to mean that he does not happen to have made or to have read of experiments which have been made with a view to proving the trustworthiness of such an assumption in the very matter—the rapidity of working of various apertures of lenses—that is in question. Some long time since Mr. A. Cowan produced a series of negatives taken with lenses and diaphragms having apertures with a great difference of range. The time of exposure with each was strictly in accordance with calculations made upon the accepted standard system, and the resulting negatives were shown. No difference in the apparent exposure could be detected, showing that at all events the law which Mr. Barnard calls in question applies with sufficient strictness to the case to which it has been applied.

Mr. Dean objects to the Society's standard base of $\frac{f}{4}$, because he says many photographers—probably himself among the number—never use a lens with larger opening than $\frac{f}{4}$. The essential condition of a standard is that there should be some accepted unit, and to take $\frac{f}{4}$ because that happens to be the aperture of some particular lens or class of lenses, and thereby exclude or cause fractional numbers to be employed with such a large class of instruments as that which contains portrait lenses, is rather unreasonable. $\frac{f}{4}$ is about the aperture of many lenses of the rapid symmetrical or so-called aplanatic lenses, which have been so largely adopted by most opticians since their introduction some years since by Steinheil. There is, however, no finality in this particular proportion, and several makers have recently introduced lenses of this type with an aperture of about $\frac{f}{6}$. Steinheil's antiplanatic has a still larger aperture. $\frac{f}{4}$ includes almost all portrait lenses, and, after doubtless due consideration of other proposed units, is the one settled upon by the committee specially appointed to decide the matter. Some really valid reason should be given for attempting to alter a standard, as, in addition to the inconvenience attending a change, the uncertainty which would be generated might lead to the general abandonment of a standard altogether.

Other objections which have been raised against the standard may be briefly replied to as follows:—It is suggested that not aperture alone, but the colour of the lenses and the number of reflecting surfaces, will affect the rapidity of the instrument. As to the latter objection it may be mentioned that Mr. Cowan's experiments included lenses differing in this respect, without showing any difference that could be detected in speed due to the number of surfaces. The effect of colour in the glass of photographic lenses has, probably, been greatly over-estimated; but, if any particular lens be shown by actual experiment to have its rapidity affected in a marked degree by its colour, the stops for that lens should be so much larger or smaller as to compensate for the difference due to colour, and still work with the rapidity marked upon them in accordance with the standard or universal system. This last consideration, in fact, affords an additional argument in favour of the use of such a standard as has been adopted, rather than depending upon the marking of diaphragms with the fraction of focal length describing their aperture. In the latter case, after the calculation has been made to get at the speed according to aperture, a fresh allowance would have to be made for difference of colour or number of surfaces; that is, if such differences actually influence the time of exposure to the extent that has been assumed; whereas with the standard system the openings of stops for any particular instrument that was really found to differ from others in its speed, owing to colour or other cause, can be regulated according to the difference found to exist. W. E. Debenham.

STEARIC ACID FLAMES IN DEVELOPING ROOM ILLUMINATION.

The more immediately utilitarian demand for a standard light in photography is twofold; in the one case it is wanted for testing the sensitiveness of plates, and in the other for developing-room illumination. Captain Abney has recently pointed out the value of the acetate of amyl flame, burnt in the Siemens' lamp for the former purpose, but gave no experiments to show if it were better or worse than the phosphorescent screen already adopted by Mr L. Warnerke; and, as the latter is the cheapest and most readily applicable light for the purpose, the comparative value of the Siemens' lamp remains but speculative until this question is solved. Captain Abney could not trace any variation in the acetate of amyl light with barometric changes, but it does not follow that they were not there, or that the acetate of amyl flame is not subject to influences which govern other flames. The whole extent of the range of the barometer is about three inches, and the extremes of variation make a difference of about one candle in the illumination given by a sixteen-candle coal-gas flame. These extremes of atmospheric pressure occur very rarely; hence, with normal pressure and a flame of low illuminating power like that of the size used with acetate of amyl, Captain Abney would scarcely have been able to see the variation without great care in the photometric experiments. A temperature of eighty degrees Fahrenheit will lower the illumination of a sixteen-candle coal-gas flame by about one candle. The introduction to the Photographic Society of Mr. Siemens' cheap and simple, approximately standard light is good work done, but the value of the lamp as compared with Mr. Warnerke's standard light already in use is left without elucidation.

An approximately standard light is, however, wanted for developing-room illumination, and for this purpose Mr. Warnerke's light is not available—at least when used with the present area of the luminous source, and under present conditions.

Whether a developing room luminous all over, and with dangerous rays cut off, can be devised is a question for the future. At present nearly all photographers but dry-plate makers are using variable daylight as the initial source of light for development, whereby they are injuring their eyesight and groping constantly in semi-darkness; because, if the light in the room be safe when the daylight is strongest, at all other times the operator must be placed in an unnecessary amount of darkness, and in the climate of England he must be almost constantly working in these "other times" of reduced luminosity. In consequence of the perseverance, so characteristic of our race, with which the operator works in a light varying exceedingly in intensity from time to time, he is hardly likely to feel much interest in a scientifically-accurate standard source of light, supposing that he could obtain one short of platinum at the point of freezing, nor do I think that he would even go so far at present as to invest in acetate of amyl. If he adopted any common candle to be found in the house, and used a translucent yellow screen just intense enough to permit the use of the best powers of that candle, he would by this simple method obtain a comfortable degree of illumination in the developing room to which the red-screen daylight man is wholly unaccustomed. After a farther stretch of experience he might go so far in equality of illumination as always to buy candles of the same composition and make, and when he has reached this point the question remains whether, to get more equable illumination, it would be worth while to go to the moderate extra expense of burning acetate of amyl. Probably not. Gas or oils would not be likely to oust the candle except in the matter of cheapness, because these liquids would present greater difficulty in getting a flame always of the same size and luminosity. The Carcel standard lamp could be used for oils, but it is expensive in the first instance, and requires constant and scientific care in the management.

For all these reasons it seems probable that in improving developing-room illumination the more immediate sheet anchor of photographers in general will be the common candle, and some will go farther by using one kind of candle only, and by ascertaining in the first instance that it is specially good for the purpose. They will then find that there are three great classes of candles, namely, those made of paraffine, spermaceti, and stearic acid. Each of these has its special merits. Paraffine gives the greatest illuminating power, spermaceti is the most uniform in chemical composition, and stearic acid in candles does not bend or "gutter." The objection to paraffine is its tendency to bend when sufficient time is granted; in fact, it is not a solid in the true sense of the term, but, however hard it may be, it is classed by high-caste scientific men as a liquid. Spermaceti is expensive. Altogether a good practical candle to begin with, and one which is not liable to bend and "gutter" in the heat of a photographer's lamp, is one made of stearic acid, popularly but erroneously called "stearine." Stearine is a stearate of glycerine; the glycerine is removed in the manufacture of candles, and is made into soap or dynamite for Irish and other purposes.

For much information about the manufacture of stearic acid on a large scale I am indebted to Mr. Leopold Field, a clever experimental chemist, and the manufacturing partner of the great house of Messrs. J. C. and J. Field and Co., Lambeth Marsh, London. His family has manufactured candles for the British Government and the British public from time immemorial—the name of the founder of the establishment being lost in the dim mists of antiquity, the remains of at least six generations resting beneath the shadows of Lambeth Church. Kings and queens, bishops and archbishops, statesmen and commoners have used Field's candles as far back as records can be traced, and continue to do so to this day. Even the "fighting dips" used by the British tar are supplied to him now as they were in the days of Nelson and Drake. Who knows whether Guy Fawkes did not fail in an earlier pyrotechnical attempt because the founder of the house of Field, on the other side of the Thames from the Houses of Parliament, refused to supply him with a "farthing dip," remarking that he did not like his general appearance?

Few who have not inspected large works like those of Messrs. Field and Co. can have any idea of the amount of experience and science brought to bear in the manufacture of candles, and in the present development of the knowledge of the chemistry of the fatty acids, into which subject it is not now possible to enter at any length. Briefly stated, one method of making crude stearic acid is to mix the tallow as received from Australia and elsewhere with a cream of slaked lime; heat is then applied, stearate of lime is formed in chalky lumps, and the liberated crude glycerine is run off from the tanks. The stearate of lime is then treated with sulphuric acid, sulphate of lime is formed as a waste product, and stearic acid charged with oleine remains. This oleine is squeezed out by pressing the cakes between mats and iron plates, the heat and hydraulic pressure being gradually increased as the cakes become hard enough to bear them. The more of this treatment the cakes have received the harder is the stearic acid, and the higher is its price. A test of a stearine candle is to cut it and to notice its degree of hardness. When absolutely-pure stearic acid is required, which is never the case in candle-making, it is refined by successive crystallisations of the crude of acid from hot solutions of it in alcohol and ether, which finally yield it in pearly scales. The purer the acid the higher is its melting point, which in that crystallised from ether is 159° Fahr. It fuses into a colourless oil without taste or smell. It forms salts with certain alkalies and metals, and stearate of soda is the basis of ordinary hard soap.

The approximately standard light, when obtained from stearine or any other source, should always be placed at a fixed and invariable distance behind the yellow, translucent screen of the lamp. The uncertainty introduced by the too common neglect of this rule is remarkable. For instance: if in one experiment the flame be three inches behind the screen, and in another four inches, in the former case the illumination of the screen will be greater than in the latter in the proportion of sixteen to nine, or very nearly double. In fact, if a lamp flame were used, and chanced to be turned a little higher in the first experiment, the illumination of the screen in that case might be much more than twice as great as at the four-inch distance; yet this has often been done in public in what were supposed to be comparative experiments.

The employment of but a single candle implies the use of a screen which will not obstruct much light, such as two thicknesses of superimposed bright yellow—not orange—tissue paper, a foot square, six inches from the flame. The sheets of paper must not be gummed or pasted together at any place at which the light shines through them. The temptation to use three thicknesses of tissue paper will arise solely from the uneven texture of the fabric; hence the demand I have so often made for bright yellow oiled-silk to give good colour and feeble but even translucency. If a given plate should be found to fog somewhat when developed close to this lantern the operation should next be performed a few inches farther off, since the fogging power will diminish immensely with each small additional increment in distance.

In searching for standard candles larger than those used for gas testing, I introduced myself to Mr. Leopold Field, and was surprised to learn from him that some intelligent photographers had previously felt the want, so that for some time he has been manufacturing what are known on the premises as "photographic candles." Some of these are made of spermaceti, others of stearic acid, and others of ozokerit, all of "moon" size, which is the average size used in carriage lamps. The wicks in these candles are always of exactly the same make to promote uniformity. Extra hard hydrocarbons and fatty acids are used in the manufacture of these photographic candles; the stearic acid in them melts at 140° Fahr., the ozokerit (mineral paraffine) at 142° Fahr., and the spermaceti at 115° Fahr. The melting point of ordinary spermaceti is 111° Fahr. Reckoning the light of ozokerit at 1,000, the same weight of spermaceti will give a light of 750, and stearic acid a light of 700. The candles of each substance burn away in about the same time.

W. H. Harrison.

DEVELOPERS AND DEVELOPMENT.*

In all cases correct exposure will give the best results, but should there be, through any cause, much under- or over-exposure, this developer will afford as good if not better results than any other that I have yet tried. For some reason or other it does not seem to have been taken into popular favour in this country, though used so commonly on the continent. Many plates can be developed in the same developer, and if it be returned to a stock bottle and exposed to sunlight for a short time it will recover its power to a great extent, and is preferred to newly-mixed developer for giving softness of detail. Another developer, for which I have a soft side, is the potash developer. I saw it mentioned first in an American paper, and after I tried it and saw the bright-looking negatives resulting from its use, I was very much pleased with it and have since kept it in stock. It is an excellent developer for some plates which, with ordinary developer (pyro. and ammonia), give red or grey fog. What I mean by grey fog is the negative having the appearance, when looked at by reflected light, of not being properly fixed—having a grey or yellow appearance all over it. When looked at by transmitted light it only seems slightly filled up in the shadows; but in most cases this developer will be found to give absolute clearness in the shadows.

There are some makes of plates, however, which do not work up in a satisfactory manner, the negative being weak in contrast. When this is the result (not from over-exposure) one or two drops of a weak solution of ammonia will usually give it all the energy needed. Another very handy developer, and one which I usually keep beside me, is the ordinary pyro. sulphite of soda and ammonia. This I always use when copying anything, such as engravings from books. It is a very nice working developer, and though in most cases I prefer either of the developers I have named, yet this one is excellent. Either of these developers can be used over and over again till exhausted, and the results are equally good till the developer is exhausted—having no tendency to stain the film—and the colours of the resulting negatives are good for giving rich prints with plenty of contrast.

I have tried almost all the developers as they have appeared in the photographic journals from time to time (not that I was dissatisfied and intended to change, but just to see the effect), hydrokinone and hydroxylamine alone excepted. About these I know nothing. My feeling in the matter is that with a good plate properly exposed almost any of the published developers will give good results when carefully used, while with the same developer the good plate can be spoiled by careless treatment. Captain Abney says that any person can make a good plate by following the instructions, but to develope that plate is a science.

I shall now go over in a very short way some of the developers at present in use, and as far as I can the mode in which those developers should be employed. I have already alluded sufficiently to the ferrous oxalate, and will take the pyro. and potash developer. The formula is as follows:—

No. 1.—Pyro. Solution.

Warm water	2 ounces.
Sulphite of soda	2 ,,
When cold add—	
Sulphurous acid	2 ounces.
Pyrogallic ,,	½ ounce.

In all cases these weights are calculated at 437 grains to the ounce.

No. 2.—Potash Solution.

A.

Water	4 ounces.
Carbonate of potash	3 ,,

B.

Water	3 ounces.
Sulphite of soda	2 ,,

When dissolved mix A and B. These two stock solutions will keep a very long time. I have some made up last spring as good as when first mixed. In this developer purity of the ingredients is a *sine quâ non*. For instantaneous exposures take three ounces of water, and add three drachms of No. 1 and two drachms of No. 2. This, being a very strong solution, will usually bring out the image rapidly and with full density; but if more strength be necessary add No. 2. For ordinary exposures and very rapid plates (not drop shutter) less than half this strength of developer will be found ample; in fact, one drachm of No. 1 and half-a-drachm of No. 2 to three ounces of water will be found to give excellent results, with the shadows clear, and, at the same time, having all detail. Should the plate, however, not give sufficient density one or two drops of a solution of ammonia—one to ten of water—will be found to act very rapidly and give density to the image. Though I have given these proportions they are, of course, subject to considerable variation with the nature of subject and amount of exposure given. If over-exposed, less of No. 2 and weaker developer; if under-exposed, more of No. 2 and stronger developer—more of No. 1 for vigour, and more of No. 2 for detail. This developer does not stain or cause fog, though it is said by some to cause frilling. This, however, is not my experience.

Next, the washing soda developer:—Stock solution No. 1—Add clear crystals of soda till no more will dissolve.

No. 2.

Water	40 ounces.
Oxalic acid	96 grains.
Bromide of potassium	40 ,,

* Concluded from page 791

For use: to one ounce of water add a-quarter of an ounce of No. 1 and pour over the plate. Then take one ounce of No. 2, add one grain of dry pyro., pour the soda solution off the plate into this, mix, then pour on the plate, and you will get any amount of density and detail if you have exposed properly. Another formula gives—

No. 1.

Sulphite of soda	4 ounces.
Hot water	10 ,,

Add four ounces of sulphurous acid, and pour into one ounce of pyrogallic acid.

No. 2.

Washing soda	$3\frac{1}{2}$ ounces.
Sulphite of soda	$\frac{3}{4}$ ounce.
Water	64 ounces.

For use: take one drachm of No. 1 to each ounce of No. 2. This formula will also give plenty of density and detail where correct exposure has been given. If plates are over-exposed, twice the quantity of water must be used. The washing-soda developer seems to have very little power to force up an under-exposed plate, and an alum bath must always be used to remove the yellow colour given to the negative. Of the two formulæ above, the one mentioned first gave me the most satisfaction.

Sulphite of Soda.

There are several formulæ given in the photographic journals, but the one I like best is—

Sulphite of soda	4 ounces.
Hot water	56 ,,

Neutralise with citric acid, and then add one ounce of pyrogallic acid.

No. 1.

Ammonia	1 ounce.
Bromide	180 grains.
Water	40 ounces.

With equal parts of Nos. 1 and 2 for correct exposure. This is an excellent developer, and I prefer it in every case when copying. For under-exposure more of No. 2, and for over-exposure less. With this formula you can have thorough command over your plate, though there are some plates which give green fog and metallic stains when any attempt is made to force them with this developer; but the rule is a brilliant, bright negative. The ferrous oxalate, the potash, the washing-soda, and the sulphite-of-soda developers can be used over and over again till exhausted,

For a rapid developer the one I like best is Swan's :—

No. 1.

Pyrogallic acid	30 grains.
Water	10 ounces.

No. 2.

Ammonia	1 drachm.
Bromide of ammonium	1 ,,
Water	10 ounces.

With equal parts for correct exposure. This developer acts very rapidly, and, therefore, requires to be watched closely. For under-exposure more of No. 2, and for over-exposure less. The best way when using this developer is to add No. 2 a little at a time till sufficient strength is obtained. New developer must be mixed for each plate.

In the remarks I have made I have said nothing new, and I have only intended them for amateurs who know less than myself, and I have to ask the pardon of professional photographers and proficients for taking up their time, when they were better able to speak with authority on the subject. Alfred Guthrie.

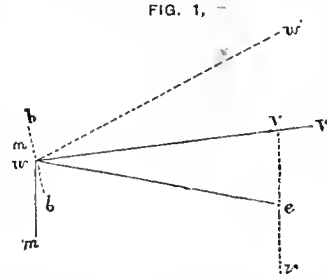
AVOIDING REFLECTIONS AND GRANULARITY IN COPYING.

[A communication to the London and Provincial Photographic Association.]

In copying photographs and other pictures by the camera, the two chief difficulties that occur to those otherwise skilled in photographic manipulations are the fogging or weakening of the shadows in parts, caused by reflections from the surface of the picture to be copied ; and the granular appearance caused by photographing not only the picture itself, but the grain or irregularities of surface of the paper or other material upon which the picture has been produced. I have known a skilful operator—perhaps the most capable all-round portrait photographer as poser and manipulator combined that I ever knew—copy a photograph from which an enlargement had to be made, in such a light that the irregularities of the paper of the original came out with so much strength and distinctness as to require at least an extra day's time of artist's work in finishing the enlargement. Even then, probably, the resemblance to the original would not be so good as might have been the case if the picture to be copied had been placed in favourable conditions of lighting. In this particular instance the original print was upon paper, the albumen surface of which had cracked all over, as was not unfrequently the case a few years ago, when very highly-glazed surfaces were sought for.

In order to get at the principles which govern the occurrence or avoidance of interfering reflections when copying, let us take a case of a typical kind, and suppose that a mirror has to be so photographed, that the glass shall be represented by blackness, and the frame and any tracery, drawn (say) with French chalk here and there upon the glass, shall be represented in their proper form and gradations in the copy. This supposition is not a fanciful one, but actually represents very closely the copying of a daguerreotype, and may be shown, though somewhat less obviously, to represent the copying of any picture where there are reflections to be avoided. It is assumed that the mirror is vertical to the direction of the camera. Well, an eye placed in the position of the lens will see itself reflected in the centre, and in the various other portions of the mirror will see those objects reflected whose images fall upon the mirror at the same angle as, but in the contrary direction to, lines drawn from the eye to each portion of the mirror. This fact is expressed in the well-known law of optics that the angle of reflection is equal to the angle of incidence. Perhaps a diagram may help to make matters more clear. Let *m m* be a mirror, and *e* the eye of the observer, then if a window exist in the direction W, the eye will see itself in the centre of the mirror (about the centre), the face of the observer, and at *w* an image of the window, together with the various other objects which fill up the intermediate space. All this in face of the blackness which the conditions assume as desirable and even necessary for the object required. The portion of the mirror where the image of the window is seen will appear so bright that the chalk marks on the mirror, which were to represent light on a black background, will be dark by comparison.

FIG. 1.



Now, let *v v* be a black velvet curtain, with a hole at *e* for the eye to look through : the pattern traced upon the mirror will show clearly against the black background of the velvet curtain. In order that this blackness may be more perfect, and not interfered with by reflections of the pile or folds of the velvet, or by the reflection of the eye looking through the hole, let there be no source of light in front of the curtain —that is, between the planes *m m* and *v v*, if both of them were extended infinitely—but let the light come from behind the plane of the curtain over its top and round its sides.

It will be noticed that the curtain *v v* must be of such dimensions that lines drawn from the eye to the extremities of the mirror, and returned at equal and opposite angles, shall fall within the surface of the curtain ; therefore, if the curtain be upon the same plane as the eye, it must be of at least double the dimensions of the mirror. In practice, the dark surface must be larger than this, and for the following reasons :—The mirror is assumed and may be considered to have a perfectly plane surface. The surfaces with which we have to deal are not perfectly plane ; and, although the deviations from flatness may be very small, they will be sufficient to require a certain allowance. These deviations are of two kinds—first, such as may be most strikingly illustrated in a daguerreotype, the plate of which is bent, if ever so slightly. Suppose the daguerreotype to be so much bent that that part of it which is at *w* lies in the direction of the dotted line *b b*, the angle of incidence would be in the direction of the dotted line *w w* ; and in order to prevent reflections from any light object being seen in the plate, and appearing as false light in what should be the shadows, the screen would have to be extended until it cut that dotted line. A picture to be copied is not likely to be as much out of truth of level as is shown in this diagram, but it is difficult to make slight variations from flatness evident in a sketch. Nevertheless, these variations occur, and must be provided for by a certain extension of the non-reflecting surface.

The second kind of irregularity of surface which requires the extension of the non-reflecting screen is that which arises from the nature of the surface of the picture to be copied ; that is, in the case of paper pictures, each elevation caused by the grain of the paper will have a surface on one side inclined towards, and on the other side from, the source of light. This inclination is very small, but unless it is taken into account, and if the non-reflecting screen be not large enough to include lines drawn from the lens to each part of such inclined surface and carried back at a similar angle, there will be reflections from one side of each elevation or prominence. This will produce an effect which I dare say many will remember to have seen on the top of a copy of a paper photograph—the effect of a blanket sort of texture.

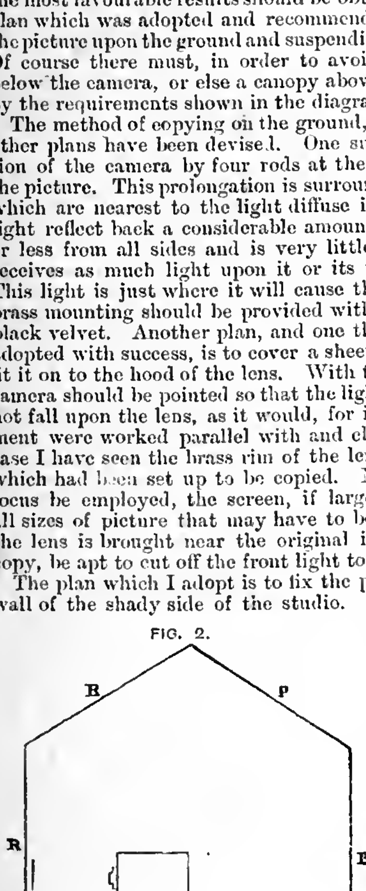
The blankety texture just referred to is not to be confounded with what is known as granularity, although both proceed from the roughness or grain of the original. The former is confined to the side or top of the picture on that edge which is nearest the source of light, whereas the latter effect is visible all over. The former effect, moreover, may be got rid off by employing light falling at an angle nearly parallel to the plane of the picture—that, is what is called strong side light—whereas the general texture or grain which proceeds from the irregularities or texture of the picture copied being lighted up more on one side than the other is aggravated by this side light (whichever side, top, or edge it comes from), and is ameliorated by the light being made to come as much from the front as possible. If a sheet of rough drawing paper be held so that the light falls upon it nearly sidewise the grain will be strongly visible; but if the light fall on its surface almost perpendicularly—say, over the shoulder of the observer who holds the paper square in front of him—the grain becomes almost invisible. If the paper be held so that two equal lights fall upon it from opposite directions the sides of the prominences that receive the least illumination from one source of light will receive the most from the other, and the surface will be greatly equalised. If, however, these lights be of the nature of what has been referred to as strongly side lights, there will be pits and prominences which receive more or less light, and some grain will still be apparent.

The question now arises—How is it best to carry out in practice the principles that have been discussed? First, the light must not come so much from the front as to cause reflection; second, the light must come as much from the front as possible, consistently with the first requirement, in order not to bring into strong relief the grain of the paper; third, there should be at least two sources of light proceeding from opposite directions. If a ring or circle of light could be secured coming from direction behind and around the observer (or the lens), and at just such an angular distance as to avoid being reflected from any shining or polished part of the surface of the picture to be copied, the most favourable results should be obtained. This is very nearly the plan which was adopted and recommended long since—that of laying the picture upon the ground and suspending the camera vertically over it. Of course there must, in order to avoid reflections, be a screen on or below the camera, or else a canopy above, of the dimensions indicated by the requirements shown in the diagram.

The method of copying on the ground, however, is inconvenient, and other plans have been devised. One such plan consists in a prolongation of the camera by four rods at the corners, as far as the plane of the picture. This prolongation is surrounded by tissue paper: the sides which are nearest to the light diffuse it, and those farthest from the light reflect back a considerable amount, so that the grain is lit more or less from all sides and is very little visible. The lens, however, receives as much light upon it or its mounting as the picture does. This light is just where it will cause the most reflection, so that the brass mounting should be provided with a tube or hood covered with black velvet. Another plan, and one that I have known to have been adopted with success, is to cover a sheet of millboard with velvet and fit it on to the hood of the lens. With this arrangement, however, the camera should be pointed so that the light from the window or sky does not fall upon the lens, as it would, for instance, if the whole arrangement were worked parallel with and close to the window. In such a case I have seen the brass rim of the lens reflected in a daguerreotype which had been set up to be copied. Moreover, unless a lens of long focus be employed, the screen, if large enough to be effective with all sizes of picture that may have to be copied, will, especially when the lens is brought near the original in order to make an enlarged copy, be apt to cut off the front light too much.

The plan which I adopt is to fix the picture upon the middle of the wall of the shady side of the studio. The studio is of the ordinary central ridge kind, and the south side of both ridge and upright wall is kept opaque. The light from the whole of the opposite ridge and glazed side fall upon the picture, but reflections are in the ordinary way avoided by using a large camera, the front being more than twice as long as the picture to be copied, with a lens of long focus, of course. If the picture be so large, or the surface so irregular, that the surface of the camera is not large enough to make sure against reflections, a background screen may be placed behind it. This, if so far removed from the picture as to receive light from the top or ridge light of the studio, should be tilted forward sufficiently to prevent that; or a simple plan may be adopted—that of placing something upon the camera just high enough to cut off reflection.

FIG. 2.



R, Opaque. P, Glazed. O, Mirror.

The light as arranged falls very much from the front, and from a considerable surface—twenty-four feet in length, and twelve on each side of the camera—so that the grain of the paper is not very evident. In order, however, to make it still less so, a mirror is placed horizontally below the picture between it and the camera. A sheet of white card may be substituted as more convenient than the mirror, but is not quite so good.

What has been said has reference principally to copying photographs upon paper, and for other subjects some modification may be necessary as desirable. Oil paintings and artistic designs generally are produced with the light coming over the artist's left shoulder, and the painting may show less grain when lit up from the same direction as that in which it has been painted than when equally lighted from all directions. In this case, while what has been said as to the avoidance of reflections will still apply, the direction of the light may be altered to what is required by blinding one-half (the right) of the studio, or by copying in the length of the studio instead of its breadth. With daguerreotypes, again, it will generally be desirable to place them upon their side, as the polishing of the plate (except those of the stereoscopic form) was in the direction of the lines across the picture. If anyone hold a daguerreotype under a vertical light, and change its position as indicated, he will observe a great difference of brightness.

Various plans for avoiding granularity in copying have been suggested, which are not based upon the considerations that have been referred to. One such plan is to copy with a lens somewhat out of focus; another is to move the lens during exposure. It is obvious, however, that with such methods the loss of sharpness of texture of the grain must be accompanied by loss of sharpness of the details of the photograph—at all events, of such details as are defined in lines not broader than the grain which has to be got rid of. Of course, cases may arise in which it is desirable to lose the sharpness of the original picture, but not when an exact reproduction of it is required. I once had occasion to make an enlargement from a pen-and-ink sketch portrait of a gentleman; the enlargement was to match and form a pair with one of a lady which had been made from a photograph in the usual way. I therefore copied the drawing with a lens possessing no sharp focus—the back of a portrait combination—and the softened edges thus given to the ink lines enabled the artist to paint the enlargement with a sufficient satisfactory resemblance to a photograph from life.

Naturally, the less grain there be upon the surface of paper photographs the less there will be to be copied; and an obvious preparation for copying is to roll the print well if the surface require it. I have known burnishing successfully adopted for the same purpose.

W. E. Debenham.

HOME PORTRAITURE.*

I have brought with me tonight some prints which I propose to enamel. They are here soaking in cold water. I have also beside me my glasses, upon which I shall place the prints later on. Now, the first thing to do is to thoroughly clean and polish these glass plates. You will see me clean them with the ordinary plate-cleaning powder. Next you will see me rub the plates with this little bag of talc; then you will see me take a camel's-hair brush and dust them, and then you will see me take this small brush dipped in albumen (white of egg) and go round the edges of the glass plates, and when done they are set aside for the albumen to dry. When this has taken place I take this bottle of collodion, coat each plate with the collodion, and again set aside to dry; while this is being done I get ready my gelatine. I take two ounces of it and soak in clean cold water. Here it is. The cold water is then drained off and hot water applied to melt it; the quantity necessary for the two ounces of gelatine will be about eighteen ounces. When the gelatine is melted I pass it through muslin into a flat dish. Here you will observe I have my gelatine ready so prepared, which I now place into this metal dish containing hot water to keep the gelatine warm.

When the plates are well set I place my prints into the warm gelatine, and make sure they are thoroughly saturated. I then take them out one by one, rapidly place them on the collodionised plate, and lightly squeegee them on. The plates are then placed aside for a short time, and, finally, I give the prints a backing by placing on them this cardboard, which is a very easy matter. I simply take the cardboard, soak it in water, and place between blotting-paper to absorb the spare moisture, and then, with a coating of gelatine, starch, glue, or paste, I press well into contact and the thing is done. Now, the only difficult part of the operation is the collodionising of the plate. Those of you who are familiar with the wet process will have no difficulty, while to those of you who have only worked dry plates I say—do it coolly and deliberately, and with a little practice you will be able to coat a plate without spilling a drop. Let me, however, give you this word of caution:—Take care not to go too near a light with your collodion, or you will have a "jolly fine" blaze all round. The plates with the prints attached are then placed away to dry. I find a very good way is to dry them at a reasonable distance from an ordinary fire (not too near). They may then be left on the mantel-shelf all night, and in the morning they will be dry and ready to be removed from the glasses.

To enable you to see the whole operation I have brought with me these plates, on which you will observe some prints. I enamelled them last night in exactly the same manner as above described. Later on you will see how they are removed from the glasses. I simply take a knife and cut round the edges of the cardboard just a little inside of where the glasses received the edging of albumen, and by gently inserting the knife the prints, with their backing of cardboard, and with their coating of collodion on the face of them, peel off the glass, with the result that they are beautifully enamelled.

I now come to the other subject which we have to consider—retouching. It is to my mind the most delightful occupation an amateur can give himself up to. It is cleanly, and can be done even in the most elegant drawing room. I should have preferred, had circumstances enabled me, to show you by daylight what little I knew of this delightful branch of our art. Still I must do the best I can with the aid of artificial light. I wish it to be distinctly understood, however, that I strongly recommend all those who are desirous of practising retouching to do so by daylight.

* Concluded from page 792.

It is now nearly fourteen years since retouching was first introduced, and for a long time there was a great outcry against it; but, like every other good thing, it has steadily advanced until it has now become a necessary branch of our art, and no gallery is complete without its staff of retouchers.

Doubtless, many of you understand this. Some members at our Association I know are quite as well able as I am to give a demonstration of it, but there are other members who have never touched a negative, and it is to those that I offer my services, in the hope that they may learn a little.

When I first made up my mind to practise portraiture I soon found out that retouching was a most necessary step to the success of my endeavours; so I set myself to study it. I read all the books and articles I could find. I was told it was very difficult, and that I had better give my negatives to a retoucher to have them properly done, as I would be sure to spoil any negative I tried my "prentice" hand upon. But I said to myself "I don't see if others can do it so easily what is to prevent me;" so I decided to take a few lessons from a competent teacher. I was given to understand from what I had read that quite a dreadful list of articles were necessary, such as powdered cuttle-fish, ground resin, powdered blacklead, Indian ink, black-lead pencils, stumps, sable brushes, &c. But I soon found out that in this, like other matters, the best thing was ocular demonstration. So I went to Mr. Horatio Paterson, who soon put me on the right road without the aid of anything but this little tool here, which is only a hard lead pencil—it is a 6 H. Faber. At first I had not a retouching desk, but I made a very good substitute for one by simply using a printing-frame. Try it, and you will be surprised how well you can get on with one. If you can obtain a proper desk, however, by all means get one. It is no doubt a much more complete and comfortable way to work with its aid.

To assist those of you who desire to learn retouching I propose to place on my desk two negatives. One of them will be a finished negative, so that I will be enabled to point out to you the difference between a retouched negative and one that has not been so treated. By this means you will more readily be able to see the inequalities. The first thing to learn is to find out the bad places in a negative. This you will soon come to understand. It is just like knowing the disease is half the cure, and the rest follows. In the first place, examine the high lights and see if there be any patches less opaque than their surroundings. If so they must be made of the same opacity. See if there be any little specks, such as freckles would make. If so they must be filled up, then blend the high lights into the shaded parts, soften down the shadows, and, having done this, you will have accomplished a deal.

I find a very prevalent notion among amateurs is that a negative requires some preparation before it is ready for retouching, such as the application of some retouching medium to cause the pencil to "bite," as the saying goes. Now it is only very seldom such is needed. If your negative has been varnished with the ordinary spirit negative varnish it will need no medium. The varnish when thoroughly hardened will take the pencil well enough, and this just brings me to another point that amateurs make an error in. They think that unless they can see the marks the pencil makes with each touch they give that the lead pencil is not doing its work, and that they must have recourse to some medium to enable them to see the work they are doing. This is just the very thing they must avoid doing.

I will just here tell you that I feel the mistakes most common to beginners are that they do not use hard enough pencils, and they do not keep them sharp enough, nor do they touch lightly enough. The negative being varnished and perfectly hardened, it is then set on the desk and the work begins, as you will see me operate presently. Let me say this before commencing: Touch as lightly as you can. Only let the lead just touch the varnish, and do not press it on. Most retouchers acquire a special touch of their own, just like learning a special style of writing. You will with practice acquire the best way of touching. Although you do not see the marks the pencil makes, you will find the flaws you are touching gradually disappear, and this is just what you require to do. Do not go too near the negative, but so far away that you can only see the patches the flaws make, and which have to be filled up.

Some of you may think it would be best to take a magnifying glass, and with its aid touch out all the imperfections. No more fatal mistake can be made; for, were you to do so after all your exertion when you come to examine the negative, and are prepared to look with pride upon your persevering efforts, you would be surprised and disappointed to find it showing nearly the same appearance as at the commencement. Yet this should not be astonishing, for it is an artistically-acknowledged fact that detail and effect are simultaneously unattainable, and this experience of retouching is further proof to the establishment of this fact. Do not use a magnifying glass. Never attempt to fill up a spot with one touch. The point of your pencil should be as sharp as a darning needle. This is obtained by rubbing it on a piece of fine sand paper. So soon as you sharpen your pencil just touch a piece of paper with it to take off the scratchy point, but do not blunt it.

At first I recommend you to practise on small heads; you will find large ones more difficult. I will show you a negative I first retouched and a print from the same. What I have done all of you are quite as well able to accomplish. Practice and patience are all that is needed. It sometimes happens that in lighting a sitter the catch-lights are not the same on both eyes. I will show you how to take out a false light and so save many a negative that would otherwise be almost worthless.

Do not be frightened to touch your negative. You will thus soon be quite at home at the work, and after a little practice you will find retouching a valuable aid to development, printing, &c. I know of nothing better that enables one to judge of proper density than the examination of a negative for retouching; it will assist you to say at once—this plate is too thin, or this too dense, or this under-exposed or over-exposed, or over- or under developed. You will find it a most valuable aid to the other branches of our art, and he who is an adept at it must be a long way ahead of his brother who is not. I strongly recommend you all to practise it.

I hope I have not detained you too long. I will now proceed to work, which will doubtless interest you more than listening to my paper.

T. N. Armstrong.

An Improved Method of Transferring the Film of Photographs, or a Film of Colour Painted upon Photographs, to Canvas or other Surfaces.

John Mitchell Downing Worsnop, 154, Leeds-road, Bradford, Yorkshire.

My invention relates to an improved method of removing or transferring the thin film, upon which an object has been photographed, or a film of colour which has been painted upon such photograph, from the glass, paper, or other surface upon which it has been photographed, on to a surface of canvas or other suitable material.

In carrying out my invention I take the photograph upon glass or paper, or any other suitable surface which has been previously prepared by coating it with a thin layer of wax or other substance to which the film of the photograph will lightly adhere, but which will afterwards allow such film to be easily peeled off. To transfer or remove the film of the photograph: the canvas or other suitable surface on to which it is to be permanently transferred is covered with dissolved gelatine or strong waterproof cement, and then pressed against the film and held there until the cement becomes firmly fixed to the film, when, by separating the canvas from the glass or paper, the film will be detached from such glass or paper and securely cemented upon the surface of the canvas, where it is intended to remain permanently.

To transfer or remove a coloured photograph, or a film of colour which has been painted upon the surface of a photograph, the film is painted in the required colours before being transferred, and is then transferred temporarily to a surface prepared with wax as hereinbefore mentioned. The film is then finally transferred to the surface upon which it is intended to remain permanently fixed, and to which it is securely fixed by dissolved gelatine or strong waterproof cement, in the manner hereinbefore described.

The inventor's claim is:—Taking photographs, or painting such photographs or pictures, upon a surface covered with a slightly-adhesive material which will admit of the film of the photograph, or the film of colour painted upon such photograph or picture, being peeled off and attached permanently to a canvas or other durable material.

Exhibitions.

EXHIBITION OF THE GLASGOW AND WEST OF SCOTLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

The second annual Exhibition of the above Society was opened in the Art Institute Gallery, Sauchiehall-street, Glasgow, on Wednesday last, the 17th instant, and closes to-morrow (Saturday), the 20th instant.

The Society is but one year old. It held an exhibition of pictures at the end of the first season, which proved so successful that it tended to greatly increase the membership, and certainly the pictures at the present Exhibition show well for the energy and talent of the members. There will not be less than five hundred pictures shown, and the work all over bears favourable comparison with that of last year.

Sixteen medals are given to be competed for in the following classes:—Landscape, figure study, instantaneous, portrait, group, animal, transparencies, and enlargements. A silver and a bronze medal is to be awarded in each class, the vote of the members themselves deciding who are the successful competitors.

The larger proportion of the exhibits sent in are "not for competition" but for exhibition only. Next week we will give a short review of the pictures, with a list of the successful competitors.

THE NORTHAMPTON PHOTOGRAPHIC EXHIBITION.

Last Wednesday night the Photographic Exhibition at Northampton was inaugurated at the Guildhall in that town, and it will be open daily until January 10th, 1885. The Exhibition has been formed under the committee of the Northampton Museum, which committee consists of the following gentlemen:—Mr. M. P. Manfield, Mayor of Northampton; the Rev. S. J. W. Sanders, M.A., F.G.S., LL.M.; Mr. John Eunson, C.E., F.G.S. (President of the Museum Committee); Mr. J. B. Hensman (Hon. Sec. ditto); T. J. George, F.G.S.; Mr. T. P. Dorman; Mr. S. S. Campion;

Mr. S. J. Newman, A.R.I.B.A. (Hon. Sec. Natural History Society): Mr. R. G. Scriven (President Photographic Section, ditto); Mr. H. Manfield (Hon. Sec., ditto).

The Exhibition is a good one, and the arrangements are of an attractive description.

Mr. J. Eunson, C.E., welcomed the company present by saying that it was an admirable Exhibition, and that the photographers who acted as jurors and had awarded the prizes said, almost without exception, that it was one of the finest collections they had ever seen. One reason why it was better than the London Exhibition was that in that room they had several pictures which had been awarded medals in the metropolis at different times. The Exhibition emanated from the Museum Committee, and the original proposition came from the Rev. Mr. Sanders and Mr. H. Manfield. The Committee gave its moral support, and allowed the Exhibition on condition that if there were a loss the proposers were to meet it, but if there were a profit the same should go to the Museum. A sub-committee of four carried out the work. Most persons considered photography to be a new art, but sun pictures were by no means novel; they existed from the time when light first shone through a small hole into a dark room. In about the fifteenth century cameras became general, though the users were unable to fix the pictures. The cradle of photography was France; but, perhaps about 1780, Professor Charles showed a picture of a human bust taken upon nitrate of silver. He could not fix these photographs. Daguerre was the first who devoted his attention with anything like success to this subject. He was born about 1780, and became the pupil of a scene painter in the opera at Paris. He used the camera when drawing the scenery for the theatre, but he worked hard for twenty or thirty years to fix the camera images, and one day he announced his success. He laid his scheme before the Principal of the French Academy of Sciences, and the managers said that it was too great a thing for one man to retain, so they gave him a pension of £240 a-year to give the world the benefit of his discovery. The daguerreotypes were taken upon silver plates, subjected in the process to the vapour of mercury. It took fifteen minutes to impress them in the camera, and, if one were to see the portrait of even his greatest enemy taken after a sitting of that length of time, the anguish upon the face would produce an impression never to be forgotten. Fox Talbot took paper pictures about the year 1840, and in 1842 he (the speaker) saw one and had no difficulty in recognising the outline of a human head. Then came the collodion process in 1847. It produced the pictures now handed over to the public at seaside resorts—all finished in five minutes, and at a moderate charge. Then came the negative process—the origin of the pictures before them that evening. He was not himself a photographer, so could say little more. When Daguerre's pictures came out men said—"Painting is dead." But photography proves to be a great aid to the artist, and it has a high educational influence; it teaches persons to go about in the country without their eyes shut. If some of the pictures before them were paintings people would say—"No man ever saw a sky like that," thus tempting observers to watch whether nature is as wonderful as photography. It had, therefore, an educational influence and a tendency to produce the highest class of art. It does not injure painting, because the colour and the ideal of the artist come into his picture, which can only be appreciated by a cultivated mind. He had great pleasure in declaring the exhibition open to the public.

Sir H. Dryden remarked that an artist could falsify in any way. He could depart from the colour of the face before him, and could alter a thick-lipped negress into a woman of beautiful proportions. Photography, however, was true, and Ruskin had defined truth to be one of the lamps of architecture. In that room were many who were making a comfortable income at photography. He knew of a miniature painter who once lived in a garret in Edinburgh, but when he became a photographer he lived happily downstairs.

The company then adjourned for coffee, after which there was a lantern exhibition.

The following is a list of the prizes awarded by the jurors:—1. For landscape or series of landscapes, above $8\frac{1}{2} \times 6\frac{1}{2}$: silver medal (No. 315), *On the Wey*, T. M. Brownrigg; bronze medal (No. 433), T. A. Green. 2. For landscapes or series of landscapes, $8\frac{1}{2} \times 6\frac{1}{2}$, or under: silver medal (No. 567), H. B. Berkeley; bronze medal (No. 319), J. P. Gibson. 3. For portrait or series of portraits, above $8\frac{1}{2} \times 6\frac{1}{2}$: silver medal (No. 136), R. Faulkner; bronze medal (No. 140 and series), H. Mendelssohn. 4. For portrait or series of portraits, $8\frac{1}{2} \times 6\frac{1}{2}$ or under: silver medal (not awarded); bronze medal (No. 537), W. Gillard; bronze medal (Nos. 13 and 16), Friese Greene. 5. For instantaneous marine photograph (or series): silver medal (No. 328), G. West and Sons; bronze medal (No. 389), W. P. Marsh. 6. For instantaneous photograph (or series), of other than marine subjects: silver medal (No. 439), William Cobb; bronze medal (No. 425 and series), Thomas G. Whaite. 7. Interior or series of interiors: silver medal (No. 419), Ed. Dunmore; bronze medal (No. 295), Thomas Fall. 8. For the best *genre* picture: silver medal (Nos. 100-105 series), Adam Diston; bronze medal (No. 458), Geo. Hadley. 9. For the best enlargement, provided it was the work of the exhibitor: silver medal (No. 190 and series), Thomas J. Dixon; bronze medal (not awarded). 10. For transparencies: bronze medal (No. 514), P. H. Fincham. 11. For a series of views, irrespective of size, taken in the county of Northampton: silver medal (not awarded); bronze medal (No. 293), Charles Law. 12. A silver medal, offered by the proprietors of the *Amateur Photographer*, for the best land or seascape from an untouched negative, the work of an amateur (No. 339), H. A. Hood-Daniel. 13. An extra silver medal, for landscape with figures, to the series of H. P. Robinson. 14. One bronze medal extra to No. 317, J. Lafayette. 15. One bronze medal extra to No. 358, for marine views, Abel Lewis. 16. One bronze medal extra to No. 281, for marine views, F. M. Sutcliffe. 17. One bronze medal extra to No. 65, for still life picture, Mrs. S. G. Payne. 18. One bronze medal extra, for series of photoreproductions, to R. Schuster.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting	Name of Society	Place of Meeting
December 23	Bolton Club	The Studio, Chancery-lane.
" 24	Bristol Amateur	Studio, Portland-st., Kingsdown.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The twenty-fifth annual dinner of the above Society was held on Tuesday last, the 16th instant, at the Holborn Restaurant. The new President, W. Ackland, Esq., occupied the chair. About twenty members were present. During the evening songs and recitations were ably rendered by Messrs. Bridge, Page, Cowan, Cobb, Debenham, Downes, and others. The toasts customary on such occasions were, as a matter of course, honoured. In responding to the toast of the President, Mr. Ackland after alluding to the great loss the Society had sustained by the death of their late President, the Rev. F. F. Statham, M.A., F.G.S. took the opportunity of reminding the members present that next year the Society might be said to enter a new life, and he asked those around him to exert themselves to make it as flourishing as it had been of old. He further remarked, now that it had been decided to carry on the Society with energy instead of breaking it up, that several influential members who had sent in their resignations had now withdraw them. It was also mentioned that already the Society had nearly sufficient papers promised to carry them up to the vacation.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on Thursday, the 11th instant, the chair was occupied by Mr. C. H. Trinks.

Mr. Gordon showed a washing machine for paper prints, designed by Mr. Sturrock, of Dundee. The machine consisted of a box or tank of japanned tin, into which frames fitted, covered with open canvas or wire netting. These frames formed either simple trays to hold one large print each, or were furnished with dividing strips to hold several prints of cabinet or other size. In any case only one print was laid in each division, so that both surfaces of the paper were exposed to the flow of water unhindered by contact with another print. By an arrangement which worked automatically the water did not commence running away as soon as the tank was filled, but a syphon was brought into play at regular and adjustable intervals, by which the tank was entirely emptied. The water supply was cut off during the time that the tank was being emptied, and the water was entirely drained off before the supply was renewed. By these contrivances the top prints were kept covered for some length of time after each filling, and the bottom prints had time for sufficient draining before the renewal of the water supply.

Mr. W. E. Debenham had seen one of these machines at work at the house of a gentleman, who was highly pleased with its performance. The automatic filling and emptying of the tank was so perfectly regular that when set so as to work at intervals of an hour it had been found to perform with the regularity of a water clock.

The Chairman then called upon Mr. Debenham to deliver his lecture on *Avoiding Reflections and Granularity in Copying*. [See page 808].

At the conclusion of the lecture,

Mr. F. W. Hart said that during the early days of photography he had had many daguerreotypes and glass positives to copy. He met with the difficulties from reflection which had been referred to, so he had constructed a frame of four feet in diameter and somewhat of a saucer form. The inside of this frame was lined with mirrors—each placed at such an angle as to throw back light upon the picture to be copied—and the picture, of course, was some distance in front. The whole arrangement was pointed at the sun, the direct light from which was kept from the lens by the picture and the backboard against which it was fixed.

Mr. Debenham said that the arrangement spoken off by Mr. Hart as nearly as possible fulfilled the conditions mentioned as theoretically desirable for illuminating with a circle of light, in the centre of which was the lens.

Mr. A. L. Henderson said that a good plan for copying had been proposed by the late Mr. C. Jabez Hughes. This plan was to enclose the space between the lens and the object to be copied with white muslin. In order to get the picture copied, and easily and properly centered upon the plate, he had marked the wall against which he placed the picture to be copied with measures in inches, reckoning a certain distance from the ground. The rising portion of the camera stand was similarly marked, and to whatever number the picture was placed over upon the wall, the camera was raised to a similar figure upon its stand. The non-reflecting screen spoken of by Mr. Debenham would, if it were placed between the lens and the picture, be apt to shade the centre or lower portion of the latter too much, especially when enlarging if a short-focus lens were used. In order to avoid the evils of vibration he thought it desirable that the picture to be copied should be attached to a frame to which the camera was also affixed. The picture and camera would then vibrate together, if at all. He had recently in America seen an arrangement of this kind, in which the whole appliance was suspended from the roof. This was in order to secure as much immunity from vibration as possible. One plan, and he thought it a good one, for securing squareness of the camera with the original was to have a stick projecting at a right angle from the wall.

The Chairman said that the suspension from the roof of the copying arrangement was common in the phototypic establishments on the continent. He had seen it in use some years since in Vienna and Berlin.

Mr. W. K. Burton had listened with great pleasure to the lecture, chiefly because of the precise manner in which the subject had been dealt with.

There was one point—which was, however, only an incidental one—upon which he would like to ask a question. The lecturer had referred to the use of the back lens of a portrait combination in a case where he had wished to avoid sharp definition. Did he understand from this that the back lens was supposed to possess more spherical aberration, and consequently less definition, than the front one?

Mr. J. BARKER said that Mr. Debenham had mentioned almost everything in connection with the subject. There was just one point, however, that had not been referred to, and that was the use of a glass in front of the picture. This he found advantageous.

Mr. A. HADDON said that by laying a wet print against a glass, and so securing optical contact, greater freedom from granularity could be obtained.

Mr. W. M. ASHMAN, like Mr. Barker, copied under glass. He always covered up the lens in front of the camera to prevent reflections.

Mr. SALMON said that Mr. Henderson had spoken of the use of a stick to ensure parallelism of the plate with the picture to be copied. He thought that a better plan was that of having the camera to run in a tramway.

Mr. A. COWAN said that the method he used in copying was to have a board or frame with a vertical stand at one end to which the original was affixed. The camera was made to slide to any required distance along the base-board, remaining parallel all the time, and a mask or screen with a central hole in front of the lens kept off reflections. A sheet of white card under the original was used to reflect light. The whole arrangement could be placed in any part of the studio so as to secure the best light.

Mr. DEBENHAM, in replying to the various speakers, remarked that many of the observations and suggestions made did not bear reference to the subject of the lecture, which was the avoidance of reflection and granularity in copying, and did not include mechanical contrivances for ensuring steadiness or parallelism. With reference to what Mr. Henderson had said, he would remark that the method of employing muslin, attributed to Mr. Hughes, for diffusing light and preventing granularity, was one which he (the lecturer) had described in effect as the plan with rods acting as prolongation of the camera, and surrounded by tissue paper. Instead of marking wall and camera stand to get the latter of proper height for the picture to be copied, he preferred to use the camera in its lowest position on the stand (in which position it was steadiest) and to mark the wall on a level with the lens. A series of measures on the wall, one, two, three inches, &c., up and down from this zero point, would ensure that a picture which was placed so that an equal number showed at its top and bottom, should be central on the camera screen, and no movement of the camera stand was required. The question of the shading of the original by a non-reflecting screen was one that had been treated in the lecture. The screen referred to by Mr. Cowan would be especially apt to shade the original if a short-focus lens were used for the purpose of enlarging; and as to the advantage of being able to place the whole copying arrangement in any light that might be found most desirable he had endeavoured to show what position in the studio was the best for copying. In reply to Mr. Burton he said that he used the particular lens referred to, as, in addition to its absence of definition, it happened to be of the length of focus required. Further discussion on the optical question would not belong to the subject in hand. As to the use of glass in front of the print referred to by Mr. Barker, there was an advantage in the way in which the squareness and flatness of the original were preserved. If, as was probable, the glass referred to was that of a pressure-frame (Mr. Barker signified his assent), there was also the advantage that the pressure might somewhat flatten the irregularities of the surface. The plan of copying a wet print laid against the glass he did not recommend, for the following reason. He thought that the whites of the paper were somewhat lowered and the faint details in the lighter half-tones a little lost.

The usual votes of thanks were accorded to the lecturer and the Chairman, and it was announced that, on the 8th of January, Mr. W. W. Cobb would discourse on the difficulties attending instantaneous photography in the streets of London.

THE PHOTOGRAPHIC SOCIETY OF IRELAND.

THE usual monthly meeting of this Society was held in the Royal College of Science, Stephen's Green, Dublin,—Mr. Thomas A. Bewley in the chair.

The minutes of the previous meeting having been read and confirmed, Mr. Frederick H. Campbell was elected a member. Messrs. Haslam, Sherlock, Ree, and Adency were proposed for membership, and will be balloted for at the January meeting.

The CHAIRMAN then called on Mr. Geo. Mansfield for his communication on *Paper Negatives.*

In the course of his paper Mr. MANSFIELD drew attention to the old method of producing negatives on paper and then waxing the material to render it translucent, and gave a most interesting account of his recent experiments with various gelatino-bromide papers, both on what is known as "negative" as well as "positive" papers. Those produced on the "positive" paper yielded in his hands the best results, while the "negative" paper gave the most trouble in obtaining semi-transparency on account of its extra thickness. He also handed round several excellent negatives, and proofs from the same, of 10×12 and whole-plate size, the difference between the prints and those of ordinary plates being hardly distinguishable.

In the debate which followed Mr. J. V. ROBINSON ventured to predict that the future basis on which all negative films would be held would be the material now brought under the notice of the meeting, the great advantage to be gained being the lessening of the weight to be carried by doing away with the glasses, which at the present stage of photography are indispensable.

Mr. Robinson also exhibited an interesting collection of very old waxed negatives which, for brilliancy and delicacy of detail, were hardly to be beaten even by gelatino-bromide plates or the still older collodion films.

Dr. SCOTT, who also has been experimenting in the same direction as Mr. Mansfield, detailed the results he had obtained, and passed round several negatives and prints—also an instantaneous view of Kingstown harbour—taken on gelatino-bromide paper, which was highly creditable as instancing the results that paper is capable of yielding.

Mr. Woodworth also exhibited a collection of paper negatives enlarged from quarter-plate transparencies, and some platinum prints from same.

The next meeting is intended to be held on January 9th, 1885.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held at the Manchester Technical Schools, on Thursday, the 11th instant,—Mr. John S. Pollitt, President, in the chair.

The minutes of the previous meeting were read and confirmed, and the following gentlemen were elected members of the Society:—Messrs. B. Ellston, F. Barker, J. Rogers, and C. Estcourt, F.C.S.

Mr. J. W. LEIGH read a short paper, and gave practical illustration of several methods of effecting the printing of skies, &c., in landscape pictures. Mr. Leigh explained that where, as was often the case, the sky portion of a landscape negative was defective the first thing to be done was to screen the sky portion during printing so as to get a print with a white sky. This he effected by taking a sheet of cardboard and tearing it so as to follow roughly the sky line. This was then attached to the printing-frame by pins, and the whole exposed to diffused light. The sky mask being given a slight curl upwards did away with any mark or line at the junction. The print was then taken out of the frame, laid on a large sheet of glass, and the cloud negative laid upon it, the right position being easily determined by looking through negative and print together. To mask the landscape portion of the picture, Mr. Leigh placed over it one or more pieces of cloth—such as the pads from the printing-frame—and rolled these back at the sky line in order to soften the edges, again exposing to diffused light till the clouds were sufficiently printed. Mr. Leigh also showed a simple plan he made use of when any part of a negative was much thinner than the rest, and would necessarily give an uneven print. He commenced the print in the usual way, and as soon as the thin part was done enough he masked that portion by attaching a tuft of cotton wool by means of gum, &c., to the back of the negative, pulling out the edges to get the necessary softness. At the conclusion of his paper, Mr. Leigh referred to a question in the question-box at the last meeting as to the quantity of hypo. necessary for a given number of prints, and, quoting from Captain Abney's book, called attention to the necessity for using the hypo. solution strong to ensure perfect fixation and the complete removal of the hypo. during the final washing.

Mr. RISHTON agreed with Mr. Leigh on the hypo. question, and remarked that it was desirable to have the fixing bath in an alkaline condition. He was in the habit of adding ammonia for this purpose.

Mr. ATHERTON said common washing soda answered the purpose equally well, and suggested three ounces of hypo. to the pint of water as about the correct amount for fixing one sheet of paper.

The CHAIRMAN said he had found the use of tepid water in the final washing a great advantage. Referring to Mr. Leigh's plan of masking with cotton wool, he had for some years made use of Prussian blue painted on the back of the negative, and softened by dabbing in the usual way. In the printing-frame he had also found it desirable to lay a sheet of thin cardboard next to the sensitive paper, and he found that by this method he obtained complete immunity from cockling of the print in damp weather.

Mr. CHILTON asked the Chairman if warm water for washing prints affected the surface and brilliancy of the prints.

The CHAIRMAN replied that if the water were used tepid he had never found any ill effects, but if the water were made hot the prints would certainly suffer.

Mr. GREATOREX asked for information as to the best method of masking a sky in which there was a church steeple, tower, &c.

Mr. LEIGH said he should block the sky out with black varnish or other medium.

Mr. M'KELLEN recommended taking a print, cutting out the image of the steeple, &c., and laying the mask so formed on the negative with the smallest quantity of paste.

Mr. ALAN GARNETT showed two very charming prints on alpha paper, which were much admired. He also exhibited an ingenious contrivance for the gas jet in an amateur's dark room, by which the gas could be turned apparently out, and on turning the tap up again the flame at the burner was rekindled by the small spark kept in, it being concealed by a metal cup round the jet.

The HON. SECRETARY (Mr. W. J. Chadwick) exhibited a simple contrivance which he made use of when mounting prints on plain boards, remarking that he had frequently seen amateurs fail in getting the print in the centre of the mount or square with it. His plan consisted in using a guide or mask made from one of the mounts in use, in the centre of which an opening was cut one-eighth of an inch each way larger than the print to be mounted. This mask was laid on the mounting board and attached thereto by a pair of American clips. The print coated with the mounting medium was then placed in the opening of the mask, which latter being removed the print was rubbed down on its board, when its central position could be relied upon.

The members now adjourned to the basement of the building, and inspected a magnificent collection of large photographs of the Yosemite Valley, California, exhibited by Mr. Charles Harris, F.R.G.S., and collected by him during his tour round the world. He (Mr. Harris) spent several weeks in the Yosemite district, and while there made the acquaintance of the celebrated photographer, Mr. Watkins. Aided by a number of lantern slides exhibited on the screen, he gave a most interesting recital of his experiences and a graphic description of the magnificent scenery of this remarkable valley.

The CHAIRMAN, in thanking Messrs. Leigh and Harris for their interesting contributions to the meeting, hoped that their example would stimulate other members to bring before the meetings any subjects of interest.

Mr. LEIGH remarked that he always found the effort to impart help or instruction to his fellow-members, in addition to being a pleasure to him, resulted in extending his own knowledge of the subject, and he was glad to say that he had learnt a lesson from the Chairman's remarks that evening which would be of value to him in his own work.

Mr. HARRIS, in responding, said that it would afford him pleasure at some future meeting to give the members a further account of his travels in other parts of the world.

The meeting was then adjourned to the 8th January, 1885.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

THE above Association held a popular meeting in the Christian Institute, on Wednesday evening, the 10th instant,—Mr. John Urie in the chair.

A very fine series of transparencies were shown by Messrs. Geo. Mason and Co., which were much appreciated by a large audience.

A vote of thanks to the lecturer, Mr. Geo. Bell, brought the meeting to a close.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

THE ordinary meeting of the above Association was held on Tuesday, the 9th inst., in the College of Physical Science, Newcastle, at half-past seven o'clock p.m.,—Mr. P. M. Laws in the chair. The minutes were read and passed.

The CHAIRMAN announced that the Council had decided to join with the Tyneside Student's Association and three or four other societies in a *conversazione* to be held on the 8th January, and asked members to contribute pictures.

Mr. H. G. TEMPLETON, of Gateshead, read a paper on *The Platinotype Process*, and gave a very successful practical demonstration.

At its conclusion Mr. Templeton was awarded a hearty vote of thanks.

Mr. LAWS gave notice of a motion to alter Rule 14.

The nominations for President, Vice-Presidents, Officers, and Council for next year were proceeded with.

On the request of Mr. Pae,

Mr. PROCTOR gave some interesting details of the method he had adopted in taking his "view without a lens," shown at the Society's recent exhibition. The pictures, taken late in October, had fifteen minutes' exposure, the distance between the plate and aperture being about twelve inches.

A vote of thanks to the Chairman concluded the meeting.

CHELTENHAM PHOTOGRAPHIC SOCIETY.

A MEETING of this Society (until recently known as the Cheltenham Amateur Photographic Society) was held on Thursday, the 11th instant,—Colonel Dawson, C.B., in the chair. The following gentlemen were elected members of the Society:—Messrs. White, R. Dighton, W. L. Ferguson, and Joyner.

Mr. BAYNHAM JONES, exhibited one of McKellen's new patent cameras, half-plate size, square, with reversing frame. This camera possesses many distinctive features, and appeared to give general satisfaction to the members present. The rapidity with which it could be erected and closed, and the simplicity with which both front and back could be set at any desired angle, as well as the perfect rigidity of the camera in any position, called forth expressions of high praise. The stand, folding in three parts, and affixed in a very simple way to a rotating disc let into the base of the camera, appeared in every way suitable for its work.

The CHAIRMAN then read a short account of a potash and soda developer used by himself for some time with great success, his formula being—

Carbonate of potash (London pharm.)	480 grains,
Washing soda	480 ,,
Potass. bromide	20 ,,
Dissolved in water to make	20 ounces.

This solution contains three grains of each alkali in every drachm. In each ounce of developer one drachm of the above is used with two grains of pyro.

Prints were exhibited by several members, those of Mr. Beetham from negatives taken in the neighbourhood of Torquay, being very much admired.

Some transparencies on Fry's special lantern slide-plates were also shown, and the meeting was adjourned.

COVENTRY AND MIDLAND PHOTOGRAPHIC SOCIETY.

THE annual meeting of the above Society was held at the residence of the Hon. Secretary, Hill House, Hill-street, Coventry, on December 4th, 1884,—the President in the chair.

The minutes of the previous meeting having been read, the officers were elected as follows:—*President:* Mr. Andrews.—*Vice-Presidents:* Messrs. Danks, Ambrose, Seymour, and Jones.—*Treasurer:* Mr. Danks.—*Secretary:* Mr. J. I. Weatheritt.—*Auditors:* Messrs. Walker and Winstanley.—*Committee:* Messrs. Baynton, Lloyd, Walker, and Winstanley.

The Treasurer's account was then read, showing a balance in hand of £1 13s. 9d., against a loss of 9s. 7½d. last year.

The meeting then adjourned to a large room, where the lantern and screen had been set up for the exhibition of members' slides, as was arranged at last meeting. A blow-through jet made by the Hon. Secretary was used, the light from which was thought to be above the average of this form of burner. Mr. Ambrose showed some slides made on Hill Norris's dry plates, which were very good. Mr. Lloyd's slides on the gelatino-chloride plates made by Mr. T. Baynton (the formula for which was given at the last meeting), and developed with ferrous oxalate, were exceptionally good, one subject in particular being especially admired.

After an interesting discussion the meeting broke up at a late hour.

VIENNA PHOTOGRAPHIC SOCIETY.

THIS Society met for the first time for this season on the 7th October, when the chair was taken by Dr. E. Hornig, President. The minutes of the previous meeting having been approved, several new members were admitted.

The CHAIRMAN then intimated that the Society had lost three members by death since they last met before the autumn vacation. The memory of the deceased was honoured in the usual way.

Dr. EDER then rose, and spoke of the successful experiments made in Herr Löwy's studio with Professor Vogel's azaline plates, which showed great sensitiveness to green, yellow, and above all to red rays. Dr. Eder also showed photographs of oil paintings, water-colour drawings, and embroideries in colours, which he had taken—using an interposed sheet of yellow glass—upon gelatino-bromide of silver plates stained by himself. He (Dr. Eder) proposed that, as the name "isochromatic" had been adopted by the patentees of the French process, viz., Clayton and Tailfer, and since in optics the term "isochromatic" is used in a special sense not applicable to plates which represent the colours of objects in their true values, the latter should preferably be called "orthochromatic" plates. The photographs shown were taken upon bromide of silver emulsion prepared by Herr Plener and stained by Dr. Eder, and the exposures took place in Herr Löwy's studio as the former ones did. Of the many dyestuffs examined by Dr. Eder the following were found to be sensitisers for gelatino-bromide of silver emulsion, and most of them showed bands of increased sensitiveness to colour corresponding to the spectrum of absorption of dry gelatine stained with the same. Amongst them are sensitisers as far as the extreme red (for example, iodine green and acid green). These dyes are eosine blue and eosine yellow, erythrosin, pyrosin, aureosin, æthyleosin, methyleosin, phloxin, Bengal rose, cyanosin, muriatic aniline rose, acetic anilino rose, Coupier's toluidin red, solid green (bitter almond-oil green), brilliant green, acid green, iodine green, methyl green, picrate of methyl green, Aldehyde green, Hoffmann's violet, dahlia, methyl violet, Paris violet, benzyl-rose aniline violet, gentiana violet, resorcin blue, fluorescine, cyanide of iodine, cyanide of chlorine, nitrate of cyanogen, sulphate of cyanogen, Coupier's blue, coralline red, naphthaline red, acid violet, chlorophyll. Small—though often difficult to recognise—bands indicating sensitiveness to red are furnished, especially along with ammonia, by carthamine, turmeric, soluble Berlin blue and menophenyl-rose-aniline chloro-hydrate, and hämatoxyline (to the last of which Dr. Eder's attention was directed by Dr. Albert). Dr. Eder also showed an instantaneous photograph of a flash of lightning taken by Dr. Kayser, an instantaneous shutter by Herren Thury and Amey, Geneva, an academy camera by Messrs. Marion and Co., London, a travelling camera by Herr Wanaus, Vienna, and some samples by Herr Obernetter, Munich, of his new process of heliogravure in half-tones after pictures from nature. The half-tones were transferred with great delicacy to the copper plate.

Herr SCOLIK called attention to a collection of studies from nature by an amateur, Herr Hamsen, the negatives of which were developed by Scolik's modification of Monckhoven's developer. He also showed a collection of seascapes and views of shipping by an amateur, Herr Riemer, and street scenes by Herr Rupprecht.

The CHAIRMAN showed a number of artists' studies and photographs from celebrated masterpieces of sculpture (as the *Laocoon*).

A great variety of other objects were exhibited, and after some conversation the meeting was adjourned.

THE same Society met again on the 4th November,—Dr. E. Hornig in the chair. The minutes of the previous meeting were approved, and Baron Stillfried and Herr Konkoly were admitted as members.

The CHAIRMAN then acknowledged the receipt of fifty marks from the Danish Photographic Society, and of a second subscription from the Parisian Society towards the monument to Dr. Martin.

The members of the judging committee of the Voigtländer prize fund were appointed, and, after some minor matters had been dealt with,

Major VOLKMER gave a long and interesting lecture on the value and application of electrolysis to the graphic arts. The lecture was listened to with great interest and heartily applauded.

The SECRETARY then read an essay on artificial lighting for taking photographs.

Herr SCOLIK reported on his work with orthochromatic plates (azaline, cyanide, and eosin plates) and also his analysis of a commercial sensitisor.

The question-box on being opened was found to contain only one question, which related to a point of law affecting photographers and settled by a recent decision of a magistrate.

This concluded the business, and the meeting was adjourned.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

THIS Association met on the 17th October, when the chair was occupied by the President, Professor H. W. Vogel. Two new members were admitted, one of whom, Herr Markl, a provincial member, sent his portrait—an example which the meeting expressed a wish to see followed by all future new members.

The CHAIRMAN laid on the table a specimen number of the *Electro-Technical Anzeiger*, the programme of the winter course of study at the Humboldt Academy, and the seventh number of Professor Eder's *Lehrbuch der Photographie*, being the number which deals with the wet collodion process, ferrotypie, and allied processes. He (the Chairman) remarked that, though gelatine was gradually pushing collodion out of the field, the latter was preferable to the former for copying oil paintings, &c.

A discussion of this question followed, in which Herren Quidde, Roloff, Haberlandt, and others took part.

Herr QUIDDE then called attention to Herr Fuhrmann's large collection of stereoscopic slides, mostly transparencies on glass, which are being exhibited at the Passage Kaiser Panorama. The pictures are arranged in sets of fifty, so that twenty-five persons at a time may see them, and about every half-minute they are automatically changed. The Swiss views are from Paris; the Scotch ones from G. W. Wilson, of Aberdeen. Herr Fuhrmann has as yet been unable to get good views of the Berlin streets, but Herr Quidde thinks he may now be able to obtain what he requires from Mr. Kilburn (of New Hampshire, U.S.A.), who has recently been "doing" Berlin.

Captain KISS showed a travelling apparatus. It is an apparatus for amateurs arranged for plates rather less than cabinet size. The camera was generally admired.

The CHAIRMAN then showed a number of photogravures by the Photographie Company, intended to be added to the permanent exhibition in the photographic section of the Technical High School at Charlottenburg.

The results of Professor Eder's experiments with orthochromatic plates were then discussed, but these need not be gone into here, as the same subject came up at a recent meeting of the Vienna Photographic Society on 7th October.

Herr SCOLIK, who has been experimenting with plates stained with azaline, found that he got a portrait representing the colours of the sitters' faces and dress in their true values, with an exposure of three times the length of the usual one. Some of the sitters were officers dressed in very bright uniforms.

The meeting was shortly afterwards adjourned.

Correspondence.

[*All communications for the* EDITORIAL *department of the Journal should be addressed to the "Editors, 2, York-street, Covent-garden, London, W.C."*]

THE CARBONATE OF SODA DEVELOPER.

To the EDITORS.

GENTLEMEN,—I was much surprised to read in the last issue of the Journal that Mr. Wainwright's experiments with the washing-soda developer resulted in "absolute failure." I have used it for years, commencing at the time when Mr. H. J. Newton recommended it as a developer for collodion emulsion plates. Ever since 1880 it has served me well with gelatine, and many of your readers will remember that I devoted an article to it in the ALMANAC for 1883, the formula then given being substantially the same as the one now advocated. Lately I have substituted for it the carbonate of potash *simply for convenience*, a solution of this salt taking up far less space. But I only use potash to develope negatives; for transparencies soda is *par excellence*. If it have any fault at all it will be found in the direction of density and harshness, both of which, however, may be obviated by employing a minimum of bromide. For this reason I have preferred to add the bromide with a dropping tube instead of introducing it into the stock solution. I can fully endorse all that Mr. Macdona has said concerning it, and, what is more, several who have adopted it on my recommendation can tell the same tale.—I am, yours, &c., B. HOLLAND.

Stanwick, Higham Ferrers, December 15, 1884.

To the EDITORS.

GENTLEMEN,—Perhaps Mr. W. Wainwright, Jun., has been using the soda developer with pyro., mixed with sulphite of soda or citric acid. If so, I think this may account for his failing to produce a transparency. I failed entirely upon first trying Mr. Macdona's recommendation, owing to the retarding effect of the pyro. thus mixed when used with washing soda; but upon using dry crystals of pyro. I produced immediately a most beautiful transparency.

Since then I have tried with plates—common commercial plates—by several makers, exposing both by contact and with the camera, and always with the same satisfactory result. If Mr. Wainwright will try with dry pyro. I feel certain he will succeed.—I am, yours, &c.,

Arley Parsonage, Northwich, December 17, 1884. HALCOTT ASH.

To the EDITORS.

GENTLEMEN,—If Mr. W. Wainwright, Jun., who complains of the soda developer being slow and not giving density, will try the following formula, using *no* bromide, he will be pleased with it:—

Sulphite of soda	1 ounce.
Citrate of soda	1 drachm.
Water	1 pint.

To one ounce of the above add two grains of pyro. *(dry)* and about a drachm of carbonate of soda solution (saturated).

This works very cleanly. Give a dip in the alum bath after fixing.—I am, yours, &c., G. V. J. POIRIN.

2, Eardley Villas, Eardley-road, Streatham, December 16, 1884.

To the EDITORS.

GENTLEMEN,—In reference to the letter of Mr. Wainwright regarding the carbonate of soda developer: after many trials I have come to the conclusion that this developer will not work unless the plate be made by some of the ammonia processes.

I usually prepare my own plates, boiling with carbonate of ammonia, and with such plates the soda developer works perfectly. Some time ago I tried a "batch" of simply-boiled emulsion, and although the plates worked very well with an ammonia developer they could not be developed by soda at all—at least not satisfactorily. I believe that this accounts for the differences of opinion as to the merits of the soda developer.

The quality of a "soda"-developed negative, both as to vigour and gradation, is so great an improvement on an "ammonia"-developed plate that, rather than go back to an "ammonia developer," should my plates refuse to work with "soda," I should have no hesitation in reversing the usual order of things, and in place of selecting a developer to suit my plates I should select a plate to suit my developer.—I am, yours, &c.,

Dundee, December 12, 1884. J. K. TULLOCH, M.B.

LANTERN TRANSPARENCIES AT THE RECENT EXHIBITION.

To the EDITORS.

GENTLEMEN,—I read with much interest the letters of Messrs. Brooks and Smith respecting the award of the medal for lantern slides at the Photographic Exhibition, and I waited with some little impatience for the official reply, by which it appears Mr. Gale's slides were in possession of the Secretary for exhibition. Now, although this is satisfactory to a certain extent, it is extremely unsatisfactory from another point of view. Whatever may be the object for which the Exhibition is held it is certainly looked upon by amateur photographers from the provinces as an exhibition of the best work produced during the year, and the medal pictures are by them eagerly scanned and criticised as the standard to which they have to attain It is also distinctly understood in connection with all other exhibitions that exhibits must be as the very word indicates—"on view;" and I hold that not only has a serious injustice been done to Mr. Gale by not exhibiting his slides, but that the visitors have been deprived of their right to examine them by the action of the executive in keeping them out of the catalogue and away from the other exhibits. That this was done I can personally vouch; for, taking as I do a great interest in lantern matters, on my visit to the Exhibition the lantern slides were most carefully examined by me. Having seen some of Mr. Gale's work on a previous occasion, I specially looked to see if he had any in the Exhibition, and, not seeing his name in the catalogue or his slides on the table, I naturally concluded he was not exhibiting; thus not only I but all other visitors were deprived of the opportunity of seeing wherein his slides were superior to those on exhibition. This view may appear to the Council of the Exhibition not worth considering, but I can assure them the Exhibition will soon loose its high position if medal pictures are to be kept in the possession of the Secretary, and not exhibited in the room.—I am, yours, &c., T. W. T.

December 16, 1884.

THE SOIRÉE OF THE ASSOCIATED SCIENTIFIC SOCIETIES OF LIVERPOOL.

To the EDITORS.

GENTLEMEN,—In the report of the Photographic Exhibition of the Liverpool Association at the recent *soirée* there is an accidental omission of the name of Mr. J. A. Forrest from the list of gentlemen who formed the hanging committee on that occasion. Mr. Forrest's co-operation was so valuable then as ever that I shall be glad if you will allow me to acknowledge it gratefully now.—I am, yours, &c., H. J. PALMER, *Hon Sec.*

December 17, 1884.

MERCURY INTENSIFIER.

To the EDITORS.

GENTLEMEN,—In answer to the request of "H. B. H." I send the formula required, and also a developer suitable to work with it:—

Intensifier.—Stock Solution A.

Bichloride of mercury	2 drachms.
Bromide of potassium	2 „
Water	5 ounces.

B.

Sulphite of soda, $1\frac{1}{2}$ ounce in 6 ounces of water.

In wide-necked bottles, used over again till exhausted and then strengthened. The negative must be soaked in water half an hour before intensifying; then flooded with A till sufficiently dense, next washed five minutes and placed in B till the negative is blackened through and becomes transparent in the shadows. Afterwards soak half-an hour, and then dry.

Developer for quarter-plate.

A. Sulphite of soda, thirty grains in half-an-ounce of water.
B. Pyro. (dry), three grains.
C. Washing soda, thirty grains in half-an-ounce of water.

Stock solutions of A and C can be made in quantity for use. Place A in a measure; add B, and immediately before developing add C. No restrainer is required. If preferred add one-quarter of a grain of bromide of potassium. The negative will appear as an over-exposed one, but will gradually grow to full density if the exposure have been correct.

I am of opinion that the negative ought to be left short of full density and afterwards intensified, as a better print is obtained by so doing.—I yours, &c., J. C.

December 13, 1884.

PHOTOGRAPHIC NOMENCLATURE.

To the EDITORS.

GENTLEMEN,—I have just taken up the *Journal* and *Transactions* of the Photographic Society of Great Britain for November 28. In the report of the meeting of Tuesday, 22nd July, I find the following:—"Mr. ——— remarked that lately he had been experimenting with bromide added to excess, and although it prolonged," &c. The remark is made in connection with alkaline development. Were this an isolated case of the misuse of the word "excess" I should not think it worth while to trouble you or your readers in the matter, but I find the same mistake occurring continually, and often in works laying claim to great scientific precision.

The terms "in excess," "to excess," "excess of," when used in connection with chemistry or chemicals, as I understand them, always refer to a chemical combination, and indicate that of the two substances which go to make up the combination there is more of the one than will combine with the other to form the compound—the quantity which is over remaining in its original form and being "excess." The substance of which there was, to begin with, an unnecessarily large quantity to exactly combine with the other was "in excess." It did not, however, follow that there was more of it than of the other substance. In an emulsion made with one part of ammonium-chloride and three parts of silver nitrate there would be excess of the former chemical. It is, however, absurd to talk of "excess" of bromide or bromide used "to excess" in the alkaline developer when we do not know the function or the manner of action of the bromide at all, and may only be pretty sure that it makes no chemical combination with anything either in the developer or in the plate. In the particular case alluded to it would have been incorrect even to talk of an *excessive quantity* of bromide, since the results apparently showed not that an excessive quantity had been employed, but that just the right quantity had been used. All that was meant was that there was a large—or an unusually large—quantity of bromide in the developer.

Such, gentlemen, is my protest against the use of a word which has a most precise scientific meaning, but which is continually misused.—I am, yours, &c., W. K. Burton.

Notes and Queries.

E. C. wishes to know how to account for the periodical emptying of his water tank. He starts work with his tank full, yet sometimes, although he feels sure he cannot have drawn off one-half the water it contains, he suddenly finds it empty—a *contretemps* which, of course, usually happens at an awkward time, such, for instance, as when the pipes are empty. This nuisance he is occasionally subjected to through a neighbour having an engine supplied from the same branch, which passes up a private court. He further states that the noise produced when the water ran dry through this cause, combined with the splashing noise of the tank in refilling, was so irritating that he could only get rid of it by attaching a piece of rubber tube to the exit pipe of the ball-cock, so that the water was led to the bottom, and, having no fall, produced no noise.——In reply: we may inform E. C. that this remedy against the noise is doubtless the cause of the water running dry in his tank. The pipes are full, we will say, at a certain moment and his neighbour begins to draw water, thus relieving the pressure; the pipes to his tank begin to empty themselves, and, acting as a syphon, draw off all the water stored in his tank—a method which, though useful to his neighbour in assisting to feed his boiler more quickly, is naturally annoying to E. C. If, therefore, he remove the india-rubber tube, the stored water cannot be drawn off again, and if he place a sloping board for the water to drop upon he will avoid the irritating noise of its splashing. We can only suggest as a remedy against the other noise complained of that he obtain a new water service direct from the main.

"Can you inform me what to do under the following circumstances? Determined to collect my hypo. residues, I gradually filled two petroleum-oil casks, and then placed in each of them half-a-pound of sulphide of potassium which I had already purchased for the purpose. After stirring well up I allowed the precipitate to settle, and, after pouring the liquid away, collected the deposit, dried it, and sent it to the refiners. They refuse to allow me anything for it, stating that it does not contain more than a trace of silver.—Anxious."——In reply: if you had preserved a small quantity of your precipitate it would have been an easy matter to make an assay of it; but, seeing that this is now impossible, we may say we are strongly of opinion that the refiner must be right, for it is extremely unlikely that any attempt at a fraud like this would be made by anyone in the trade. We should explain the loss by supposing that the sulphide of potassium was completely decomposed, and that it had entirely lost its precipitating powers. The freshly-made salt should, when broken in pieces, show a rich, liver-coloured fracture contrasting strongly with the opaque, dirty-yellow appearance which quickly forms upon the cake when exposed to air. The sulphide, after keeping, gradually decomposes from the outer surface inwards, till, at last, its whole composition is altered, and the changed mass rendered unable to thrown down silver at all. It was probably this almost insoluble product, mixed with dust and dirt fallen into the vats, which you sent to the refiner. If so, you need not wonder at his declining to allow you anything for it.

W. J. (Camberwell) disputes the correctness of our advice about "lights" in a late issue, and he calls our attention to a contrary view given in a quotation from a well-known popular book on the law between landlord and tenant, which we may here repeat:—"If an occupier alters ancient windows, or constructs new ones, in such a way as to vary his prescriptive right to the prejudice of his neighbour, and such neighbour from the position of circumstances cannot obstruct or stop up such altered or new windows without indirectly infringing upon other prescriptive rights which have not been altered or varied, then such latter unaltered rights may become legally impaired or extinguished in the lawful effort to extinguish the altered ones." A further illustrative paragraph shows that these "other" rights may refer to windows.——We would, in reply, say that our advice was not given to initiate a controversy on the matter, and we should recommend anyone having any such contention in hand to take no important action in reference to it without legal advice. "The man who is his own lawyer has a fool for his client." At the same time, we recommend our correspondent to look to the date of the work from which he quotes. We admit his quotation represents the rulings once in vogue; but modern cases have established a positive precedent entirely to the contrary of the law quoted, and quite in keeping with our advice, which was founded upon them. These latter rulings have been on the presumption that a man does no wrong in putting windows in his walls, and that, therefore, he cannot be punished for that which is not a crime.

"A photographer of my acquaintance, who I have reasons for knowing makes use entirely of "pyro." in his development, never has his negatives of such a yellow colour as my own. Can you tell me the cause? It is not any treatment after fixing, for I have seen him take them out of the fixing bath, and they have just that beautiful clean appearance which oxalate of iron gives.—M. E. W."——In reply: the mode of attaining such results is simple enough, and has been described by us in these pages more than once. It consists simply in putting the prints in acidulated water before fixing, the precaution to wash well after this bath and before fixing being necessary. It is also advisable to add alum to the acidulated water to prevent the frilling tendency which otherwise might be induced with some makes of plates. The following formula has been communicated to us as that in constant employment by a well-known photographer:—

Citric acid	½ ounce.
Chrome alum	1 "
Water	1 gallon.

The plates are placed in this mixture directly after developing without more washing than a mere rinse, the acid neutralising what little ammonia is present, and so arresting development at the same time that it prevents the formation of the yellow stain, or destroys it when already produced.

A Country Photo. writes that an enlargement he has just received from the artist, who finished it in monochrome, has got injured in transit. By some means oil or other greasy matter has come in contact with it. He says the grease has penetrated the mount as well as the picture, and asks if there be any means by which it can be removed; also, whether he is entitled to any compensation from the railway company.——In reply to the first query: the only method we know by which the grease can be removed is by treating the soiled part with benzole. If the benzole be applied lavishly, and after soaking for a short time be blotted off with clean blotting paper, then a fresh quantity applied and again blotted off, we have no doubt the grease will be extracted without injury to the picture. At least, we have successfully removed oil from a coloured photograph in this manner, so that it could not be detected. With regard to the second query: the injury should have been pointed out when the railway company delivered the picture and a claim made at once, which we imagine could be sustained if the picture had been carefully packed, and labelled as a picture to be treated "with care."

W. wishes to know what light is best for photographing open landscapes.——The best negatives are not usually obtained in strong sunlight, but when there are clouds about. Hence the best pictures are likely to be obtained only by watching and waiting sometimes even for a fortnight, perhaps, which fact gives the tourist an advantage over photographers more pressed for time. Mr. M. Carey Lea long since pointed out that a very good negative is always valuable, whilst one of average character is not so, whether it be required for exchange or any other purpose. Therefore, the best principle to be adopted by those who can spare the time is to take a few super-excellent negatives rather than many of but average quality. England is especially favoured with a general run of fine cloud scenery, in which perhaps it is surpassed by no other country. In drier climates fine scenery in the mountains is often photographically spoilt for a week or two by lack of clouds, when first-class results are desired. The best alternative, if the operator cannot wait, is to take the view when the sun is low.

A "Country Cousin" wishes to know if we can inform him how to get tones of great richness such as he has lately seen in a number of photographs, the deep shadows being so much richer than he obtains, though professional photographers have told him his negatives are of first-rate printing quality. "The prints look as though they were varnished," he says.——Our correspondent evidently has not had much experience, or he would be aware that the effect he describes is owing to the prints having been passed through a "burnisher" [see our advertising columns] made hot before use. The effect is to give a polish or gloss (which we dislike very much) and to alter the tone to a redder hue, at the same time materially adding to the richness and transparency of the shadows.

R. S. is troubled about the continual marking of his *cartes* in the post by the stamping violence, and wishes to know a remedy.——This is an everyday experience, and surely it must have occurred to him that it could be remedied by efficient packing. Perhaps the simplest mode of doing this is to enclose the *carte* between two plain cards before placing it in the envelope. Any professional friend would show him the method he employs, and very likely be willing to sell him a few of his own book-post card wrappers, which are made in immense quantities for the purpose.

Exchange Column.

I will exchange a 10 × 10 double swing-back mahogany camera, one dark slide and rackwork for focussing, by Ross; seven and a-half-inch burnisher, French; two half-plate bellows cameras, two dark slides to each, and focussing glass; two 10 × 8 glass baths, in deal cases; two whole-plate glass baths; stereo. glass bath, in mahogany air-tight case; pedestal, four different sides; patent lever open-faced, gold-plated watch, jewelled in thirteen holes; silver hunting watch; silver watch, open face. Wanted, mansion house set, backgrounds, boat, rocks, or anything useful in photography.—Address, G. S., 4, Bernard-street, Southampton.

I will exchange The British Journal of Photography for the years 1881-82-83-84, all in good and clean condition, unbound, for a half- or whole-plate light tourist's camera of modern make, with dark slides;

difference in cash, or a good gem camera and four splendid lenses, to take four, eight, or twelve on a quarter-plate.—Address, PHOTO. ARTIST, Callington, Cornwall.

I will exchange a Lancaster's quarter-plate instantograph, quite new, for any useful studio accessory to value.—Address, PHOTOGRAPHER, 19, Beckenham-road, Penge.

I will exchange 100 carbon slides and sixty Woodbury slides for Ross' rapid symmetrical lens, $8\frac{1}{2} \times 6\frac{1}{2}$, or offers.—Address, J. MALINS, Crosswood, Aberystwyth.

Wanted, the *Photographic News* for 1882 and 1883, clean and perfect. Good exchange offered.—Address, J. H., 365, Lodge-road, Hockley, Birmingham.

Wanted, a half-plate bellows camera with double backs. Will exchange a good dark room on wheels.—Address, PHOTOGRAPHER, Withernsea, near Hull.

I will exchange a folding retouching-desk for a fourteen-inch Gladstone bag; would give a little cash if good.—Address, W. H. H., 180, Villiers-road, Willesden Green, London.

I will exchange model vertical engine, will drive sewing machine or small lathe, for good whole-plate view lens. Particulars sent.—Address, W. HUDSON, Ripon street, Preston, Lancashire.

I will exchange a new bellows-body camera, eleven inches square by two feet six inches long (no fitting), for a 15×12 glass bath.—Address, GEO. ATKINSON, 40, Cambrian-view, Chester.

I will exchange an autograph letter of H.R.H. The Prince of Wales, and Edward's combination printing-frames, ditto for printing opals, for a camera and burnisher; difference in cash.—Address, HERBERT SEELY, 108, Albany-road, Old Kent-road, London.

I have twelve ounces of re-crystallised nitrate of silver, also a four-lens gem camera, takes twelve on a quarter-plate. What offers in exchange? 5×4 or half-plate group or view lens wanted, good maker.—Address, PHOTO., 21, Bartholomew-street, Exeter.

I will exchange the full numbers of THE BRITISH JOURNAL OF PHOTOGRAPHY for 1883 and 1884, up to the present, December 5th, for a double dry-plate slide, $6\frac{1}{2} \times 4\frac{3}{4}$, or anything useful in photography.—Address, W. JONES, 272, Uxbridge-street, Burton-on-Trent, Staffordshire.

I will exchange, for anything useful, three backgrounds, quarter-plate repeating-back camera and lens, two whole-plate lenses by Lerebours, an orthographic lens by Ross, rolling press, plate 21 inches × 15 inches, and burnisher, 10-inch roller.—Address, FRIESE GREENE, 34, Gay-st., Bath.

I will exchange THE BRITISH JOURNAL PHOTOGRAPHIC ALMANACS and *The Year-Book of Photography*, in 10 vols., cloth, for the last 15 years, for lantern slides and electrical apparatus.—Address, E. FIELD, 16, Hills-road, Cambridge.

I will exchange an instantaneous shutter and changing-box, to carry twenty-four half-plates, also a large dark room, fitted with shelves, sink, and tap, in perfect working order, suitable for a gentleman, for anything useful.—Address, C. GRAYSON, Naylor's-yard, Iregate, Bradford, Yorks.

I will exchange an eight-feet gas bag, twenty-feet screen, pressure-board (nearly new), various slides, chromotropes, &c., for Ross's portable symmetrical lens, any size. Difference, if any, adjusted.—Address, J. H., 10, Victoria-road, Penrith, Cumberland.

For exchange, Seavey's boat; cameo press for cabinets and *cartes*, by Marion, cost £5 5s.; three patent spring blind rollers for studio, cost £1 5s. each; *carte* rolling press; large square, rigid camera, by Meagher, for plates 20×24 and under, cost £13. Wanted, portable dry-plate camera by a good maker, with two or more dark slides, for plates 10×12 and under; also, effect and other slides for lantern.—Address, E. GRANT, Swindon, Wilts.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

NOTICE.—*Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a* NOM DE PLUME *as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.*

J. F. RUNCIMAN.—The index when issued will indicate the article referring to the subject. It is now in the hands of the printer.

S. not having complied with our rule by sending name and address, of course his query is unanswered.

PERPLEXED.—Dab the silver plate over with a piece of glazier's putty. This will dull the surface and prevent reflections.

J. W. H.—1. Any fancy boxmaker will make them to your order.—2. Apply to Messrs. Sands and Hunter.—3. No.

THE correspondent who inquires about grooved paper boxes, and whose signature we cannot decipher, had better apply to Mr. E. J. Edwards.

A. B. We regret we are unable to give you the desired information. The only source from which you can obtain it, we imagine, will be from some manufacturer of gelatine. Better write to Messrs. Nelson, Dale and Co.

KING LUD.—You have proceeded wrongly. The salts should be dissolved separately in water, and mixed at the time of using. The solution will not keep after mixing.

A. H. S.—You will find what you require by referring to some of the old volumes of the Journal. We cannot spare space to describe an obsolete process in which our readers take no interest whatever.

CAMBRIAN.—No. 4 will be the most useful lens to you, as, with a small stop, you can very possibly utilise it as a wide-angle lens on the larger size plate.

TINTO.—The best work on the subject is Wake's *Photographic Colouring*, but it is now out of print. The "flash" is caused by light gaining access to the plate—probably through some defect in the dark slide in the camera.

A. J. GRIFFITHS.—1. Mr. G. F. Williams, 36, St. Martin's-lane, W.C.—2. Yes.—3. The paper is not usually cemented to the glass.—4. Yes. The gentleman named will supply the right kind.—5. We believe not at present.

AN ASPIRANT.—Unless any of the processes are protected by a patent you can, of course, work them without hindrance. If you let us know which particular one you wish to employ we will inform you if it be patented. Very few of the processes are protected by patent.

ANGLER.—No. 2 on your list will include a much larger angle than the lens you now have, but No. 1 will include a larger still. We fear No. 3 will not cover the size of plate you require with sufficiently-even illumination. There is no satisfactory method of reducing the intensity of mercury-intensified negatives.

A. H. S.—If you dilute the strong liquor ammonia ·880 with an equal bulk of water as soon as you obtain it, the strength of the diluted solution, if kept with ordinary care, will for all practical purposes remain constant. If you do this you need not go to the trouble of chemically testing the strength of the ammonia every time before using, as you propose.

G. W. AUSTEN.—There has been such a process described, but for the moment we cannot recollect the working details. The carbon process is largely utilised for the purpose. You will find full working details of zinc-etching processes in the articles on photo-mechanical printing which appeared in our volumes for 1878-9.

R. S.—Treat the suspected sulphite of soda with chloride of barium, which will throw down a precipitate of sulphite of barium. This is soluble in either hydrochloric or nitric acid, while the sulphate is not. Consequently if the whole of the precipitate is not dissolved by the acid, you may know that the sulphite of soda contains sulphate. All sulphite of soda is liable to decomposition by keeping.

CHRISTMAS DAY.

NOTICE.—THE BRITISH JOURNAL OF PHOTOGRAPHY for the week ending December 26th will be published at nine o'clock a.m. on WEDNESDAY next, the 24th December. Advertisements intended for insertion in that issue should therefore reach the Office by MONDAY EVENING next, the 22nd December. Small Advertisements will be received up to Nine o'clock on Tuesday Morning next, the 23rd December. Orders for Advertisements of the same class, addressed to the "Printing Department," 32, Castle Street, Liverpool, will be received up to Two o'clock p.m. on Tuesday next, the 23rd December.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The next monthly technical meeting of this Society will take place on Tuesday next, December 23rd, at 8 p.m., at 5A, Pall Mall East.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician,
For two Weeks ending December 17, 1884.
THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

Dec.	Barometer.	Wind.	Dry Bulb.	Wet Bulb	Max. Solar Rad.	Max Shade Tem.	Min. Tem.	Remarks.
4	29·24	W	50	48	—	51	44	Raining.
5	29·78	W	41	39	—	54	39	Bright & Clear.
6	29·71	W	54	52	—	55	40	Raining.
8	29·81	W	50	49	—	51	49	Overcast.
9	29·95	SW	42	41	—	43	41	Raining.

17	29·60	W	40	39	—		34	Cloudy.

CONTENTS.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1286. Vol. XXXI.—DECEMBER 26, 1884.

THE PAST YEAR.

Once more it becomes our duty to record the events of the passing year, and once again we feel the difficulty of the task. Not that there is nothing to record, for there is a plethora of matter; but simply or chiefly because there is difficulty in laying emphasis on any particular items of novelty with which the year 1885 can be identified.

The chief portion of the really practical work of the year has been of course devoted to dry-plate work, but scarcely in the same direction or to the same extent as in the past few years. The important discussion of the question of lighting the developing room has attracted a considerable amount of attention, and Mr. W. E. Debenham's recommendation to substitute a combination of green and yellow for the previously-employed ruby media has found favour in many quarters. At the same time a pure yellow light is perferred by many, and the real fact seems now to be that any light may be employed, if it be employed with sense.

Another point in connection with dry plates that has received its full share of attention during the year is the substitution of one or other of the fixed alkalies for ammonia, in conjunction with pyrogallol, in development. This is a matter important not only from the point of view of convenience and excellence of result, but also as a matter of hygiene. The constant respiration of the fumes of ammonia—however dilute—has been shown to exercise a more or less injurious action upon the system, the extent and the character of the injury being dependent on the constitution. Anything, therefore, that tends to the suppression of this evil, without necessarily involving any falling-off in the quality of work done, must be hailed by all photographers as a step in advance. At present there appears to be a growing feeling in favour of soda and potash as the adjuncts to pyro., but we are not alone in the opinion that ammonia is still able to hold its own.

One other branch of negative work with gelatine plates to which much attention has been given during the last year or two, but more especially during the last few months, has been the colouration of the film with the view of rendering it more sensitive to certain of the less refrangible rays of the spectrum, and so enabling the photographer to render in monochrome the various colours of nature in their due gradations as seen by the eye. The late Dr. Draper, some thirty and forty years ago, was the first to call attention to the fact that certain sensitive films which absorbed particular rays of the spectrum were proportionately more sensitive to those rays than to others. Since Dr. Draper's observations the matter has been taken up by others, and Dr. H. W. Vogel, some twelve or fourteen years ago, showed that collodion films stained with various dyes became sensitive to the colours which the stained films absorbed. Mr. M. Carey Lea and Major—then Captain—Waterhouse took up the same line of investigation, the latter being the first, we believe, to recommend eosine for the purpose. But from collodion films, for various reasons, no very profitable results were attained, and it remained for MM. Attout-Tailfer and Clayton, of Paris, to revive with success the old idea in connection with gelatine plates. Since the introduction of their "isochromatic plates" Dr. Vogel and others in Germany have experimented with stained films, and it is now beyond question that for special purposes, particularly for copying oil paintings, the coloured films are invaluable.

Gelatine emulsion also promises to play an important part in the future of printing. It is now two or three years since gelatino-bromide paper took a hold on the public, chiefly for enlarging purposes; but just within the last months of the year it has become possible to use a similar paper for even the smallest work, the exposure extending to seconds only by artificial light, while the tones obtained will rival albumenised paper in variety and in quality. There is little doubt that this process will be greatly developed during the coming year.

In connection with other printing methods there is little alteration to record. Silver, despite its numerous detractors, still holds its own. Carbon in its various forms remains in the hands of the few; and platinotype, with the exception of the production of some new tones, is scarcely in a different position from that occupied by it last year. Photo-engraving has, however, been brought to a higher degree of perfection than before—not merely in line work and reproductions, but in the rendering also of the most delicate gradations of a photograph from nature. It is to be regretted, however, that the process by which the particular specimens we have in view were produced is a secret one, and as such not likely to forward photography to any extent.

In photolithography and kindred methods there has been great activity, and it is scarcely going beyond the bounds of truth if we venture to say that there is not an illustrated paper or publication in the country which does not now utilise photography in some manner.

The hand of death has fallen heavily upon us during the year, and several well-known names and faces have disappeared from amongst us. Mr. J. H. Dallmeyer, the famous optician, whose death was reported early in January, was the first on the list, followed with painful rapidity by the announcements of the deaths of the Rev. F. F. Statham—for five and twenty years President of the South London Photographic Society—of Mr. H. Baden Pritchard and Mr. Jabez Hughes, both old and well-known representatives of English photography. In America, too, there have been several losses amongst them—Dr. J. J. Woodward, whose work in connection with photomicrography has gained him a world-wide reputation; Mr. F. A. Wenderoth, of Philadelphia, one of the leading portrait photographers in the United States; and, finally, Mr. Henry T. Anthony, of the firm of E. and H. T. Anthony. Mr. John Hubbard's death brings up particularly sad thoughts of the uncertainty of life, for he was an exhibitor at the last Exhibition of the Photographic Society, and was awarded a medal for his clever composition picture, *Mother's Love*, but did not live to receive it from the hands of the President. Other less familiar forms will be seen no more in the ranks of practical photography, and as we write these lines the grave has scarcely closed over the remains of Mr. Henry Greenwood—the printer and publisher of this Journal since its commencement, and its proprietor for nearly thirty years. After a personal intercourse of over twenty years it is needless to say that we feel the loss keenly, and it is with more than ordinary sadness we close the present volume.

In consequence of the lamented decease of Mr. Greenwood, certain changes in the conduct of the Journal are absolutely necessary, and will be commenced with the New Year. It is impossible, and indeed unnecessary, to specify them in detail, but it may be stated that the printing office will be removed from Liverpool, and in future The British Journal of Photography will be printed as well as published in London.

THE DIRECTION OF THE WIND AND ACTINISM.

Does the direction of the wind influence the exposure in the camera? If so, from what quarter does the highest actinic effect occur? In the early days of photography—even so far back as the time of the Daguerreotype process—it was considered that when the wind blew from certain directions there was always an increase in the actinic power of the light, and when it came from other quarters the reverse occurred. In some of the earlier works on photography it is mentioned that, if the wind be in the east, a much longer exposure is always necessary. Not only was this asserted, but some writers have given a theory why this should be the case. However, it is not with the theoretical part of the question it is our intention to deal in this article, but to treat the subject from an entirely practical point of view.

There can be no question that, in the neighbourhood of large towns at least, the direction of the wind may, under certain conditions, very materially affect the quality of the light. This topic, it may be mentioned, is no new one, as it has before been dealt with in our columns; yet, evidently, it is one that is not thoroughly understood by many.

We were forcibly reminded of this fact quite recently, when at the close of a meeting of one of the photographic societies the conversation of a number of photographers turned upon this subject. One gentleman remarked that with a south wind his exposures were always longer than with a north, while another asserted that with an east wind his exposures, as a rule, had to be at least fifty per cent. longer than when it was west, however good the light might appear to the eye. This gentleman also said that not only did the east wind increase the exposure in the camera, but the printing operations were correspondingly retarded. Others present gave their experiences also, which differed very materially from those already mentioned, but no one offered any explanation as to the actual cause of this discrepancy. It may at once be mentioned that the gentlemen who gave such diverse opinions resided in different parts of the metropolis.

After a little consideration it will be easy to conceive why a photographer located (say) in a northern suburb of London will find a material diminution in the actinic value of the light when a gentle breeze is blowing from the south, simply because the wind wafts the fog and smoke from the town in that direction. When the wind is in the north it, of course, blows from the country, and if by chance the atmosphere be at all foggy the fog or vapour partakes of the character of a light mist, which in some instances enhances the active quality of the light rather than otherwise.

The fog or vapour constantly present, more or less, in all large towns where coal is the staple article for fuel, particularly during the winter months, is always of a highly non-actinic character. As an example of the total absence of actinism in a London fog, we have known instances of prints being exposed for an entire day in the open air without the slightest outline of the negative being impressed on the paper—a fact that can hardly be realized by our continental friends. Although such a fog may cut off the whole of the actinic action of the light, it frequently happens that it is comparatively only a thin layer, sometimes not extending to the top of moderately-high buildings. It is no very unusual circumstance for persons, out of curiosity, to ascend to the top of St. Paul's Cathedral during a London fog, for the express purpose of looking down upon it, while the sun is to be seen brightly shining overhead.

Some curious phenomena are frequently observed during a dense fog, which will illustrate how this yellow-brown vapour, when once formed, holds together and may be blown about in a comparatively compact mass. On one occasion we happened to be in the city and witnessed one of those dense, yellow, smoky fogs approach slowly up the street, almost like a wall. At one end of the street for a short time the sun could be seen shining brilliantly, while the other end was in a dense fog. In a few minutes the whole thoroughfare was enveloped in darkness, which for a time was sufficient to put a stop to all vehicular traffic. This fog did not remain long, and it cleared off nearly as suddenly as it made its appearance. Now, when a fog of this description is dispersed by the wind it, of course, becomes attenuated, and its highly non-actinic character is, so to speak, diluted, but it is not destroyed.

In the presence of a brisk wind fogs are never formed, as the smoky or other vapour is carried away and becomes diffused. Still in whatever direction it may be carried it is generally sufficient when the wind is slight to materially affect the actinic power of the light, although this may not be manifest to the eye. Hence it is in the vicinity of large towns that one photographer may find the wind from a given quarter to retard the chemical action of the light, while another, on the contrary, will find it considerably accelerated. The same will necessarily follow from every point of the compass from which the wind may come according to the location of the studio. This brings us to the practical part of the question.

It is very clear that in the neighbourhood of large cities a material advantage may be gained by judiciously selecting a situation for working. Unfortunately the most suitable locality for the studio in the case of portraiture has to be considered from a commercial point of view alone, namely, where the best business can be commanded. Not so, however, with establishments which confine their operations more particularly to copying and enlarging, or such like work. These are usually situated in the suburbs, in order to be as much as possible free from the town fogs and haze; so also are the printing establishments of most of the leading London portrait photographers. In these cases the selection of a locality is less restricted.

The preponderance of wind during the maximum period of late years appears to be from south through west to north-west. Hence, a south, west, or north-western suburb would appear to be the best to select, in order to secure a position where the prevailing wind for the greatest period in the year blows from the open country instead of from the town. We know that several of the largest London houses have their printing establishments in the north and western districts, these districts being chosen, we believe, for the reason just indicated.

What has been said in reference to the fogs and haze from the metropolis applies equally well, though in a larger degree, to all large towns, at least in this country, where coal is the principal fuel consumed.

PHOTOGRAPHY: THE REDUPLICATION OF MANUSCRIPT RECORDS.

Attention has often been drawn in these pages to the important aid which photography is capable of rendering in the multiplication or reduplication of valuable documents, whether in the possession of the state or of individuals; and yet what has been done, so far, to utilise the aid of which it is capable? We hear of a few isolated instances of private enterprise in bringing before the public photographic copies of manuscripts of great interest and extreme value. Now and then one of the societies treats its subscribers to an occasional photographic reproduction of some old work; while others, whose value depends entirely upon the reading to be given to a particular passage only half legible, are printed in modern type, without chance of individual criticism or conclusions being formed from personal inspection. But what steps does the Government take to guard from destruction the priceless treasures of records and manuscripts committed to its charge, beyond providing a grand warehouse for their storage? Within certain limited restrictions these documents of untold value are within everyone's power to examine, criticise, and of necessity to wear away by the mere process of handling, be it ever so tenderly done.

It is stated by those who are well fitted to judge that already a distinct depreciation may be discerned in some of these collections of ancient writings, and as population multiplies, and that scrutiny of old evidence now so much the fashion increases, it needs no prophet to point out what will be the ultimate fate of these concrete and tangible messages of times gone by—messages, it must be said, that we hold in trust only for our successors.

The last quarter of a century has seen vast strides taken in the critical exegisis of their antique scrolls. What may be done in its succession can only be guessed; but one thing is certain—a heavy accusation will be against us if we let these things perish, or even be injured, for want of a little expense, a little care, a little forethought.

Comparatively few years ago it might have been objected that there was no practical process of reproduction by any permanent method, and that it would be absurd to incur the expense of making copies of these things that would not last a generation out. Now, however, as our readers know—for some time past it has been so—there are numbers of accurate modes of photographic duplication by which copies may be made as durable as anything on the shelves of the British Museum, and at a price little above what would be entailed by setting up the words in type, and printing in the press in the usual fashion.

We are glad to find that the subject is being earnestly taken up by many who view with something like dismay the possible annihilation of these only witnesses we possess of the doings of past ages, and a decision has been arrived at to petition Parliament upon the subject.

At the annual meeting of the Library Association, held the month before last, the following resolution was passed:—"That a memorial be presented to Her Majesty's Government, urging the great necessity of making, by means of photography, copies of parish registers and other important documents, whether printed or manuscript, books, pamphlets, &c., in public libraries, in order that the public may be secured from the serious consequences of the loss of such documents, &c., and, further, may be supplied with copies of the same at a reasonable price. That this Council prepare, and the President be requested to sign, such memorial on behalf of the present meeting, and that members of the Association be requested to use their influence with Members of Parliament in its support."

Our remarks, so far, refer mainly to manuscripts of great age, the number of which in the world can never be increased, and is, indeed, decreasing by the remorseless hand of fire or decay, although it is possible, by the properly regulated expenditure of an annual sum of no great moment, so perfectly to reproduce them that the world would, in effect, be no loser if every one of the originals was destroyed by fire. But it will be seen that the framers of the resolution we quote have gone much further than this, by recommending the copying of records to be extended over a very wide field, and this, it is evident, means the expenditure of sums of money which in the aggregate would be immense. Still it is a query whether it would not merely be a transference of payments from her Majesty's Stationery Office to the pockets of photographers and their *employés*. Indeed, we do not hesitate to say that a process of photographic reproduction could be devised which would not necessarily result in any increase of total expenditure. The same thing in another form has been said before; hence there is no novelty in our suggestion that such records could be copied on a greatly reduced scale instead of one simile in size as well as structure. Expense would be saved, and the work of reference actually simplified.

It is suggested that every parish be compelled by law to have its register so reproduced in *facsimile*, a copy deposited in the nearest local library, and one at Somerset House. The expense of carrying out such a plan for past registers would, no doubt, be very great, though if spread over a number of years it would not be felt. As to future registers: it is evident that they might be arranged in such a form as to enable the many pages to be copied at a time on, as we say, a reduced scale, and at a cost which need not exceed what would be paid to an expert trustworthy copyist. As to the older records, it is likewise evident that the actual cost of photographic *facsimiles* might amount to a smaller sum than would be charged by a writer skilful and trained enough to be able to decipher the old and crabbed handwriting that so often characterises records dating back a century or two ago. The vastly-increased accuracy which would follow the adoption of such a course no one would presume to question.

In the paper by Dr. R. Garnett, which gave rise to the discussion of this topic and the final adoption of the above resolution, it is recommended that a photographic department be established at the British Museum, with the view of facilitating the cheap reproduction of important manuscripts and records. This is treading on delicate ground. There is no doubt that a department of this kind, under the control of Government, would be of great value; but the British taxpayer would very probably insist upon its being self-supporting, as indeed it well might be. Then, however, would at once arise trade jealousy. We all remember how the stationers rebelled at the idea of the Government interfering with trade by making a present of the then so-called "post-card" to the purchasers of the halfpenny stamp thereto attached, and how, in consequence, the price of post-card message was increased by more than ten per cent. Similary we are afraid the mechanical photographers might complain of the Government taking their trade out of their fingers, if they undertook on a large scale the photographing of registers and the selling of copies either at a profit or at cost price.

This, however, is a difficulty which would follow all state manufacture, and we apprehend it would not be difficult to surmount it. Therefore, we feel no hesitation in giving our cordial support to the resolution based upon Dr. Garnett's recommendation, and it would, we feel assured, be a subject of congratulation not only to the profession but to the public at large to see it acted upon in one shape or another with zeal and energy.

The season of the year has approached when, in some districts especially, the photographer is at his wit's end how to get rid of the effects of smoke. If his studio be cold he can heat it; if warm, he can ventilate it (or try to); but if a good rich, thick sample of fog, which is mainly trapped smoke, gain entry he may ventilate and he may heat his room without getting rid of this monster, for such, indeed, the invasion becomes. It has been stated that electricity will dissipate this smoke-fog; but we are afraid that the largest of electrical machines grinding by the whole force of the establishment would have little effect upon some of the peliginously-protected spherules of water that, at this period of the year, come between the photographer and his client to the detriment of all transparency of shadow, not to say serenity of mind.

There is, however, hope of better things in the future for the photographer. Modes of bringing about the abatement of smoke occupied considerable attention at the Healtheries, and no doubt will be still more to the front at the Inventories. Meanwhile we may direct attention to a very interesting correspondence which has lately been carried on in the *Journal of the Society of Arts* upon this subject, some very remarkable results in the direction of smoke-abatement having been described by Mr. Fletcher, well-known for his gas apparatus, as having been brought about in furnaces, &c., under his own supervision by means of a very simple character. It must be remembered that studio fog—during the prevalence of which the taking of good photographs is next to impossible—does not always owe the whole of its intensity to the thickness of the external air. It is too frequently aided and abetted by the clumsy furnaceman or the untidy housemaid, and any hints that may be gained from Mr. Fletcher's experience in avoiding this additional cause of the optical impurity of the atmosphere will be of real and substantial benefit to the photographer in the damp and cold seasons, though it may be years before their effect upon the atmosphere in general will be seen.

The very instructive letter upon the care of the eyes, and the effect of civilization upon eyesight, by Dr. Brudenell Carter, which appeared in *The Times* a month or two ago, has been issued in a separate form, with a few explanatory diagrams by the author. This is one of those useful small publications which everyone—particularly the photographer, whose occupation borders, or is liable to border, so closely upon the injurious—should carefully read.

"They manage those things better in France," and so they would have had us to believe when the wonderful balloon ascents were made from Meudon. In the first case, no spectators were present, and the balloon was steered against the wind in a dead calm; and, in the second, it was brought home in a cart after a successful battle with the wind blowing in the direction it was steering. Consequently the successful and skilful aëronautic experimentalists are reaping the reward of their exertions. One of them is named in the list for the distinction of a Chef de Bataillon, another made a Knight of the Légion d'Honneur, and a third, who received a wound in preparing the gas, is similarly distinguished. At the same time it is interesting to learn that the bubble, we should say "balloon," is metaphorically burst, seeing that it is put on the shelf *sine die*, for its resuscitation; and strange not to learn that the commission appointed by the Academy to report has reported upon its powers.

The wonderful sky-glows have been, if possible, more beautiful than ever at intervals during the last month or two; yet we have seen no other photograph of any phase of phenomena than the one engraved in *La Nature* last year. Our esteemed contributor, Professor Piazzi Smyth, writing from Edinburgh to *Nature* describes an effect—still stranger than any yet observed—in the form of a series of clouds all brilliantly iridescent, glowing masses of beautiful colours quite distinct from any of the ordinary sunset hues which gild the sky so beautifully. In the same paper an effect almost similar is described by Mr. J. E. Clarke as having been witnessed by himself on the same night, the 11th instant, and, in a still more brilliant form, by a large number of spectators a couple of days later.

In photomicrography with a good light, a low-power objective and a fairly-transparent object, considerations of steadiness of stand do not occupy an important position; but when the amplification is great with a high power and a diminished radiant area for light, and a consequently long exposure, it is of the greatest importance that the stand be thoroughly rigid, on account not only of tremor of the whole arrangement, but of the slightest difference of rates vibration between object and objective causing blurring. At the Royal Microscopical Society's meeting on the 10th instant, Mr. Mayall described a new instrument made on the general principles of Mr. Wenham's radial microscope, but modified in certain directions. The particular instrument (belonging to Mr. J. D. Cox) was said to have the perfection of balance of the Wale form, and to be so steady as to lead Mr. Mayall to expect it to be eminently suited for photomicrography.

We described last week the photograph of electricity (illustrated in *La Nature*) in the form of lightning as exemplified in the effects of a single flash of lightning. Now we have to chronicle the presentation to the French Academy of electric prints in another form, M. Jannin having exhibited photographs of the electric spark obtained direct on the film by M. Ducretel, by passing the spark through the film on the glass plate.

We have before now expressed our opinion of the real work done by the Liverpool Astronomical Society, and we learn that they are again showing the spirit of the true love of science that animates them. They are now establishing an educational branch for the purpose of delivering lectures upon the more popular sections of the fascinating science. It is proposed by them to hold, during the winter, fortnightly classes for instruction, and to deliver lectures upon the more popular branches. The skill with which photographic astronomical work has been conducted by the Society will, no doubt, render those classes very popular with photographers and others who wish to learn the practical details of that class of work.

Dr. Phipson writes to the *Moniteur de la Photographie*, Paris, that a Greenwich photographer advertises:—"To-day being the anniversary of the death of my mother-in-law, photographic portraits will be taken at reduced price."

In the recent International Copyright Congress, held at Berne, the question of proprietary rights in photographs was omitted. The project of the Berne Conference has been submitted by the French Minister of Foreign Affairs to the Syndical Chamber of Photography at Paris, and M. Sauvel, supported by M. Davanne, proposed that the following clause should be inserted in the Berne scheme:—"The photographic works of the subjects of each nation in the Union shall enjoy in other countries in the Union the protection which the respective laws now give, or may hereafter give by international arrangement, to works of this nature." The Syndicate approved and forwarded this suggestion.

MISCELLANEOUS USES OF GELATINE.

Gelatine being now in ordinary use in the photographic laboratory, it may not be out of place to point out some of the purposes to which it may be applied, otherwise than in the manufacture of sensitive dry plates.

Mr. Woodbury has already published that a thin five-per-cent. solution of gelatine coloured a strong yellow by a sufficiency of bichromate of potash makes a good cement for uniting pieces of broken glass. The glass must be warmed, wiped dry, the cement then applied, and the mended glass article be then exposed to light for several days. He has also published that a strong solution of gelatine to which a little glycerine and red colouring matter, such as carmine, have been added makes a substitute for wax for covering the corks and upper part of the necks of bottles.

In the form of capsules gelatine is used by druggists to hold many liquids of a greasy nature—such, for instance, as castor oil—so that they may be swallowed without the unpleasantness arising from their nauseous taste. The capsules are made by the aid of a small egg-shaped, highly-polished little knob of iron, having a pointed iron stem by which it is held. The knob is rubbed with a slightly oily cloth, then dipped in the warm gelatinous mixture, after which the pointed stem is put into a hole in a board, while the gelatine on the knob is cooling and hardening. The gelatinous mixture usually consists of six parts of gelatine, twelve parts water, and one part sugar. In a short time after dipping the capsule is cold enough to be removed from the mould, which is done by cutting the gelatine round the upper part of the stem with a knife, then pulling off the capsule dexterously with the fingers. At this stage it should be elastic enough to pull off without tearing, and to shrink nearly to its moulded shape directly afterwards. A syringe with a nozzle bent at right angles to the axis of its cylinder is used to fill it to about three-fourths its capacity; if more were forced in, the gelatinous envelope might possibly break afterwards with changes of temperature. The hole is closed with a touch of a strong solution of gelatine, and the same end of the capsule is then dipped in a weak solution of gelatine to give greater security by the thin cap thus applied. The gelatinous solution used for sealing the capsules always contains a small proportion of gum. The capsules having been allowed to dry, a polished appearance is given to them by rubbing them with a slightly oiled cloth.

Gelatine is one of the many substances sometimes used for the coating of pills, in order that they may not stick together in the box and may not be tasted in the act of swallowing them. The solution used for covering them consists of one part of gelatine to two parts of water. The pills are cleared from any dust or powder which may be on their surfaces; then each pill is stuck upon the end of a piece of wire four or five inches long, and the lower end of the wire is thrust into a basin of sand, which acts as a kind of pincushion. The pills are next dipped one at a time into the warm solution of gelatine; then the other ends of the wires carrying them are replaced in the sand, where they look like an assemblage of large pins standing while their gelatine-coated knobs are setting and drying in the air. Sometimes on removing the pills from the wires a little tube of gelatine from the outside of the wire comes off with it; this tube is carefully cut off with scissors. The hole in the gelatine where the wire pierced the pill is then closed with a little warm solution of gelatine, applied by means of a small brush of camel's hair.

One fact about gelatine does not seem to have received that attention in photography which it deserves, namely, its curious power of dissolving phosphate of lime—the chief constituent of bones. Furthermore, it always contains a little phosphate of lime, which may or may not by double decomposition introduce a trace of phosphate of silver into all gelatine argento-bromide emulsions. The late Dr. William Gregory, Professor of Chemistry at Edinburgh University, says: "The property of gelatinising depends on the presence of phosphates; for when gelatine is long boiled with water alone, or with a little alkali, phosphate of lime is deposited, and the solution no longer forms a jelly on cooling." If this be so, the functions of phosphate of lime in gelatine and in photographic emulsions deserve more attention than they have hitherto received.

W. H. Harrison.

HEAD-RESTS.

A QUARTER of a century's photographic experience allows a retrospect that includes vast alterations in the practice of our art, and in few things has more change been shown than in the head-rest and the mode of its employment. Time was when the head-rest was indeed a nuisance, its cold hard claws being equally and remorselessly applied to the bare cranium of the octogenarian or the curly locks of "sweet sixteen." It was part of the sacred paraphernalia of the studio—"gallery," it was oftenest called then—and as much a portion of the place as the camera and stand. When the sitter entered the room, whatever his experience as a sitter might be, he never missed the one nor ceased to anathematise the other. There was no mistake about the matter. Let him assume ever so graceful an air, and behave with the utmost nonchalance, feeling steady as a rock and not betraying a trace of nervousness, he had to submit to the cold steel wielded by the photographer, and in frosty weather taking his chance of its freezing to his head.

The dentist will dip his instruments in warm water, or otherwise take the chill off, but who has ever heard of a photographer taking the chill off his apparatus, although it were applied for more minutes than the former was used for seconds? It was an uncomfortable affair altogether in its rigid straightness and its jerky adjustment. When Mr. Sarony introduced his patent rest he initiated a revolution; but its high price, and the fact that it was, practically, only able to be used in one spot in the studio, rendered it only an occasional accompaniment of even first-class studios. Its charm, however, was broken. Comfort in connection with a head-rest—comfort of a modified sort, it is true—was spoken of, and from that time we may date not only the introduction of vastly-improved forms of the instrument, but, strange to say, notwithstanding these improvements, a growing and powerful objection to the instrument at all. The resignation with which sitters in the early days submitted to its employment—a state of mind too often reflected in their features—gave way to decided objections to its use under the most improved system; and the odious comparison between photographer and dentist, so often made, became intensified by the occasional sarcastic offer to allow the rest to be used if the sitter might be taken under the "influence of gas," after the manner of the former gentlemen.

In fact, there was ever after this period a smouldering rebellion against the "instrument of torture," as ran the slang designation of this most useful adjunct. The photographer sometimes had to give way to avoid a scene, and when in other cases he had convinced his sitter of the actual necessity for its employment the latter generally yielded with so bad a grace that the result was visible in the finished portrait.

That the rest is, and has been, of great utility cannot be gainsaid, and if judgment in "fixing" it had always been shown I have a strong impression that we should never—or "hardly ever"—have had it objected to; but it has been, as a rule, persistently and ruthlessly employed in every instance, often without care and with entire disregard of the sitter's comfort, till at last he has metaphorically kicked against it, and with such effect as to have sent it clean out of the studio in some cases. This state of affairs is in many respects most unfortunate. The professional portraitists' first aim should be to put his sitter at ease, and, if possible, introduce interesting topics of conversation, so that his mind is led away from the work in hand; but this is impossible when, in the first case, a heated discussion has to take place about the rest, and, in the next, the half-convinced sitter has to submit to an experience which he dreads and dislikes, and is only half persuaded, or half coaxed, into permitting. We have all read of the photographer who, in reply to the old lady's speech, when "fixed" with the "rest," that "she did not feel at all comfortable," remarked—"we don't photograrf feelin's here, marm," but, I take it, we do photograph feelings; in too many cases the face is seen to be an index of the feelings. It is an unfortunate thing that so bad a name has attached to the head-rest, for, in some instances, it materially facilitates the production of good work.

My object, however, in writing at the present time is to give some idea of my own experiences, and not to complain of the inevitable. Numbers—perhaps the majority—of professional photographers have been working as I have; but, as they have put nothing on record upon the matter, I feel sure that a knowledge of how I have fared in discharging the head-rest from active service will be useful. I may at once say that for some time previous to the introduction of gelatine plates I began to take portraits without the rest whenever possible, and since the introduction of gelatine I have gradually discarded the instrument, till at last for two years past it has been kept in an out-of-the-way corner in the studio, and only occasionally brought out for use, and when brought out it mainly applied to the body rather than the head. I have thus found a saving of time, a comfort in working, and, altogether, a vast improvement over the old style of things to which, indeed, it would now with me be next to impossible to revert.

It may be asked—"How about the sitter moving?" Well, in reply, I can only say that not only do I use no rest, but, further, I rarely tell my sitter when the moment of exposure has arrived; indeed, he is usually secured with two exposures, when I am able to inform him it is all over before he imagines the operation has begun. Yet, notwithstanding all this risk, the proportion of plates spoiled through the sitters moving is by no means large, and whatever the loss may be it is well repaid by the increased comfort and the pleasure the sitter experiences at the comparatively new sensation. If a sitter move I say nothing and expose afresh; for, of course, the whole effect would be lost if he were made aware that he had spoiled a plate, the main object being to put him and keep him at his ease. I must say there are cases where the method is not a success, and I will conclude with an example.

A lady came to my studio one day and, in a stronger manner than usual, made the ordinary complaint, exclaiming, "if I could only be taken without knowing it!" I took her portrait—a very nice one it was—without her knowing it; but what can my readers guess was the verdict? She brought the proof back and wanted to be retaken, for, said she to my secretary, "Mr. Webster did not tell me when he was taking me or I should never have put on that expression." What a piece of rank ingratitude!

G. WATMOUGH WEBSTER, F.C.S.

MODERN "DARK ROOM" IMPROVEMENTS.

No. III.

Now that the wet collodion process is so little used, few establishments keep the old dipping bath in employment, even when, for special purposes, the silver solution is resorted to occasionally. Flat dishes are much more convenient for such limited use, and when enlarging forms a considerable feature in the business they become a necessity; so it is rather strange that the dealers have not paid more attention to this photographic requisite. Of course I am not now speaking of the small developing dishes, which leave little to desire, but of large sizes—say, those accommodating plates from twelve inches to three or four feet. Porcelain ware is so uncomfortable in use and so breakable that it may be left out of consideration. Dishes with glass bottoms seem to have been the favourite, but they have the disadvantage of being very slippery, and you can seldom divest yourself of the feeling that a plate might slip and go through. A large swing-bath of the Burton pattern I had cased with boarding below the glass bottom and the intervening space run full of plaster of Paris. This was some security against breakage, but it did not get rid of the one other disadvantage of this form of holder—that is, the wooden sides—which, however well coated with shellac solution or black varnish, have inevitably a bad effect on the bath if the solution be left long in contact with them. This may not be of much consequence where the use of it is infrequent and the solution is decanted as soon as done with, but it is better to use a dish that is beyond all suspicion, both as to chemical action and as to security from breakage or leakage. Such a dish is a simple wooden tray lined with *pure* rubber. It is far more pleasant to use than glass or any hard substance, the soft cushion-like material breaking any fall or jarring of the plate against it. Joints are easily made, and above all, with a fairly close-fitting lid, the solution may be left in it with as much confidence as would be felt if it were in a glass bottle. After the lapse of any number of months it will be in just as pure a condition, as regards any reaction from the rubber, as on the first day it was put in. Years ago these rubber-lined, flat dishes were to be purchased from some of the dealers, but of late inquiry for them has proved in vain. I have, therefore, taken the direct course of making them for myself, and the matter is surprisingly easy. All the difficulty lies in screwing the courage up to what *looks* a rather formidable undertaking. The tray of wood is first formed, but not put together; it is made ready in five separate pieces, comprising the four sides and bottom. No dovetailing being required, the most amateur carpentry suffices. A tin of rubber solution furnishes the compound to rub over the inside of all the pieces rather freely, but taking care that it is smoothly distributed on the planed wood. Leave these to dry whilst the rubber is cut to proper sizes to cover each piece of board on one side; of course, *pure black* rubber is the kind. Unfortunately it is not very easy to get, but Charles Macintosh and Co., of Manchester, make it in pieces about eleven inches wide and thirty-six long, with a thickness of about a-sixteenth of an inch and upwards. This rubber may be treated very slightly with the solution on one side, for if too freely done it would soften and become unmanageable. The two surfaces thus treated with solution—the wood freely, the rubber slightly—and both having dried, are laid face to face and the rubber rubbed down. Thorough adhesion is easily ensured, and where joins are needed to make up the requisite width the rubber edges only require just pressing together to make all quite water-tight. All that is necessary after the wood pieces are thus coated is to put them together with ordinary screws and screw up tightly. The faces of the rubber which come into contact may as well be smeared a little with solution before screwing up. The result is a dish surpassing any other for silver or other chemical solutions. In the most delicate operations with collodion and bath, as, for instance, in opal enlarging, it is simply impossible to retain a bath in working condition if it be held in a dish having what is usually accounted sufficiently-protected wood in contact with the liquid, even though the latter be decanted after use; whereas, the solution left standing in an innocuous dish of this kind is workable with the best results month after month. The cover or lid should have a hole in which the funnel can be set whilst filtering the solution into its place, and this hole closeable with a moving shutter.

A silver hook is a handy thing for raising plates from the sensitising bath and other solutions. Most studios will have old carriers with silver wire corners laid away. One of these corners as strong as can be got, after straightening out, should next have about a-quarter of an inch turned at right angles, and the end of the turn sharpened off, chisel shape, to catch easily under the glass. A little bit of the other end is turned on the opposite side so that it can "let in" to the narrowed end of a wooden arm, about twelve or fifteen inches long, to which the little wire hook is firmly bound, and the whole then coated with shellac solution. For raising plates from the developer in dry-plate work this is, perhaps, better than any other contrivance, and something should be *used* if the appearance of the finger nails be cared for at all.

A rubbing pad of narrow calico rolled up tight and tied fast should be handy, with a box of common salt, for cleaning plates, backs of negatives, and washing off waste plates.

I have already referred to enlarging in the dark room by the aid of daylight through a second window or a supplementary portion of the one in use, but there remains the necessity not infrequently for some means of making a hurried enlargement in an emergency by means of artificial light. This indicates the possession of some form of optical lantern, and it is entirely a question for the individual photographer whether he will adopt one of the highly-finished articles in the market, or whether he will fit it up for himself. Supposing him to possess the usual amount of amateur mechanical ability that so largely characterises our profession, he need have no difficulty in making a useful enlarging lantern. Like the man who had found honesty the best policy, I have tried both the home-made and the bought; and whilst, of course, a neat thing is almost a *sine quâ non* if the lantern be used for entertainments, for home use a less elaborate get-up is quite as efficient. Without exactly coming to the "biscuit-tin" standard advocated by some, a capital instrument may be constructed with a little care. Wood well seasoned is as a rule better than metal, except for the neighbourhood of the chimney. One special point to be observed is plenty of room inside. The condenser is purchasable at any wholesale optician's, a three and a-half inch double combination costing about thirteen shillings. The lens may be the ordinary *carte* lens, or the secondary one retired from active service that most establishments possess.

Sometimes one sees statements to the effect that any French quarter-lens, even of doubtful quality, will do for this purpose. This must be taken *cum grano*, and a large grain too, for the better the lens the better the picture. It is true enough that a bad lens is of less consequence for lantern entertainments than in the production of enlargements, just as ephemeral images are of less consequence altogether than transfixed pictures which carry with them the producer's reputation; but for any purpose as regards the lens for the lantern I have always found "the best as good as any." A good definition cannot be given by the "lens" having no real focus, whilst the increase of light with an objective of wide-angular aperture is such an advantage that the mere matter of size if for exhibition only is comparatively of much less importance.

A further use for the optical lantern is in showing a customer the effect of a portrait enlarged on the screen. This idea in doing business was introduced, I believe, and largely used by the late Oliver Sarony, who was able to use daylight for the purpose. This employment of the lantern may be mentioned here, although the subject hardly comes under the head of the contents of the dark room proper. It is rather suited to some spare passage or space that is either dark or can be darkened at will, and is at the same time easily accessible by the customer to be enlightened in the possibilities of enlarging, and, of course, of ordering. The most suitable kind of light is a matter of individual convenience. Unquestionably the ordinary oil lantern will serve a very useful turn. One would suppose from the double and triple wicks and all sorts of lights advertised for the lantern that it is a difficult thing to secure a good light. Personally I have found nothing better than a *large* flat wick, the burner being purchased and mounted on a flat-bodied receptacle fitted up by the local tinman. A lamp of this kind in a home-made lantern has served me better than more pretentious instruments at much greater cost. The image should be thrown on a sheet of ground glass, mounted at a suitable height on a sort of rigid easel; this should run backwards and forwards with ease. A simple little tram can be laid down of thin iron rod, drilled at intervals and screwed down to the floor. Little pulleys which are sold by ironmongers fixed on the screen easel and standing on the rods will enable it to travel readily with the slightest touch.

Two or three words as to the general conditions of the dark room may be permitted. Order is absolutely necessary if systematic success is to be achieved. Things to be found quickly must be in their places; the penalty has a right to be paid when it is too much trouble to put things back in their own place. The same consideration applies to the labelling of bottles. How many solutions have to be thrown away through neglect of this precaution? A packet of blank labels should be readily available when wanted. Labels, however, will not be long legible on acid bottles, or near fuming acids; these should be treated with a little sizing and then varnished, or the glass itself may be painted on with two or three bold letters of black varnish. Speaking of black varnish: the common Brunswick black of the oil shops may be made a most useful servant to the photographer for coating woodwork, protecting metal, and the hundred and one little purposes continually cropping up. As bought it is a rather nasty, gummy, viscid article, and not a very good drier, which is an important point; but it is wonderfully altered and improved by the addition of a couple of ounces of methylated spirit and the same of turpentine to each pint. It will then dry in a few minutes.

Cleanliness it should not be necessary at this time of day to say much about, but like most things this good quality works in different ways. The operator will not be much the better for the fussy sort of cleanliness which involves continually moving things about to "dust" under them. Disturbing the "photographer's *un*settled enemy," when he might fairly have let it alone, converts its sort of armed truce into active hostilities on his plates, or in some position where he is pretty certain to get the worst of it. The kind of cleanliness required is to be very cautious about "kicking up a dust," and to have one eye at least wide awake to the chemistry of the subject. For instance: a glass funnel which has just been used for albumen solution may look nice and clean, and is so to use for that same purpose again; but for filtering a sunned bath it is nothing less than abominably dirty with organic matter, and so on through the range of chemicals. One man, by keeping things for special uses, will have everything right with a minimum of trouble, where another, taking more pains apparently but forgetting his chemistry, will find himself tripped up. Shelves and counters should be spread with white blotting paper; it shows things up and makes them easy to grasp. For the sake of certainty it is also as well to enlist the services of the sense of feeling as well as that of sight by having bottles of different shapes. Take the case of two developer bottles—the pyro. and ammonia; they may be well enough labelled, but if the bottles are just alike, the operator is sure, in spite of labels, to get hold of one when he wants the other now and then. Let the bottles be different in size or shape, then the labels become almost superfluous.

Lastly, and perhaps one might say firstly, there remains one important requisite for good dark-room work—*thought*. The best of helps is the growing intelligence of the worker. The "animating soul" will convert the most unlikely means into steps towards success. The same weapons in diverse hands ensure victory or court defeat. BENJAMIN WYLES.

ISOCHROMATIC PLATES.

IN Mr. W. Goodman's interesting communication to the Glasgow and West of England Photographic Association on the above subject, he raised several questions which, if explained, would probably lead to an earlier solution of the problem "how to obtain relative tone values on a sensitive film to the luminosity of the various colours," or, in other words, to be able to make plates most sensitive to the yellow rays of the spectrum instead of to the blue, as at present.

He says—"The method used to obtain such plates is the addition of some substance to the film capable of absorbing and converting into chemical energy those rays which are inactive on an ordinary plate." If the addition, however, slows the plates, what we require to know is—Does such addition increase the sensitiveness of the film to the red and yellow rays, compared with the power of such rays on an undyed film, or does it only cause a decrease of sensitiveness of the film to the violet, blue, and green rays, leaving the power of the yellow rays the same?

Perhaps some of your readers can tell me if Dr. Vogel claims that the new substance "azaline," which he has discovered, renders a film dyed with that substance as sensitive to the yellow rays as an undyed film is to the blue rays. Both films are made of the same emulsion; the only difference is that one is dyed and the other not. If, on placing a film dyed with azaline behind a glass of the colour to which the film is most sensitive, it do not give a higher sensitometer number than an undyed film behind a blue glass, I do not think we can say that with the addition of that substance the sensitiveness of the plate is actually increased.

I hope I have clearly shown that this is the keynote of the whole matter; because, if the addition of azaline increase the sensitiveness of the plate to the yellow rays, we have a substance which, like ammonia or the boiling process, decomposes the gelatine and makes the plate more sensitive to light. I showed in an article on this subject about a month ago how, when silver bromide is held in suspension in gelatine, the latter protects the silver haloid from the alkaline developer, except when the action of light has destroyed that protecting power. After decomposing the gelatine by either the ammonia or boiling process, on exposure to light the vibration of the particles is more quickly able to destroy that protecting power, and if the boiling be continued so as to decompose the gelatine beyond a certain point it loses the power to such an extent that we get fog all over the plate directly the developer is poured on. We get the same effect by over-exposure, because the action of the light on the particles has so burst the protecting cells of the gelatine that the developer is able to reduce them to a metallic state at once all over the plate, instead of only those particles which would have been acted upon by the more rapid vibrations of light if a proper exposure had been given.

As I said before, if the addition of azaline increase the sensitiveness of the films we have a new power for obtaining more rapid plates; but if its use be only to decrease the power of the blue and violet rays its action would simply be the same as a coloured screen. What we want will be a substance that will cut off the actinic power of the blue to one-twentieth the force of the yellow rays, and our experiments will require to be made in that direction with the aid of the spectroscope.

To my mind there are three points which throw a doubt as to whether Captain Abney's theory is a correct one. He holds that the dye in absorbing oxygen acts as a developer similarly to pyrogallic acid in the alkaline developer, this slight reduction serving as a nucleus for a further deposit of silver during development of the plate:—

1. If the bleaching of the colour be sufficient (in the few seconds' exposure that is given) to oxidise the dye so as to form a nucleus for further development, the greater the amount of dye used the larger would be the nucleus formed, and, in consequence, the more sensitive the plate would be; but, so far, our experiments do not show that it is so.

2. If the dye act as a developer similar to pyrogallic acid in the alkaline developer, it would commence to reduce the silver haloid to a metallic state in the dark, because we know that the alkaline developer will reduce silver bromide to a metallic state without any nucleus or sub-bromide being formed by light; and, as the dye is in the gelatine, it would be in contact with the silver particles.

3. If we photograph through yellow glass we obtain the same restraining power over the blue and violet rays as we do with the dyed films, and in that case there is no absorption of oxygen to act as a developer or a nucleus for further development or reduction.

Dr. Vogel's theory is that the energy absorbed in bleaching the dye is transmitted to the silver haloid, upsetting its equilibrium, and rendering it capable of development. If it be so, we have rays of a slow rate of vibration, *first* bleaching—that is, oxidising—the dye, and *then* acting on the silver haloid; whereas the energy of the rapid vibrations of the blue and violet rays must be annihilated (because they neither oxidise the dye nor act on the silver haloid)—that is, if the absorption theory of light be correct. Have we any proof that such a short exposure produces a bleaching action at all?

With all due respect to such scientific observers as Captain Abney and Professor Vogel it seems to me that they have accidentally overlooked a well-known action of coloured light when thrown on surfaces of another colour, which, I think, perfectly explains the matter. It also explains the experiment quoted by Mr. Goodwin in support of Professor Vogel's theory, namely, that a dyed collodion film exposed to the spectrum will, if coated with collodio-bromide emulsion and developed without further exposure, give an image of those parts of the spectrum to which the dye is sensitive.

If we throw the colours of the spectrum on to a screen, and then take a red flower or ribbon and hold it in the red rays, the colour will shine out bright; but if we put it in the green rays the colour will be invisible. The thermopile shows that the power of the green rays has not been absorbed or annihilated; their rate of vibration has simply been made slower than that of the red rays, and they have been converted into the slow vibration of the heat rays.

Now, if we put a dyed collodion film coated with collodio-bromide emulsion in the place of the screen and expose to the spectrum, the red rays would pass nearly unchanged in rate of vibration through the dyed collodion film, and would produce the invisible image on the collodio-bromide film ready for development. But where the green rays fall they would be lengthened by the dyed film to the slow vibrations of the invisible heat rays, and would have no action on the silver haloid. Of course the same law will hold good in the case of the yellow rays being more rapid on a film dyed yellow than the blue rays thrown on the same film.

Herbert S. Starnes.

THE OPTICAL LANTERN AND ITS MANIPULATION.

No. II.

The next thing to a good luminant is some method of concentrating or condensing the light on the transparency, and about this there seems to be some uncertainty with the public as to size and requirements. If the luminant is transparent, such as the flame of an oil lamp, a reflector behind collects the rays and directs them on the first lens, A, of the *optical system*. This lens should be of such a size and focus as to take in as many as possible of the rays coming from the light, and when combined with another, B (for double condensers give the best result), should concentrate the rays so that the transparency be fully illuminated. The size of the condenser will be governed by the size of the transparency to be illuminated, and it is now generally accepted that the best for commercial photographic-lantern transparencies is four inches or four and a-quarter diameter; for, if larger, the light is wasted, and if smaller—at least for the lens next the picture—the area of illumination would not be sufficiently large for the cushion or square-shaped picture. For enlargement from negatives then four and a-quarter or six inches diameter should be employed.

As regards the focal length of these condensing lenses, that must be regulated by the objective or front lens employed, and varies from three to five inches combined focus. The one I like best for lime-light lanterns and general use is three and a-half inches focus.

It will be seen in *fig.* 1 that the condensing lenses (A B) are more

FIG. 1.

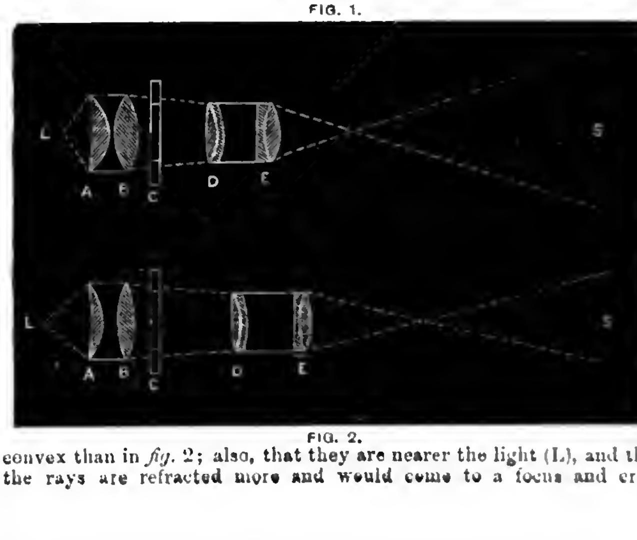

FIG. 2.

convex than in *fig.* 2; also, that they are nearer the light (L), and that the rays are refracted more and would come to a focus and cross quicker than in *fig.* 2. It is necessary that the objective should be fully illuminated, and if the light is kept in its best position in relation to the condenser, and a long-focus front lens is required to be used, a satisfactory result could not be obtained with a short focus condenser; for instead of a clear disc being projected on the screen (S), one with dark edges or centre will be the result. For instance: the front lenses of *fig.* 2 system, if used with a condenser, as shown at *fig.* 1, would not be fully illuminated.

I have known several instances of apparatus being unsuitably fitted with condensers, and the owners not knowing the cause of failure have attributed it to the objectives. A condenser of the correct focus for the average focus objectives (six inches) can generally be made to answer for one of four and a-half or eight inches equivalent focus by a slight adjustment of the light nearer too or further from the condenser respectively; but if the condensers are the shortest possible focus to work with a short-focus (four and a-half inches) objective, they cannot be used satisfactorily with one of eight inches focus. Theoretically, then, the optical lantern should be fitted with condensers to suit each particular focal length front lens or objective, and in the higher class of apparatus, such as Mr. Malden's triple lantern, three sets of condensers are often supplied for various-sized slides and focal length front lenses.

The position of the slide or transparency must be governed by its size in comparison with the condensing lens; but, if other than a circle, the greatest diagonal measurement must be taken. If this be one inch less than the diameter of the lens, half-an-inch from the condenser will be the best position, and, if only half-an-inch less, then as close to the lens as practicable for drawing in and out without scratching the face of the condenser. If more than one inch, then further away, so as to get in the smaller part of the cone of rays. There is, of course, a limit to this, as, otherwise, such a very great adjustment would have to be provided in the front lens to remove the slide-holder and focussing lens bodily away from the condenser; and it is better now and then, when using a small picture among a number of large ones, to sacrifice a little light on it rather than disturb the general adjustment.

It will be fair to sum up, for shewing commercial lantern slides, that an adjustment of half-an-inch is all that is required. It can be done by moving the stage away from the front; or, what is more rigid, let the stage remain fixed and move the condenser in a bayonet catch groove or by a coarse screw. Mr. J. H. Steward is now having made a double stage, so that a tinter or alum trough to stop the heat, when showing valuable slides or delicate objects for a long time, can be put in one stage and the slide in the other. The first stage will be best for square pictures, and the second, or that farthest from the condenser, for three-inch circles. The dividing plate being removable, a large stage is available for chemical and optical experiments.

Another point to be regarded is the cutting off of marginal rays after passing through the condenser; and, as all pictures are not circular, and the old shape of diaphragm in the stage plate is not suitable for all pictures alike, I would suggest that runners or grooves should be made just in front of the condensers, so as to insert the shape most suitable to obtain a clear disc with the particular form of picture employed. This is done in some of the photographic carriers; but, as they would not be available when using effect slides, I have had the other arrangement fitted to lanterns, made under my superintendence, for different customers of Mr. Steward.

As shown in *figs.* 1 and 2, the shorter the focus of the front lens the larger the disc; hence, if the apparatus be required to be near the screen, a short-focus lens must be employed. The limit, however, under any circumstances is a distance equal to the diameter of the disc. This, on account of the great difference between the length of rays at the margin and the centre, is difficult to obtain without distortion. Therefore, the most suitable is an objective which will give a disc at double the distance of its diameter—that is to say, a disc of nine feet at eighteen feet distance from the screen—and one of about six inches equivalent focus will do this. In some rooms it is necessary to have a considerable distance between the apparatus and the screen, and then the front lens must be of very long focus (about twelve inches equivalent) to produce a nine-feet disc at thirty-six feet. Long-focus lenses cannot be worked satisfactorily with oil light, and their use is recommended for the lime light, only under exceptional circumstances, the maximum light and definition combined being obtained by the medium-focus front lenses.

G. R. BAKER.

THE PLATINOTYPE PROCESS.

[A communication to the Newcastle-on-Tyne and Northern Counties' Photographic Association.]

I HAVE no doubt the platinotype process is already familiar to many of the members of this Association, and in bringing it before you this evening my apology would be the earnest request of our indefatigable Secretary for a paper to fill in a gap in his programme for the session.

Although this process has not yet become so popular as it ought to be, yet I think if its merits were better known it would be more appreciated by the public than it now is. Allow me, then, briefly to point out what I would claim as the peculiar merits of the platinotype process before I proceed to explain and demonstrate it to you.

First, I would claim for it the permanency of its prints—a point on which so much discussion has arisen of late with regard to silver prints, which have been a source of anxiety and vexation to photographers so far, and I am afraid will continue to be until we have more light thrown on what is the precise nature of a silver print. In the platinotype print, as its title denotes, the image is formed by the deposition of metallic platinum, so, if the cause of fading in silver prints is due to complex silver salts, this difficulty is entirely removed. Again: no sulphur compounds are employed in the development and fixing, and if hypo. be the scapegoat in silver prints we have nothing to fear from that source.

Next, I would claim for it the greater rapidity in printing, namely, from one-half to one-third the time required to print from the same negative on silver paper, especially in dull weather, when the platino paper has the decided advantage. This has been accounted for by supposing the blue rays of the spectrum are equally as active on the platino paper as the violet, whereas the violet rays are necessary to impress the image on silver paper.

In the next place, I would claim the artistic softness and delicacy of the prints, which, when properly printed from a suitable negative, more resemble a fine engraving or well-executed pencil drawing.

And last, but not least, I must not omit to mention the simplicity of the process, which renders it so admirably adopted to the requirements of amateurs who have not the time or convenience for the more troublesome washing processes necessary in silver printing, as the prints by this process can easily be finished off in half-an-hour, and when done they offer an excellent medium for the artist to colour upon without any fear of defects showing themselves afterwards. One of the chief objections raised against platinotypes is the coldness of the tone, but this has to a great extent been overcome by the introduction of specially-prepared paper and toning solutions, which give a sepia tint.

Another field has recently been opened for the phototype process, namely, enlargements for the artist which can be readily executed by means of the solar camera or electric light and form an excellent basis to receive the colours. Neither is this process confined to paper, as equally good results can be obtained on linen or silk fabrics, and even on wood.

Having now put forth the merits of the process, allow me to explain the *modus operandi*. The paper, of which I have here a sample, is coated with a solution of ferric oxalate and potassic-chloro-platnite, and if I expose it to the action of light the ferric oxalate will become converted into ferrous oxalate, and if exposed behind a negative will give a faint, brown image, such as you see on this piece. All that now remains to be done is to cause this image to throw down the metallic platinum it contains, and this is readily done by floating it on a hot solution of neutral oxalate of potash, 130 grains to the ounce, and which I have raised to a temperature of 170° Fahr. in this enamelled iron dish, when you will see the iron salts are dissolved out and the metallic platinum thrown down *in situ*, forming a black image; or, if I use the special paper and add some of this toning solution to the bath, it will give a sepia-tinted picture. It only remains now to dissolve out any traces of iron salts which may remain in the paper by passing it through a two-per-cent. solution of hydrochloric acid, changing the solution when any trace of redness appears in it, and then washing them in frequent changes of fresh water for about thirty minutes, when they may be hung up across a string to dry.

Simple as the process may appear, there are, nevertheless, some precautions which must be observed:—First, the paper must be kept absolutely dry by being placed in a canister with calcium chloride, seeing that the printing-frames and pads are dry, and, especially in damp weather like the present, placing a piece of rubber cloth or oiled silk behind the paper in the printing-frame. By taking these precautions there is little fear of the paper keeping; indeed, some I am using tonight I have had in my possession nearly two years. Second, not to continue the printing longer than is necessary to have a faint but distinct image on the paper. Third, to regulate the temperature of the bath to the amount of exposure the prints have received, under-printed ones requiring a higher temperature and over-printed ones a lower temperature, always bearing in mind that the prints will appear darker when they are dry. Fourth, to see that the last acid bath is not in the least discoloured if you want to have pure whites. And, lastly, to obtain a license from the Platinotype Company to work this process, which is a patent one, but which is not a serious obstacle, as for the payment of five shillings you can obtain a license for the rest of your natural life on condition that you buy all your materials from them, which they supply at market prices.

I trust I have now made the platinotype process not only clear but interesting to you, and that before long we may see more workers of it, more examples, not only in our albums but also in our exhibitions, and possibly a special medal given for platino prints.

HENRY G. TEMPLETON.

ON THINGS IN GENERAL.

A KIND friend, sagacious, far-seeing, and reading men like a book, a lover of our art-science, who was ever anxious to further its interests and uphold its dignity, the father of photographic journalism, the proprietor of this paper, has gone from among us. The well-remembered face will be seen no more. On Saturday I formed a humble unit in a large assemblage, drawn not only from Liverpool but from London and places more or less distant, to pay the last mark of respect to our dead friend at the Liverpool Necropolis. He was always ready to encourage rising talent, and the pages of THE BRITISH JOURNAL OF PHOTOGRAPHY have been the stepping stones made use of by more than one of those who have made for themselves a niche in the temple of fame. He had gathered round him a band of earnest, talented workers to whom, under his pilotage, aided by the skilful pen and brain of the editor in chief, the great success of this Journal is due, and will, doubtless, carry it forward to further successes. I am sure I echo the sentiments of all my fellow contributors in avowing my intention to carry out Mr. Bolton's plans.

I was glad to see last week that the Editors had set their foot firmly down on that everlasting bit of pseudo-science as they justly term it—the diminution of the light according to the square of the distance from the window. Of all the preposterous rubbish that does at times find its way into print nothing is so utterly misleading and incorrect as this piece of ignorance upon stilts.

Good photographers who read their *Times* would be rather startled the other day, not only to find it chronicling a real photographic novelty but at the subject matter itself of an article on a new photographic process describing Messrs. Marion and Co's. new photographic paper for printing by development in lieu of the time-honoured albumenised paper. They deserve the thanks of the community for working to a practical end a process of undoubted value which, if I mistake not, will in the future take a far more important place than it is likely to do for a while. Messrs. Morgan and Kidd were first in the field with a gelatine paper for the development of enlargements, and they have, I notice, quickly adapted their formula for a like purpose to Messrs. Marion's. These papers will be a real boon in many cases.

I notice that in a lecture on photography for those engaged in industrial pursuits, at Burlington House, by Professor J. M. Thomson, he said of the swing-back that its only use in portraiture was when it was necessary to reduce the size of a portion of the image—as, for instance, the feet of a sitting figure. If the sitter were a professional model gaining his half-a-crown an hour he would have no objections to such a course; but an ordinary sitter so posed as to require a swing-back to keep the feet from becoming enlarged, would require such a lengthened exposure from the small diaphragm necessary to be used under such conditions that he would decidedly object. My idea of the use of swing-backs is that it is for objects in focus, not out. Perhaps, however, the professor was slyly poking fun at one of the English photographers who, we read, accompanied the British Association excursion to America, the story about whom goes that he was riding upon an elephant with his leg hanging out of the howdah, when a native called out, "Take in that foot, we can't see the elephant!" I do not know, either, why Professor Thomson recommended beginners to use the single lens, for many single lenses—cheap and dear—that I have seen sent out, have needed the diaphragm to be adjusted before anything could be done with the lens worth looking at, while the compound lenses now made need no such skill to be bestowed upon them.

Mr. W. K. Burton's remarks upon the improper use of words borrowed from a scientific terminology came not a moment too soon. It is positively exasperating to see the calm way in which some photographers have used expressions such as these he quotes. Photography is long past its babyhood, and jargon such as this—for it is jargon, and nothing else—should not be allowed to pass unnoticed.

The idea of the Edinburgh Society to improve the art-training of its members by criticising works brought before them, including the productions of artists of well-known merit, is excellent and deserves to be followed; but I humbly venture to suggest that it should be done *in camera*. I have every respect for the array of talented names given in the account of the proceedings on this day of the critics, but I think they cannot but bear an unfriendly aspect when printed in unfeeling printers' ink, without power of conveying the excitement of the discussion and the tones and expressions of the speakers.

The discussion in *re Gas Bags* v. *Bottles* is one of the most interesting that has appeared in the Journal for some time: conducted, too, as it has been, in perfect good humour, it has been quite a pleasure to read what both sides had to say. I think there will be very few who have closely perused what has been written without being instructed and seeing the subject in many new lights. I think the bags have the "ayes" at present.

But if the question of bags *versus* bottles be not new what will be thought of the last meeting of the London and Provincial Photographic Association, were the question was "freezing or heating" to prevent frilling. It is quite true that though any one can make a plate, it needs a man of skill to develope it; the fact is the art of development is like that of making a salad—it needs genius.

What mournful reading was the report of the last meeting of the South London Photographic Society—the society that for so many years was a very model of a society, well attended and with plenty of first-class papers read, lively discussions, in fact, a real honest, hard-working, useful society, the most popular in the kingdom. And now to read that a proposition has actually been put to the vote as to whether the Society should cease to exist or not. There was a large majority against the proposition when put to the meeting, and it is to be hoped that this unpleasant affair may be only an episode, and that the Society may prosper and do as much good in the future as it has done in the past.

IMPROVEMENTS IN GLASS AND OTHER ROOFING.
CHARLES FOWLER, Architect, Leeds.

THE object of my invention is to construct a simple, cheap, and perfectly waterproof roof. It is also arranged to conduct away the water caused by condensation on the under or inner side of the roof.

The longitudinal ribs or rails may be of wood or metal. These are stepped or rebated at the top side sufficiently deep to receive the sheets of glass, metal, or slates. A tongue is formed along the centre of the rib separating such sheets of glass, metal, or slates from each other. The sheets of glass, metal, or slates are laid in the rebate between the ribs or rails; and I cover over the joints outside with strips of wood or metal—such strips being preferably about the width of the rib. These strips of wood or metal are secured to the ribs through the tongue by means of ordinary screws.

Between the sheets of glass, metal, or slates, the rib or rail, and also the strips of wood or metal, felt, asbestos, or other suitable packing is applied. Such combined arrangements render the joints perfectly waterproof, at the same time firmly fixing the sheets of glass, metal, or slates in position.

In order to catch the water that condenses on the under or inner side of the roof I provide longitudinal grooves in the sides of the ribs to form gutters for carrying off the water to some convenient outlet.

[The specification is accompanied by drawings.]

AN INSTRUMENT TO BE CALLED THE "MICROPHOTOSCOPE."
ROBERT GALLAND-MASON, of Hambleton House, Promenade, Douglas, Isle of Man.

THE microphotoscope consists of a pair of spectacles, eye-glasses, or an eye-glass with one or a number of minute photographs arranged in or along the rim of the spectacles, eye-glasses, or eye-glass.

The minute photographs are placed behind suitable minute magnifying glasses, and are so arranged in or along the rims of the spectacles or eye-glasses that the eyes of the wearer may see either one or all of the photographs without moving the spectacles.

The rim, in or along which the minute photographs are placed, may be either the rim of the spectacles themselves or a detachable rim, which may be applied to any spectacles, eye-glasses, or eye-glass.

The minute photographs may be photographs of written or printed matter, maps, charts, views, landscapes, or any object or group of objects from which a photograph may be taken.

Some of the uses to which the "microphotoscope" could be applied are the following:—

For a Student.—The series of microphotographs in the rims of the spectacles might consist of copies of an epitomised grammar, history, geography, or any subject the student wished to study. Thus, the subject he was studying would be constantly before his eyes for reference in his spare moments without the trouble of carrying books about with him.

The rims containing the microphotographs being detachable he could at any time change the subjects.

A lecturer might have the heads of his lectures photographed and placed in the rims of his spectacles; a lawyer—his briefs; a clergyman—his sermons; a bicyclist, tricyclist, or other tourist—maps, views, and plans of the country through which he travelled; a shopkeeper—a calendar ready-reckoner and so forth; a timber merchant or builder—cubes, measurements, and rules; travellers on the Continent—list of foreign terms, names of articles, foreign money, tables, and so on; a correspondent—an abridged dictionary of technical or difficult words; a member of Parliament—facts and figures relating to the subject of his speech; a doctor—formulæ; a public entertainer—recitations, songs, *bon-mots*, &c.; a musician—whole pieces of music; a detective—criminals wanted.

The inventor says:—"It will also be evident that the microphotoscope may be applied to a variety of other uses too numerous to mention."

It will be understood that the spectacle or eye-glass frames may have in them ordinary reading glasses when worn by those who need them, and when worn by those who do not, they may have either plain glasses or no glasses at all.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on the 19th inst., the chair was taken by Mr. W. H. Prestwich.

Mr. W. E. Debenham referred to the loss which the Society, photography generally, and himself as a friend particularly, had sustained in the death of Mr. Henry Greenwood, bearing testimony to the worth of the deceased gentleman.

Mr. W. M. Ashman moved that a vote of condolence with the family be passed, and that the Secretary be instructed to write a letter in accordance therewith.

Mr. W. K. Burton seconded this proposal, which was carried unanimously.

A gentleman from the firm of Messrs. Marion and Co. then proceeded to demonstrate the printing and development of the "Alpha" paper recently introduced by that house. Papers were exposed under negatives for periods of from ten seconds to half-a-minute to the light from an albo-carbon gas burner. It was explained that this light being about three times more actinic than ordinary gas-light the exposure to the latter would have to be, if at the same distance, about three times as long. After being exposed the prints were immersed in a weak ferrous oxalate developer compounded as follows:—

No. 1.

Oxalate of potash	1 pound.
Bromide of ammonium	320 grains.
Warm water	64 ounces.

No. 2.

Sulphate of iron	4 ounces 250 grains,
Water	80 ounces.

Equal parts of these solutions were used. It was stated that after a print had been put into the solution the latter would lose its power if kept for more than a-quarter of an hour. Many prints might be developed in the same solution so long as they could safely be turned and watched, provided that this was done within the time mentioned. It was best to put the prints in one at a time at short intervals. They would then finish developing one at a time; for if many were put in at once it would be difficult to hit the right moment. After development the prints were immersed in a dish of clean water and then rapidly changed into a second dish. This quick removal of the developing solution from the print was necessary in order to prevent the action from going on and the print becoming too dark.

Mr. A. L. Henderson suggested the addition of bromide to the first washing water in order to stop development.

Mr. Debenham said that common salt might answer the same purpose, and would be much cheaper.

After being washed the prints were immersed for ten minutes or a-quarter of an hour in a dish of alum water; this served to remove the last trace of iron solution. If any of the latter were left in the print the gold which was used in the next part of the process would be reduced all over the print and spoil it. The prints after toning were fixed in hypo., and washed as usual. The exposure might be greatly varied without spoiling the print. The characteristic of a print under-exposed and fully developed was that the tones were very black, whilst by very long exposure and short development very warm tones were obtained.

Specimens of the prints which had been previously produced were handed round. Most of them had a glossy or enamelled surface, which it was explained was obtained by laying wet prints upon glass and allowing them to dry there. In order to prevent the prints from sticking to the glass, the latter was rubbed over with powdered talc (French chalk) previous to placing the prints upon it.

The Chairman inquired whether any of the members had had any experience with the paper which had been the subject of demonstration.

In reply to this question, Mr. W. K. Burton said it was, perhaps, not quite fair to speak after only one evening's work, but as the result of that meeting was favourable he would do so. His view was that it was better to expose fully and develope but slightly. He thought that in order to stop development it would be well to use bromide or chloride in the first washing water. As to latitude of exposure, he found that he could, after printing for twenty seconds or a-quarter of an hour, get prints that appeared equally exposed. He would have brought his results with him, but having laid them upon glass which had not previously been rubbed with talc he could not get the prints to strip. From weak negatives better prints could certainly be obtained upon this paper than upon albumen.

Mr. J. Barker inquired whether the washing necessary to remove spots would not show very much upon the glazed surface.

Mr. Henderson thought that the paper, being very absorbent, should show touching but little.

The Chairman said that the plan he adopted for prints which had to be burnished was to mix albumen with the touching colour, and, when dry, coagulate this with alcohol.

Mr. Henderson believed that alcohol would not coagulate dried albumen.

Mr. Archer Clarke thought that the method which had been demonstrated that evening was undoubtedly the printing process of the future. As to the use of powdered talc, he could not get a print from the glass unless it was used. He had brought with him a press containing a negative and a piece of the alpha paper. This negative he had exposed to the various lights he met with—for instance, the lamp in the railway carriage—on his way to the meeting. The negative was a very intense one, and at this time of the year required several days' exposure to daylight to get an albumen print. He would ask the demonstrator to develope it. [This was done, and the print proved to have been rightly timed as to exposure.]

The Chairman noticed that the surface had blistered from the paper in one of the prints, and inquired the reason.

It was replied that a warm hand had been in contact with the print during development.

Mr. Henderson showed a gelatino-bromide made some years since by Mr. Burgess. He had toned it successfully after fixing by immersion in an acid solution of gold mixed with alum. At first the print was all right, but now had become pink in the lights. He believed that if it had been immersed in hypo. after the toning this would not have occurred.

Mr. Debenham said that no doubt this would have prevented the subsequent discolouration. Silver and gold solutions acted upon gelatine, and formed compounds with it which could not be washed away by mere water, but required to be dissolved by a fixing agent such as hypo.

Mr. Leon Warnerke said that as the Chairman had asked for experience he would mention that he had experimented with paper of his own preparation, presumably similar to that now under discussion. He found that if the negative were clear the printing was very quick, but if slightly stained with pyro. so as to be yellow, the exposure must be ten or twenty times as long.

Mr. Archer Clarke said that a toning action went on in the hypo. with those prints. If left in the solution for an hour they became perfectly blue.

A Member inquired how long the paper would keep.

It was answered that it was believed to keep indefinitely.

After a vote of thanks to Messrs. Marion for their demonstration, a discussion took place as to the desirability of having a union amongst the various photographic societies in London, so as to engage permanent premises which might be fitted with a dark room and other conveniences. Several members were strongly of opinion that the other societies should be communicated with in order to see whether anything could be done, and it was pointed out that by using such premises on different evenings each society could carry on its own work independently.

Mr. Warnerke said that Mr. Glaisher had gone further than that, and suggested such a union amongst all the scientific societies in London for the purpose of obtaining the best accommodation in the way of premises.

The question next entered upon referred to the disposal of the five-pound prize offered by Mr. H. Trinks, and after some discussion it was decided, upon the motion of Mr. Burton, "That the prize offered by Mr. Trinks be given not to a specific article, process, or such-like proposed as matter for competition, but be given for whatever article, improvement, or process brought before the Society by a member which shall appear to be of greatest benefit to photography in general; a limit of time to be fixed and the determination to be by a ballot of the whole Society, the condition to be that all details connected with the matter shall be open to the Society." It was further decided that a limit of six months should be fixed.

Mr. E. Sollas was elected a member of the Society.

BOLTON PHOTOGRAPHIC SOCIETY.

The December meeting of the above Society was held on the 4th instant, at The Baths, Bridgman-street,—Mr. Robert Harwood in the chair.

Mr. J. W. Austwick was elected a member of the Society.

The Rev. J. W. Cundey gave a lantern exhibition, the slides including an interesting set of Switzerland from the lanternist's own negatives. Dr. Johnson also exhibited a set illustrating a recent visit to Norway, many of which elicited applause. Slides were also shown by Messrs. Parkinson, Dalton, Knowles, and Leach, those of Mr. Knowles being especially worthy of remark.

At the conclusion Mr. Robert Knott moved a vote of thanks to Mr. Cundey and the exhibitors, which was seconded by Mr. John A. Walker, and suitably acknowledged by Mr. Cundey.

ST. HELENS ASSOCIATION FOR THE PURSUIT OF SCIENCE, LITERATURE, AND ART.

Photographic Section.

A meeting of this Section was held on December 17th, at the Association Rooms, 4, Salisbury-street,—Mr. Heather in the chair. After the ordinary business of the Section was disposed of,

The Chairman showed a number of positives of a brick-red colour by transmitted light, for which he was at a loss to account, as the emulsion was prepared in the usual way.

Mr. J. T. Houghton said that Mr. Taylor had a similar experience, which he attributed to grape sugar.

The Chairman stated that he did not use it in this emulsion, though possibly some may have got in.

Several of these unexposed plates were then distributed for experimental purposes.

Mr. D. Thomason exhibited about sixty views of Scotch and English scenery.

Mr. Brook then read the concluding part of his paper on *Photographic Experiences with the British Association in America.*

After passing a vote of thanks, to which Mr. Brook briefly replied, the meeting adjourned to an upper room, where Mr. Thomason's views were projected on the screen by the aid of Mr. Sherlock's lantern.

The meeting then closed.

Correspondence.

[*All communications for the* EDITORIAL *department of the Journal should be addressed to the "Editors, 2, York-street, Covent-garden, London, W.C."*]

PHOTOGRAPHIC SOCIETIES.

To the EDITORS.

GENTLEMEN,—A notable feature in connection with photography is the remarkable increase in the number of these associations. It is evident from the large amount of space which is allotted to these reports in the photographic papers that the interest taken in the work is great.

It appears to me, however, that the general plan upon which by far the greater number of these associations is conducted is not altogether the test which might be adopted, and I wish to suggest a way in which, as I believe, still greater advantage might be obtained by the great body of members of these societies.

In the first place, it will always be found that when one of these societies has a regular president and vice-president, the tone of the proceedings necessarily gets into a certain groove, with the natural consequence that by degrees a regular clique is formed to which all others must bow. Discussion in the full sense of the term becomes oppressed, if not stifled. This is not the case in those societies where the chairman is chosen, either in rotation or otherwise, from among the members, all being eligible.

In the second place, the usual meetings once a month are quite inadequate; once a week would be far better, and this for several reasons.

Most new members join the societies for the purpose of gaining information upon a thousand and one little details of practice, all important to their own personal success, but which they are very doubtful about being sufficiently interesting to occupy the time of the meeting. Of course, an absolute tyro might come with such a string of elementary questions as to completely stop all the real work of the Society, which, of course, is in explaining and elucidating technical difficulties of manipulation as well as the progress and details of new practice.

I will, therefore, assume as a first condition that new members should be content to listen only until they have once succeeded in producing a good negative and a good print of any kind from it. After that there would be no question, however trivial in its nature it might appear to him, which would not be discussed with the greatest interest by many present, and patiently listened to by all. Indeed, these apparently trivial questions are, even to old hands, infinitely more interesting than papers on scientific points, for they relate to failures of their own often overcome, yet still more frequently unexplained.

In London we can take our choice; we can go, if we like, and hear a paper on the effects of the spectrum on haloid salts of silver, and either feel unutterably bored by it, or try to take an interest in it and be snubbed for making a remark, as, indeed, has happened to myself once on a subject which I thought I had studied. The subject under discussion was *Green Fog*, when something like a definition of its cause was asked for. No member of the Society had a reply to offer. I was present as a visitor, having received a special invitation from the Secretary to attend, and I ventured most timidly to give my explanation—that it was a forced development of an unexposed film. The very polite snubbing I then received decided me never again to attend a meeting of any photographic society with a president.

We have also the Photographic Club, to which I can truly say I am proud to belong. The principles upon which this Club is conducted are exceedingly simple, and have been found after five years' trial to be thoroughly practical. We meet weekly, an hour being supposed to be devoted to the discussion of just those little trivial questions which I have described as so important and so interesting. Another hour is supposed to be devoted to some definite question proposed the week previously, and which is always announced in the photographic papers. But it most generally happens that the trivial questions prove so useful and so interesting that the second hour slips by, and everyone is glad that the definite one has to be postponed. In short, the trivial questions are the main object of our existence, and the serious ones play but a very secondary part. With one single exception, which I have no doubt the well-meaning though offending member now regrets as much as we all do, there has never been the slightest whisper of discontent from the moment the Club was established to the present time. This I attribute mainly to the fact that the chairman of the evening is elected generally and as far as possible in rotation; but I must not omit to state that we owe much also to our indefatigable Secretary, Mr. Edward Dunmore, to whose thoughtful foresight our excellent rules are mainly due.

Not the least advantageous part of our system is that our proceedings are not necessarily reported. Think for a moment what this means as regards freedom of discussion. Very few people have such decided opinions on many photographic questions that they would wish to rush into print with them, and those who do can easily find a way of publishing their views. We of the Photographic Club like to air our opinions and discuss them with the certainty that they will *not* find their way into the public press unless we desire it. Indeed it has happened to me to find that I had made an error in conclusions I had drawn, and so got them withdrawn from the minutes of our proceedings. These proceedings are published annually for private circulation, but any of them considered to be of interest to the profession generally are at once published in the photographic press.

In the country it is somewhat different. The two kinds of societies seem to me to be both necessary and useful, but they might be combined—a weekly meeting for the discussion of the most interesting little questions as well as the monthly meeting for more serious business. The report would be all the more improved if it contained a digest of these little questions, too, omitting the names of members unless the subject was considered, as it often might be, of general importance.

In conclusion: I would ask all the members of the many photographic societies to remember that the meetings of the Photographic Club take place every Wednesday evening, at 8 p.m., at Anderton's Hotel, Fleet-street, and that they are cordially invited to attend. They will always find a full attendance, including many earnest workers; one and all are anxious to communicate every possible information within their knowledge, and to whom no point is too trivial to receive the fullest elucidation. I may further add that although my connection with photography dates back over thirty years, and though I have enjoyed special facilities for becoming acquainted with its details from the fact of my having held responsible appointments in several of the largest and highest-class photographic establishments in the world, I rarely attend one of our meetings without learning something.—I am, yours, &c., GEORGE SMITH.

December 15, 1884.

FIXING AND TONING IN ONE BATH.

To the EDITORS.

GENTLEMEN,—Why is this good old mode of treating prints gone altogether out of fashion? I used constantly to follow it in the old collodion days, and never found it to fail. The tones on albumenised paper were quite as rich as those produced with the separate toning system, and considerable time was thereby saved.

Here is a formula which may be relied on as absolutely certain, and successful with the ready-sensitised papers of most of the London makers:—Four ounces of hypo. dissolved—by heat, if necessary—in four ounces of distilled water; four grains of chloride gold—not *sel d'or*—dissolved in three ounces of distilled water. Pour the gold solution gradually with shaking into the filtered and cooled hypo. solution—not *vice versa*. This bath is ready for immediate use. The prints are then to be washed in two changes of water, and immersed in the above. At first they will turn of a brick-red colour, but in ten minutes or less will change to a fine rich chocolate, and are, of course, perfectly fixed. The bath improves as chloride of silver is being dissolved, and the quantity given will tone between two and three whole sheets of paper. The bath can be renewed by filling up with concentrated hypo., and gold solution added when the toning becomes slow. Ten minutes is the proper time.

As to their permanence: I have some prints thus treated, and, so far as I know, they have not changed since they were framed and exposed to the light fifteen years ago. The final washing must, of course, be thorough.—I am, yours, &c., ETHEL CONSTANCE MAY.

Darmstadt, December 16, 1884.

"THE CAMERA OF THE FUTURE."

To the EDITORS.

GENTLEMEN,—May I trespass on your courtesy to allow me the least space in your Journal to reply to a statement made in your issue of the 5th inst. on the above subject.

Mr. W. H. Harrison closed his very interesting and important communication of that date with the following remark:—"I did not see that it (Mr. McKellen's camera) contained anything to remedy the chief defect of the present tourist's camera, namely, that of unnecessarily wasting the time of the operator."

May I be permitted, as one who is fortunate enough to possess a camera of Mr. McKellen's construction, and who has given it a careful and accurate trial, to say that in my experience it contains everything calculated to *shorten* the time of the operator. Indeed, this is to my mind its unique characteristic, as the camera can be fixed in its very ingenious turntable, the bellows extended by touching a spring, and, finally, fixed to the utmost state of rigidity as quickly as I write it—in fact, in a few seconds. I have tried all kinds of patent cameras, but none equals this for rapidity of adjustment, simplicity, and lightness of construction.—I am, yours, &c.,

H. VICTOR MACDONA, M.A.

LANTERN SLIDES.

To the EDITORS.

GENTLEMEN,—I read the article on the colour of lantern slides as affected by different clearing solutions, by Mr. B. Wyles, with great interest, and was thoroughly taken by surprise to find that one could get colours varying from "warm red" to "cool brown" by such very simple means.

I at once mixed four clearing solutions—those numbered 1, 2, 5, and 7—and having specially procured Britannia plates, in order that every condition might be accurately complied with, I gave the proper exposure to five plates in contact with the same negative, and developed them as mentioned in the article in question. I had as the result five clear transparencies, and put one into each of the four solutions. After a suitable soaking in the clearing solutions—say, rather over an hour—I took them out, having carefully examined them from time to time, and found that No. 1 was pure black, No. 2 was pure black, No. 5 was the same, and No. 7 ditto.

All this surprises me a good deal. When one reads of "warm red," "photographic brown," "sepia," &c., and can see no such colours, even with the aid of friends beyond the suspicion of colour blindness, there is left a feeling of bewilderment. Has Mr. Wyles tried his own prescriptions? Has he omitted some essential part of the experiment? or, can he send either to the writer or to the Editors a warm-red slide prepared in the manner he describes?

I enclose five slides—one plain soda development—to show what is the result on a Fry's ordinary plate, and four numbered as above, 1, 2, 5, 7, to show good black slides perfectly free from any decided tint, even after prolonged immersion in Mr. Wyles's solution.—I am, yours, &c.,

Liverpool, December 17, 1884. H. NORWOOD ATKINS.

THE GELATINO-CHLORIDE PROCESS.

To the EDITORS.

GENTLEMEN,—We see in your issue of last week that Professor Stebbing is inclined to reproach the public on our behalf for a supposed neglect of our process. We must in all humility disclaim such flattery at the expense of a public whose appreciation of our labours has given us considerably more commissions than we can conveniently do, and whose patronage has always been in excess of our power of acceptance. Our modesty recoils from asking Professor Stebbing what is the extent of the greater reward equal the merit of the exertions of—Yours, &c., MORGAN AND KIDD.

Kew-Foot-road, Richmond, S.W., December 18, 1884.

Exchange Column.

Lerebours' *carte-de-visite* lens, beautiful definition, in exchange for anything useful in photography.—Address, J. THATCHER, Potter's-lane, Basingstoke.

I will exchange THE BRITISH JOURNAL OF PHOTOGRAPHY for *The Photo. News* posted on Monday.—Address, W. J. SMITH, 10½, Windmill-street, Horsefair, Birmingham.

Wanted, background and head-rest in exchange for 1,500 ferrotype envelopes and 800 Victoria mounts, quite new and best quality.—Address, R. TANNER, Albert Villa, Kelley-street, Kentish Town.

The following are in good condition, and will be exchanged for anything useful:—Lancaster's quarter-plate instantograph, perfect; 10 × 8 Meagher camera; square half-plate lens; quarter-plate lens, by Damin; half-plate view lens, by Grubb; half-plate rigid camera, &c.; one-third of a-quire of Marion's alpha paper.—Address, FRITZ CAMERA, 41, High Street, Sydenham.

Notes and Queries.

S. P. asks about agar agar. It is a seaweed which comes chiefly from Singapore, and its gelatine is used in the south of Europe for facing silk. Japanese isinglass, which is a gelatine prepared from seaweed, has sometimes been mistaken for it. This isinglass is sold in somewhat rectangular masses of a skinny nature. The real agar agar is something like branch coral in form, and its tendons are extraordinarily tenacious. The value of vegetable gelatines in emulsions is a problem which requires working out. Past published experiments with them are few and far between.

A MINIATURE PAINTER writes:—"For some time past I have been trying to print carbon pictures on ivory by the single transfer method, and I have succeeded in getting some very good results; but in every case the ivory is stained yellow—I presume, by the bichromate in the tissue. How is this to be avoided?"——In reply: All carbon prints on ivory should be made by the double transfer method. The picture must be developed on flexible support, and then transferred to the ivory. This is the only satisfactory plan of producing carbon pictures on ivory free from yellowness.

G. R. M. asks as to the chief sources of supply of glycerine.——Glycerine is an abundant constituent of fats, in which it exists as a base united with stearic acid. When the crude tallow is boiled with slaked lime, stearate of lime is formed, and the crude glycerine is liberated as an outflow liquid, technically called "sweet water." This impure glycerine is of a brown colour. It is largely used for the manufacture of nitro-glycerine, but since the restrictions laid upon the sale of this explosive by the Government the legitimate sale has so fallen off as to have reduced the value of the "sweet water" enormously.

H.—As to the function of waxes in the wax processes, a long series of experiments was once made at Kew Observatory on this question, and the conclusion drawn was that the action of the waxes is purely mechanical. Pure bees' wax was found to answer best. Care had to be taken to avoid the legion of adulterated samples too commonly on sale in the market. Bees' wax is less absorbent of aqueous solutions than the majority of the vegetable waxes, some of which—such, for instance, as Japan wax—will retain a considerable percentage of water, even when not aided by a substratum of paper. "Bees' wax" composed of paraffine, wax, and rosin, with an outside smear of the real thing to give the smell, is said to be of American origin.

E. W. wishes to know how to make the ordinary marking ink, which is fixed and rendered darker by passing a hot iron over the writing. There are many ways of making it. One of the simplest is to dissolve a-quarter of an ounce of nitrate of silver in three-quarters of an ounce of water; then add just enough of the strongest liquor ammonia to dissolve the precipitate it at first forms. Then add one and a-half drachm of mucilage to thicken it, and a little finely-powdered indigo to give the colour. There is no difficulty in washing out the writing produced by these and some other marking inks by the adoption of certain chemical means. One which seems more likely to resist such attempts was devised by Dr. Ure. He used a strong solution of chloride of platinum, with a little potash, and added sugar and gum to thicken it.

"PUZZLED" wishes to know how to keep his paper from going yellow during the dull days that so often come on at this time of the year and delay the finishing of a print for a day or two.——If "PUZZLED" will dry his paper and keep it in a tightly-covered tin case he will find it to keep for a day or two at this time of the year without any difficulty. But by far the best plan is to lay it sheet by sheet between pieces of blotting-paper that have been soaked in a twenty-per-cent. solution of common washing soda and well dried. If placed under pressure in this manner paper a fortnight old will be scarcely discernible from paper a few hours old kept under ordinary conditions. It is the practice of some printers to use this sodic paper as packing in lieu of felt in all their printing frames, and when this plan is adopted no fear need be entertained of a print spoiling by going yellow, even if kept over a second day before toning. We may, at the same time, inform our correspondent that there is further a vast difference in the keeping qualities of the papers obtainable from the various makers.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

RECEIVED.—Glasgow and West of Scotland Amateur Photographic Association; Photographic Society of Ireland. In our next.

M. B.—The dextrine should be mixed with cold water. If it be of good quality it will not require straining.

A. C. M.—Messrs. Lechertin, Barbe, and Co., of Regent-street, supply all the necessary materials for ceramic painting. Apply to them.

QUANDARY.—Your meaning is by no means clear. Surely sufficient has already been said on the theory of development during the last few years.

MEDALIST.—In the first place, does taking the medal warrant you in styling yourself the *Queen's Medalist?* If it do, then, of course, it is a matter of taste whether you should advertise yourself as such.

HERTS.—The pictures in question *are* genuine. How would it be possible to obtain such effects of hoar frost by what you term "a dodge." Select a bright frosty morning and try your hand at similar pictures.

BOZ.—There is no objection whatever to you employing cotton-wool for the filtration of the printing bath. Some operatives use nothing else for filtering their silver solutions. The same wool will do for several filtrations.

J. A. BOTT.—You have made a mistake in taking the prints off the glass. The mounts should be cemented on to them before they are removed; otherwise the gloss will not be retained. The glaze you have obtained is about the average.

ELECTRO.—There is no better conducting surface for your purpose than that produced by plumbago. The gelatine relief should be perfectly dry before it is applied, and then a good polish must be obtained by well brushing the surface with a soft brush.

NOVICE.—Clearly you are employing a much too weak fixing solution. When did you get such a formula as four drachms of hyposulphite of soda to a pint of water for fixing prints? Read again, and doubtless you will find it stands four *ounces*, not drachms.

BERT. H.—Any photographic apparatus manufacturer will get a leather case made for containing your apparatus. If not, any saddler, we imagine, will make one to your order. We do not know when the colours are to be obtained. We have not seen the gentleman's entertainment.

H. HUNT.—To enlarge three diameters with your "rapid symmetrical," you must have a camera capable of expanding to forty-seven inches. For convenience of working, however, it will be better for it to be somewhat longer than this—say, four feet six or so. You will then be less restricted.

A. BURTON.—By some means or other you have got the chloride of silver in far too coarse and flocculent a condition. We fear that now you will be unable to get it in a finer state of division. Better commence afresh, and follow the instructions exactly as they are published. No doubt it is your imaginary improvement which has brought about your trouble.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician,

For the Week ending December 22, 1884.

THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

Dec.	Barometer.	Wind.	Dry Bulb.	Wet Bulb	Max. Solar Rad.	Max Shade Tem.	Min. Tem.	Remarks.
18	30·18	W	36	34	—	51	30	Cloudy.
19	29·60	NW	42	39	—	48	35	Hazy.
20	28·88	NW	42	40	—	42	40	Hazy.
22	30·23	NE	39	37	—	42	36	Hazy.
